Bis(fluoroformyl)peroxide, a diacyl peroxide, is a sublimable solid. It can be made in good yields in a flow system from carbon monoxide, fluorine, and oxygen at room temperature (equation 58).

$$F_2 + 2CO + O_2 \longrightarrow F(O)COOC(O)F \quad (58)$$

The diacyl peroxide has been used as a source of $FCO_2\cdot$ radicals.[73] Fluorination of the peroxide by photolysis with F_2 gives access to the acyl hypofluorite, FC(O)OF, bp ca. −55 °C, in reasonable yields. The acyl hypofluorite is a precursor to a cyclic isomer, the simplest perfluorodioxirane, CF_2O_2, made by the method shown in equation (59).[74]

$$FC(O)OF + ClX \xrightarrow{CsF}$$  (59)

X = Cl, F

This reaction may involve the intermediacy of the radical $\cdot OCF_2OF$, which cyclizes to generate the dioxirane. The dioxirane is a potent oxygenating agent that generates COF_2 as a by-product. It is thermally stable at 20 °C at modest pressures.

A wide variety of other C–O–F compounds having interesting properties, structures, and reactivity are known, and the literature should be consulted for further information. Unlike traditional C–O–H chemistry, some functional groups have unusual stability and/or reactivity while other traditional groups are unstable and cannot be manipulated under normal conditions. For example, the simplest member of the perfluorinated alcohol family, CF_3OH, is unstable to the loss of HF, as are its higher homologs, R_fOH. It has been synthesized by the reaction of CF_3OCl and HCl at low temperature. The alcohol is collected along with chlorine gas as a by-product.[75]

The simplest perfluorinated ether is CF_3OCF_3, bp −59 °C, which can be prepared by fluorination of CCl_3OCCl_3 with HF and catalytic SbF_xCl_{5-x} or by the ECF of methyl ether using porous carbon electrodes. This fluorinated ether is highly inert chemically. Many ethers can be prepared in high yields by direct fluorination of their hydrocarbon counterparts. A good illustration is the preparation of perfluorinated crown ethers. The effects of fluorocarbon sections are observed in the negligible basicity of the oxygens and the failure of these crown ethers to complex metal cations.[76]

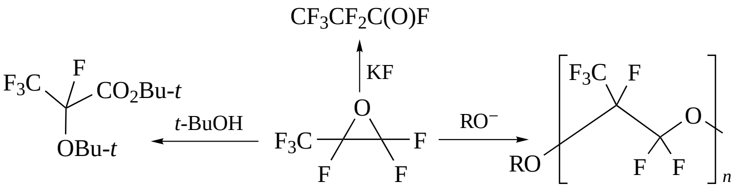
Fluorinated epoxides are very important synthetically. Perfluoroalkenes can be oxidized by numerous means to the corresponding epoxides. The most commonly encountered epoxide is hexafluoropropene oxide (HFPO), which is made from hexafluoropropene and is used in the synthesis of oligomers and as a source of difluorocarbene. HFPO is a colorless, nonflammable gas, boiling at −27.4 °C; it can be ring-opened easily by nucleophiles or electrophiles under a variety of conditions.[77] HFPO can be rearranged by fluoride ion to perfluoropropionyl fluoride and by Lewis acids such as TiO_2 to hexafluoroacetone (HFA). Nucleophiles typically attack the most substituted carbon of the epoxide, freeing the oxyanion to lose fluoride or act as a nucleophile itself. Some examples of HFPO reactivity are shown in Scheme 3.

Fluorinated ketones are important because of their versatile reactivity. HFA, the simplest perfluorinated ketone, reacts readily with nucleophiles as a result of the electron-withdrawing effect of the trifluoromethyl groups. A wide range of both linear and cyclic heteroatom adducts are accessible, as shown in Scheme 4.[78]

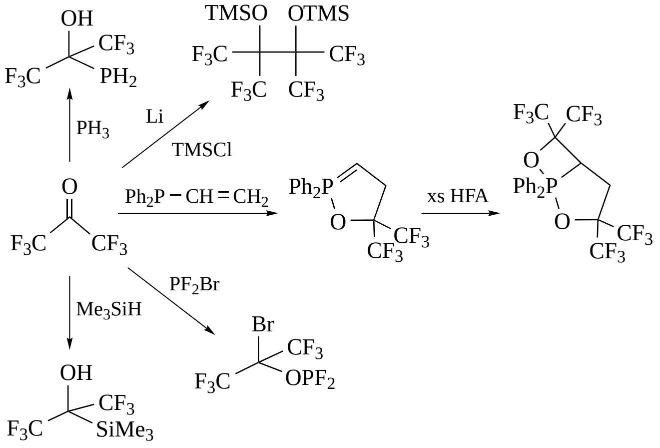
5.2.2 *Silicon Fluorides*

Of the simple binary silicon fluorides, SiF_2 and SiF_4, only the tetrafluoride is stable. It is available commercially or can be prepared on a laboratory scale from the elements or from SiO_2, CaF_2, and concentrated H_2SO_4.[79]

Silicon tetrafluoride reacts with pure silicon at low pressure in a flow system at 1200 °C to yield a transient species, SiF_2, which can be condensed to yield a fluorosilane polymer, $(SiF_2)_n$. Silicon difluoride has a half-life of about 150 s in glass at low pressure in the gas phase. The chemistry of SiF_2 shows many different reactions and has been reviewed.[80] When condensed at −196 °C, a red-yellow deposit is formed,



Scheme 3 Some reactions of hexafluoropropene oxide



Scheme 4 Some reactions of hexafluoroacetone

which turns white at room temperature. The deposit has the overall stoichiometry of $(SiF_2)_x$ and with respect to its plastic properties and composition it is similar to Teflon. Unfortunately, it burns spontaneously in air. A series of fluoropolysilanes (Si_nF_{2n+2}) can be generated by heating the $(SiF_2)_x$ polymer to 200 °C.

Other types of insertions observed for SiF_2 include reactions with boron trifluoride to yield two different fluoroborosilanes, $F_2B(SiF_2)_nF$ ($n = 2, 3$), and the reaction with hexafluorobenzene to yield $C_6F_5SiF_3$. Silicon tetrafluoride can be hydrolyzed in the vapor phase to yield silicon dioxide and hydrogen fluoride or partially to give $F_3SiOSiF_3$, a colorless gas.[28] With liquid water, hexafluorosilicates are generated (equation 60).

$$3SiF_4 + 6H_2O \longrightarrow 2(H_3O)_2SiF_6 + SiO_2 \qquad (60)$$

Many hexafluorosilicate salts from SiF_4 are known. The stable pentafluorosilicon anion $(Ph_4As)(SiF_5)$ can also be generated from silicon tetrafluoride.

The simplest oxide fluoride of silicon, $SiOF_2$, is known; it is prepared by the high-temperature reaction of silica with CaF_2 in an argon atmosphere. The other known oxide fluorides of silicon are a series of fluorosiloxanes, $SiF_3O(SiF_2O)_nSiF_3$, of which Si_2OF_6 is the best known.

5.2.3 *Germanium Fluorides*

There are two binary germanium fluorides known, GeF_2 and GeF_4. Germanium tetrafluoride can be prepared in high yields by pyrolyzing barium hexafluorgermanate, $BaGeF_6$.[81] By analogy to silicon–fluorine chemistry, germanium difluoride, GeF_2, can be made by combination of germanium and germanium tetrafluoride at 150–300 °C.[47]

Salts of trifluorogermanate, GeF_3^-, can be made from germanium difluoride in the presence of metal fluorides. Other species such as GeF_5^- and $Ge_3F_{10}^{2-}$ are also known.

The only known germanium oxyfluoride is Ge_2OF_2.[28] It was detected by mass spectrometry from a mixture of GeO_2, Ge, and NaF.

5.3 Pnicogen Fluorides and Oxyfluorides

5.3.1 *Nitrogen Fluorides*

Nitrogen–fluorine bonds (272 kJ mol^{-1}) are weaker than carbon–fluorine bonds (485 kJ mol^{-1}) but considerably stronger than oxygen–fluorine bonds (190 kJ mol^{-1}). A number of stable binary fluorides as well as nitrogen oxyfluorides have been synthesized and characterized.

Nitrogen trifluoride, the simplest perfluorinated amine, can be made by elemental fluorination of ammonia. Although unreactive like CF_4 at low temperatures, NF_3 acts as a fluorinating agent at higher temperatures, oxidizing copper and generating N_2F_4, a reactive high-energy oxidizer (equation 61).

$$2NF_3 + 2Cu \xrightarrow{\Delta} N_2F_4 + 2CuF \qquad (61)$$

N_2F_4 is in equilibrium with $NF_2\cdot$ radicals and behaves as a reactive pseudohalogen. Nitrogen trifluoride has also been considered as the oxidizer in rocket fuels.[82]

Nitrogen trifluoride can be combined with fluorine and fluorinated Lewis acids to generate NF_4^+ salts like the hexafluoroantimonate shown below in equation (62).[83]

$$NF_3 + F_2 + SbF_5 \xrightarrow{200\,°C} [NF_4]^+[SbF_6]^- \qquad (62)$$

NF_4^+ salts are usually colorless, crystalline solids. The highly sought ionic fluoride $NF_4^+F^-$ has been predicted to

have greater stability than that of the theoretical covalent compound, NF_5. Recent unsuccessful synthetic attempts to generate either $NF_4^+F^-$ or the pentavalent NF_5 have been reported.[84]

Fluorine azide, FN_3, a very explosive gas, can be prepared by fluorination of hydrazoic acid (equation 63).[85] The difluorodiazine, N_2F_2, is a thermal decomposition product of FN_3 and exists as cis and trans isomers (equation 64).

$$2F_2 + 4HN_3 \longrightarrow 3FN_3 + N_2 + NH_4F \qquad (63)$$

$$2FN_3 \longrightarrow \text{F–N=N–F}(\textit{cis} \text{ and } \textit{trans}) + 2N_2 \qquad (64)$$

The FN nitrene has been proposed as an intermediate in the reactions of FN_3. The cis isomer of N_2F_2, bp $-105.7\,°C$, exhibits a noticeable difference from the trans form, bp $-111.4\,°C$, in the reaction with AsF_5 to form a hexafluoroarsinate salt, $[N_2F^+][AsF_6^-]$.[86]

Difluoroamine, HNF_2, can be made from hydrogen abstraction by N_2F_4 from benzenethiol or acetaldehyde.[87,88] A more direct preparation from elemental fluorine can also be employed (equation 65).[89]

$$H_2NC(O)NH_2 \xrightarrow[H_2O]{F_2/N_2} F_2NC(O)NH_2 \xrightarrow{H_2SO_4} HNF_2 \qquad (65)$$

Difluoroamine can be used as a source of NF_2 group in numerous reactions, but it is dangerously explosive.

Mixed halofluoroamines can be synthesized and isolated. Chlorodifluoroamine, $ClNF_2$, can be made in quantitative yield from the reaction of HNF_2 with NaClO in the presence of HgO.[90] Bromodifluoroamine, $BrNF_2$, is prepared in an analogous way by the reaction of Br_2 with HNF_2 over HgO, but is much less stable than NF_2Cl, decomposing at 22 °C into Br_2 and N_2F_4.[82] Chlorodifluoroamine can also be prepared from N_2F_4 and Cl_2. It has been extensively studied as a source of NF_2 derivatives. Dichlorofluoroamine, Cl_2NF, is explosive in the liquid or solid phase. It is formed by the reaction of ClF with NaN_3 at $-10\,°C$ or by the reaction of $FC(O)NCl_2$ with F_2.[91]

5.3.2 *Nitrogen Oxyfluorides*

There exist a number of important small oxyfluorides of nitrogen including nitrosyl fluoride, FNO, and nitryl fluoride, FNO_2, which can be made by fluoride attack or elemental fluorination.[92,93] Nitrosyl fluoride, FNO, was first synthesized from nitrosyl chloride and silver(I) fluoride, but it is more easily prepared by reaction of N_2O_4 with metal fluorides.[94] This compound is unstable in glass, attacks many metals, and behaves as a strong oxidizer and fluorinating agent. A principal mode of reactivity involves loss of fluoride and release of NO. One application is the fluorination of chloromethanes. Another mode of reactivity involves combination with Lewis acid fluorides to yield $[NO^+][EF_n^-]$ salts (E = Sb, As, P).

Nitryl fluoride, NO_2F, can be made by fluorination of NO_2 or by reaction of N_2O_5 with metal fluorides. The chemistry of NO_2F is similar to that of NOF although NO_2F is more stable and less oxidizing. Salt formation from NO_2F is possible with Lewis acids, giving, for example, $[NO_2^+][PF_6^-]$.

Trifluoroamine oxide, ONF_3, bp $-87.6\,°C$, can be made by fluorination of nitrosyl fluoride with IrF_6 or reaction of NO with F_2.[95] F_3NO is stable in glass at 22 °C and is kinetically much less reactive than FNO and FNO_2. Most reactions involve reaction of F_3NO with strong Lewis acids to form ONF_2^+ salts.

5.3.3 *Phosphorus Fluorides and Oxyfluorides*

Phosphorus–fluorine compounds have been known since before the isolation of elemental fluorine.[96] Owing to the strong interest in the biological activity and structural properties of fluorine-containing phosphorus compounds, a large number of compounds have been prepared and characterized.

Phosphorus Fluorides. The lowest oxidation state for a binary fluoride of phosphorus is found in P_2F_4 (bp $-6.2\,°C$). After the synthesis of N_2F_4, many unsuccessful attempts were made to prepare P_2F_4 and it was finally obtained from PF_2I after a good synthesis for the latter was developed (equation 66).[97]

$$2PF_2I + 2Hg \longrightarrow 2P_2F_4 + Hg_2I_2 \qquad (66)$$

The structure of P_2F_4 is trans with angles FPF = 99.1° and PPF = 95.4°.[34] It hydrolyzes readily to F_2POPF_2, and O_2 reacts with it to give the same product. Unlike N_2F_4, it is not a ready source of the PF_2 radical.

Phosphorus trifluoride (bp $-101.8\,°C$) is readily obtained from PCl_3 or PBr_3 by direct reaction with metal fluorides such as ZnF_2, PbF_2, or CaF_2, or with NaF in a polar solvent, or by many other reactions. It is pyramidal (angle FPF = 96.3°) and is comparable to CO in donor properties, for example, $Ni(CO)_n(PF_3)_{4-n}$ ($n = 0$–4).[96] PF_3 is easily oxidized to P^V derivatives and numerous oxygenating reagents give OPF_3; Cl_2 and Br_2 add to give PF_3X_2 and ClF adds at very low temperature to give PF_4Cl.

Phosphorus trifluoride slowly hydrolyzes to H_3PO_3 and HF and in dilute alkaline solutions the intermediate monofluorophosphorus acid is observed. It can be used to prepare a variety of substituted organophosphorus fluorides but PCl_3 is far more important in this respect. Nearly all possible mixed $PF_{3-x}X_x$ (X = Cl, Br, I) have been prepared.

Phosphorus pentafluoride (bp $-84.5\,°C$) is most easily prepared by reaction of PCl_5 with AsF_3 or HF, but many other methods have been used. The molecule has a trigonal bipyramidal structure in the gas phase with longer axial bonds (158 pm compared to 153 pm for the equatorial fluorines). Pseudorotation in molecules was first recognized in PF_5 to

explain the presence of only a single fluorine resonance in the ^{19}F NMR. Phosphorus pentafluoride is a strong Lewis acid and forms both neutral and ionic adducts with many donors such as THF and metal fluorides. The PF_6^- anion is a useful counterion for many complex inorganic cations. Phosphorus pentafluoride reacts with the strong Lewis acid SbF_5 to give the tetrahedral PF_4^+ cation.[98]

Mixed pentahalides, $PF_{5-n}X_n$ (X = Cl, Br, I), are known but only the chlorides PF_4Cl, PF_3Cl_2, PF_2Cl_3, and PF_3Br_2 are well characterized as molecular species. Many of the other mixed halides are complex salts or mixtures of complex salts of the type $PX_4^+X^-$ and $PX_4^+\ PX_6^-$.

Phosphorus Oxyfluorides. Numerous phosphorus(III and V) oxyfluorides and oxyfluoride anions are known. Two oxyfluorides containing P^{III} are PF_2OPF_2 (bp −183 °C) from reaction of P_2F_4 with H_2O or O_2, or PF_2I with Cu_2O (equation 67), and the mixed P^V–P^{III} oxide $PF_2OP(O)F_2$ (bp 48 °C) from OPF_2Br (equation 68).[28] Very little chemistry has been determined for either compound.

$$PF_2I + Cu_2O \longrightarrow PF_2OPF_2 + CuI \qquad (67)$$

$$OPF_2Br \xrightarrow[Hg]{h\nu} PF_2OP(O)F_2 \qquad (68)$$

The simplest oxyfluoride is POF_3 (bp −39.7 °C). It is obtained by many methods but most readily by fluorination of $OPCl_3$ with metal fluorides or HF. The structure (C_{3v}) has angle FPF = 101.3°. Phosphoryl fluoride hydrolyzes slowly to phosphoric acid via the intermediate difluoro- and monofluorophosphoric acids, $HOP(O)F_2$ and $(HO)_2P(O)F$. The latter are best prepared by reaction of P_4O_{10} with HF. Phosphoryl fluoride has little useful reaction chemistry and the large number of $RP(O)F_2$ and $R_2P(O)F$ derivatives that are known is due to the interest in the biological activity of compounds of this type (nerve gases); they have mostly been obtained starting with chlorides.[96]

The series $OPF_{3-n}X_n$ (X = Cl and Br) are well known and excellent methods are available for the preparation of OPF_2X.

Diphosphoryl tetrafluoride, $P_2O_3F_4$ (bp 71 °C), is the anhydride of difluorophosphoric acid and can be obtained by dehydration of $HOP(O)F_2$ with P_4O_{10}, or by photolysis of OPF_2Br with O_2 for an easily purified product (equations 69 and 70).[99]

$$HOP(O)F_2 + PBr_5 \xrightarrow{100\,^\circ C} HBr + OPBr_3 + POF_2Br \qquad (69)$$

$$POF_2Br \xrightarrow[O_2]{h\nu} F_2P(O)OP(O)F_2 \qquad (70)$$

The anhydride reacts with a variety of nucleophiles to cleave an O–P bond; Lewis acids react similarly. Thus CsF gives POF_3 and $CsPO_2F_2$, and $AlCl_3$ gives OPF_2Cl in high yield.

Other polyphosphoryl fluorides have been reported but are not well characterized.

5.3.4 *Arsenic Fluorides and Antimony Fluorides*

Arsenic trifluoride, AsF_3, a molecular species, is synthesized from As_2O_3 and anhydrous HF. Antimony trifluoride, SbF_3, can be made by the action of aqueous HF on Sb_2O_3. Both fluorides are important agents for fluorination of chlorinated substrates.

The pentafluorides, AsF_5 and SbF_5, are prepared by direct fluorination of the elements or their oxides. Both AsF_5 and SbF_5 are used as Lewis acid fluoride acceptors in the preparation of many MF_6^- salts. Anhydrous HF has greatly increased acidity in the presence of SbF_5 because of the creation of the H_2F^+ cation by removal of fluoride. The hexafluoroantimonate anion stabilizes many energetic cationic species, for example, $[NF_4^+][SbF_6^-]$.

5.4 Chalcogen Fluorine Compounds

The synthesis and chemistry of the chalcogen fluorides began with Henri Moissan over 100 years ago. In the last 40 years, these fluorides and their derivatives have been the subject of intense study, which has led to a large number of interesting compounds with a wide range of properties and reactivity. Some of these compounds have important industrial applications, most notably SF_6 and SO_2F_2.

5.4.1 *Oxygen Fluorides*

There have been many oxygen fluorides discussed in the literature, including OF_2, O_2F_2, F_2O_4, HOF, F_2O_3, F_2O_5, and F_2O_6. Of these, only OF_2 is stable and only the first four have been conclusively proven to exist (Table 8).[100] During the early development of the space program, oxygen fluorides attracted much attention. These fluorides are endothermic and powerful oxidizing agents. For these reasons, they were considered for potential use in high-energy propellant and explosive systems. The hazards involved with handling the compounds and by-products, that is, HF, caused the search for propellants to move elsewhere. Still, this initial interest has contributed greatly to the development of this area.

Oxygen difluoride is a colorless, poisonous gas that condenses to a pale yellow liquid. It can be most efficiently prepared by the electrolysis of aqueous HF (equation 71).[101]

$$2HF + 6H_2O \xrightarrow{e^-} OF_2 + O_3 + 7H_2 \qquad (71)$$

An alternative procedure involves reacting F_2 gas with a 2% aqueous NaOH solution (equation 72).[102]

$$2F_2 + 2NaOH \longrightarrow OF_2 + 2NaF + H_2O \qquad (72)$$

Table 8 Oxygen fluorides

Formula	Bp (°C)	Mp (°C)	Structural data
OF_2	−145.3	−223.8	O_2F_2	−57	−153.3	O_4F_2	-79^b	−191	–
HOF	<rt	−117	
[a]Smallest known bond angle for two-coordinate oxygen in an open chain. [b]Extrapolated; decomposes at −183 °C.

OF_2 is a powerful fluorination agent that has proven effective as a source of the fluorides and oxyfluorides of many elements. Both xenon and krypton react with OF_2 in sunlight at 25 °C to give the corresponding difluorides. Reaction with nitrogen under an electric discharge at low temperature gives nitryl fluoride and fluorine nitrate, among other products (equation 73).[103]

$$OF_2 + N_2 \xrightarrow[\text{discharge}]{-180\,^\circ\text{C}} O_2 + N_2O + FNO_2 + FNO_3 \quad (73)$$

Reactions of OF_2 can give rise to high-yield syntheses of peroxides and trioxides (equations 74 and 75).

$$OF_2 + COF_2/CsF \longrightarrow CF_3OOOCF_3 + CF_3OOF \quad (74)$$

$$OF_2 + SO_3 \xrightarrow{h\nu} FSO_2OOF \quad (75)$$

Dioxygen difluoride, O_2F_2, is a pale yellow liquid that can be prepared by exposing the liquid mixture of the elements to UV light. It is much less stable than OF_2 and decomposes above 195 K to give O_2 and F_2. The mechanism of its reactions can be explained generally as cleavage of the O–F bond, leading to the formation of F atoms and OOF radicals. The very weak O–F bonds in both O_2F_2 and O_2F are reasonably explained by molecular orbital theory involving multicenter four-electron bonds.[104]

Recently, O_2F_2 has shown promise as a controllable low-temperature fluorinating agent. PuF_6 and UF_6 are produced by the action of O_2F_2 on PuO_2 and U_3O_8 at room temperature. This has technological significance because typically direct fluorination of the actinides are achieved only at high temperatures. This has led to consideration of O_2F/F_2O_2 in nuclear waste recovery.

Electric discharge through mixtures of oxygen and fluorine also provides a route to O_4F_2. Tetraoxygen difluoride, a red–brown solid, is less stable than O_2F_2 and decomposes at −183 °C, but can be stored for weeks at −196 °C. Few studies of its reaction chemistry have been reported.

Manipulation of ratios of fluorine and oxygen in glow discharge have been reported to provide entry into the homologous O_3F_2, O_5F_2, and O_6F_2.[105] Though some evidence exists for these compounds, it is not conclusive and their existence remains the subject of some debate.

Hypofluorous Acid. Hypofluorous acid (HOF) may be prepared by passing fluorine over water in a Kel-F reactor at 0 °C (equation 76).[106]

$$F_2 + H_2O \xrightarrow[\text{Kel-F}]{0\,^\circ\text{C}} HOF + HF \quad (76)$$

Warming HOF to room temperature releases HF and O_2. Hypofluorous acid is a strong oxidizer that oxidizes water to hydrogen peroxide in acidic solution. It is thought to be the reactive species when F_2 reacts in aqueous media. In general, HOF acts as an oxygen donor, or a donor of its conjugate acid OH^+, because of the great affinity between the protons and the neighboring fluorine atoms. Formally, HOF could be a source of the OF^- anion by reaction with an appropriate base but no indication of this has appeared. However, there is reasonable evidence for the generation of the anion by reaction of $FOSO_2F$ with CsF.[107]

A wide variety of oxyfluorides containing O–F bonds have been prepared and are discussed under the respective element oxyfluorides.

5.4.2 Sulfur Fluorides

The area of sulfur–fluorine chemistry is a particularly rich and diverse field. The seven known binary sulfur fluorides, FSSF, $S{=}SF_2$, SF_2, $FSSF_3$, SF_4, SF_6, and S_2F_{10}, have a range of formal oxidation states from 1 to 6 and a wide range of chemical properties (Table 9). The lower fluorides are extremely unstable while SF_6 is almost totally inert. Sulfur tetrafluoride is stable but highly reactive, and is used extensively for fluorinations in both organic and inorganic chemistry. The synthesis and chemistry of these compounds have been well developed and continue to be very active areas of research. Numerous general reviews can be found.[108–110] All of the fluorides of sulfur are colorless gases and liquids. SF_6 has the highest density of any substance that boils below room temperature (5.107 times as dense as air).

Considering the high stability of H_2S and SCl_2, SF_2 is surprisingly unstable.[111,112] It is only observed in very dilute mixtures or when trapped in an argon matrix. It is synthesized by fluorinating SCl_2 with activated KF or HgF_2 at 150 °C. This synthesis produces many sulfur fluorides, and sulfur difluoride is only a minor product. Separation of SF_2 from these other sulfur fluorides is difficult. Other difficulties arise

Table 9 Sulfur fluorides

Formula	Structure	Point group	Ox. State	Bp (°C)	Mp (°C)
FSSF		C_2	S^I	15	−133
SSF_2		C_s	S^{II} and S^{IV}	−10.6	−164.6
SF_2		C_{2v}	S^{II}	–	–
$FSSF_3$		C_1	S^I and S^{III}	–	–
SF_4		C_{2v}	S^{IV}	−40.4	−121
F_5SSF_5		D_{4d}	S^V	30	−52.7
SF_6		O_h	S^{VI}	−63.8	−50.5 (subl)

with characterization and storage of the compound because it rapidly dimerizes to form F_3SSF.

The reaction of sulfur vapor with AgF at 125 °C gives FSSF.[113] This in turn can be converted to the more stable isomer $S{=}SF_2$ in the presence of alkali metal fluorides or BF_3. Both isomers rapidly hydrolyze to give S_8, HF, and a mixture of polythionic acids, $H_2S_nO_6$ ($n = 4$–6).

Sulfur tetrafluoride is very stable when compared to the lower sulfur fluorides. It can be stored at room temperature for an indefinite period of time. It is very reactive and is valued as a selective fluorinating agent for both organic and inorganic compounds. Its remarkable fluorinating ability has been the subject of recent reviews.[114,115]

Sulfur tetrafluoride is best prepared by the reaction of S_8, Cl_2, and NaF in acetonitrile at 75 °C. It must be handled under anhydrous conditions because it will quickly hydrolyze to form HF and SOF_2 or SO_2. Sulfur tetrafluoride is amphoteric, and forms numerous stable adducts with both Lewis acids and Lewis bases. A number of nonmetal fluorides react with SF_4 to give salts containing the SF_3^+ cation (equation 77).

$$SF_4 + EF \longrightarrow [SF_3]^+[EF_2]^- \qquad (77)$$
$$EF = BF_3, PF_5, AsF_5, SbF_5, HF$$

SF_4 can also behave as a Lewis acid and reacts with pyridine and active fluoride sources to form stable adducts. With fluorides the SF_5^- anion is formed (equation 78).[116]

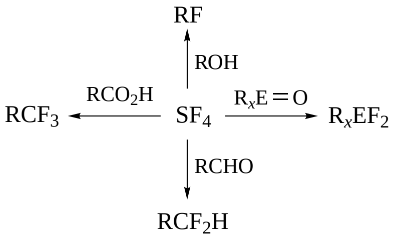
$$SF_4 + EF \longrightarrow [SF_5]^-[E]^+ \qquad (78)$$
$$EF = CsF, (CF_3)_4NF, Me_4NF$$

Sulfur tetrafluoride has been successfully used as a selective fluorinating agent in a wide variety of organic and inorganic systems. It is particularly useful for converting element–oxygen bonds to the respective fluorides (Scheme 5).

While SF_4 continues to be used as a fluorinating agent, its low boiling point presents some difficulties and a series of liquid fluorosulfuranes have been developed that react similarly under milder conditions. Commercially available dialkylaminotrifluorosulfuranes (DAST) are made by the reaction of dialkylaminotrimethylsilanes with SF_4 in a solvent at low temperatures. These sulfuranes, like SF_4, are easily hydrolyzed, but are stable for long periods if protected from water.[117]

Sulfur tetrafluoride will undergo numerous oxidative addition reactions to give S^{VI} derivatives. Reactions of SF_4 with F_2, ClF, F_5SOOSF_5, and N_2F_4 give SF_6, SF_5Cl, *cis*-$SF_4(OSF_5)_2$, and SF_5NF_2, respectively.

Photolytically, reduction of SF_5Cl with H_2 gives the largest known binary sulfur fluoride, disulfur decafluoride. It is also a trace by-product of the industrial preparation of SF_6, but it is not isolated and is destroyed by heating to 400 °C. Disulfur decafluoride is a liquid at room temperature that will completely decompose at 200 °C to SF_4 and SF_6. It is intermediate in properties when compared to SF_4 and SF_6. It is not hydrolyzed by water alone, but it is slowly attacked by aqueous NaOH. Disulfur decafluoride can be stored at room temperature as a liquid for years. Like SF_4, it is extremely



E = C, As, Ge, Sb, I

Scheme 5 Some reactions of SF_4

toxic and should be handled with care. Disulfur decafluoride reacts readily with Cl_2 and Br_2 to give SF_5Cl and SF_5Br and can serve as a source of SF_5 radicals in a variety of reactions.

SF_6 was first made by Henri Moissan in 1891 when he burned sulfur in a fluorine atmosphere. This is the heart of the commercial synthesis used today, which combines heating sulfur to 400 °C with fluorine gas, followed by scrubbing with NaOH to destroy traces of S_2F_{10}. The gas is then thoroughly dried. Sulfur hexafluoride is colorless, odorless, tasteless, and nontoxic. It is stable at 500 °C and does not react with distilling phosphorus. The compound shows some instability with certain metals at lower temperatures (200 °C), depending on the presence of water. Because of its remarkable kinetic stability, sulfur hexafluoride does not have much important reaction chemistry. It is, however, greatly valued in numerous industrial applications.[118] It has excellent insulating properties for high voltage apparati because of it high dielectric strength. Today it is used extensively in the electric power industry to protect circuit breakers, high voltage coaxial cables, power substations, and transformers. It is even used in space satellites to protect their electronic equipment. Since it is inert and has a high density, SF_6 is also used to inflate tires and tennis balls.

5.4.3 *Sulfur Oxyfluorides*

Three simple oxide fluorides of sulfur, thionyl fluoride (SOF_2), sulfuryl fluoride (SO_2F_2), and sulfur oxide tetrafluoride (SOF_4), have been known for years (Table 10). There also exists a large series of complex oxide fluorides that can be divided into two main groups. One has the –SO_2F structural group and the other an –SF_5 group. These complexes generally involve – O_n –bridging between sulfur atoms. There have been several good reviews on sulfur oxide fluorides.[119–123]

Thionyl fluoride is a colorless gas that was first prepared by reacting $OSCl_2$ with ZnF_2; however, a better method is fluorination with NaF (equation 79).[124]

$$SOCl_2 + NaF \xrightarrow{MeCN} SOF_2 \qquad (79)$$

Thionyl fluoride behaves as a weak Lewis base using the lone pair on oxygen for donation. It will react with SiF_2 to form a series of fluorosiloxanes and also with various fluorinating agents to give SOF_4.

Sulfuryl fluoride[125] is a colorless gas that was first prepared by direct fluorination of SO_2. Since then, numerous methods have been developed to prepare SO_2F_2, but the best three appear to be the reaction of SO_2Cl_2 with SbF_3, the thermal decomposition of barium fluorosulfate at 500 °C, and the reaction of KSO_2F with chlorine.[126]

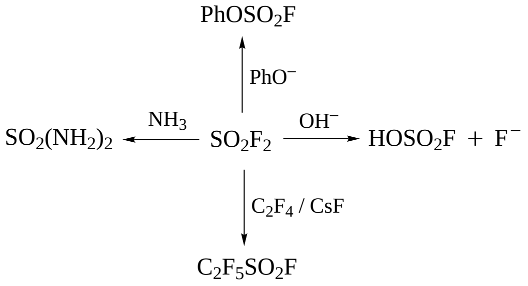
Sulfuryl fluoride is generally a chemically inert gas and its hydrolysis in basic solution is slow. It will, however, react readily with nucleophiles to give substituted products (Scheme 6). Its major use is as a fumigant in the eradication of termites and other pests.

Fluorosulfuric acid, $HOSO_2F$, can be prepared by the replacement of chlorine in chlorosulfonic acid with fluoride, but is best prepared from HF and SO_3. It is a colorless fuming liquid, and is one of the strongest simple acids known. It has been the subject of a number of reviews.[127] This acid has many remarkable properties and industrial applications. It has the unique ability to solvate electrolytes and stabilize cationic species that are not stable in less acidic media. It has been successfully used as a fluorinating agent in both organic and inorganic chemistry. It can also be used as a catalyst in many organic reactions. As a fluorination reagent it is particularly effective in replacement of OH by F in nonmetal compounds, as in the synthesis of TeF_5OH from BaH_4TeO_6. Fluorosulfuric acid can be used to prepare a variety of metal fluorosulfate salts.

As stated earlier, SOF_4 can be prepared by elemental fluorination of SOF_2 (equation 80). Sulfur oxide tetrafluoride has been observed to behave as a fluoride ion acceptor and donor, forming $Cs^+[OSF_5\ ]^-$ and $[SOF_3]^+[SbF_6]^-$. It also provides, with F_2 gas over a CsF catalyst, an excellent route to SF_5OF.[128]

$$SOF_2 + F_2 \longrightarrow SOF_4 \qquad (80)$$

Complex oxyfluorides of sulfur containing the –SF_5[129] group are SF_5OF and $SF_5O_nSF_5$ ($n = 1–3$), as well as other



Scheme 6 Some reactions of SO_2F_2

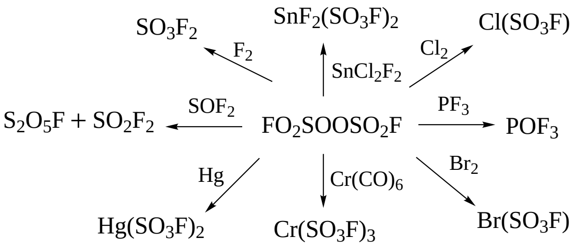
more complex compounds. Bis(pentafluorosulfur) peroxide, SF_5OOSF_5, was first prepared serendipitously when oxygen impurities in the fluorine used to fluorinate sulfur resulted in its low-yield synthesis. Recently, the peroxide has been made in excellent yield by the thermal reaction of SOF_4 and SF_5OF under high pressure in a copper reactor.[130] Bis(pentafluorosulfur) oxide, SF_5OSF_5, is produced in high yields from the photochemical reaction of SF_5OCl with SF_5Cl.

In recent years, the field of complex oxide fluorides has been dominated by the rich chemistry of peroxodisulfuryl difluoride, $S_2O_6F_2$.[131] It is a colorless liquid, best made on a large scale by the reaction of SO_3 with F_2 over an AgF_2 catalyst.

Peroxodisulfuryl difluoride reversibly dissociates into yellow fluorosulfate radicals at elevated temperatures. In a 1-l glass vessel, 100 Torr of $S_2O_6F_2$ gives a bright yellow color when heated to 150 °C. The $FSO_3\cdot$ radical is a powerful one-electron oxidant, forming the very stable fluorosulfate anion or covalent bonds with many metals and nonmetals (Scheme 7).

5.4.4 *Selenium and Tellurium Fluorides*

The range of known selenium and tellurium fluorides includes many examples similar to sulfur but important differences are found, with Se and Te often adopting higher coordination numbers (Table 11). No lower fluorides are known except the unstable species FSeSeF, Se=SeF_2, and SeF_2.



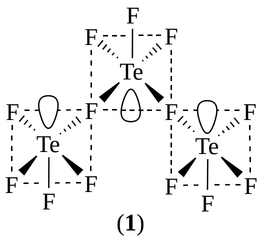
Scheme 7 Some reactions of FO_2SOOSO_2F

Table 11 Selenium and tellurium fluorides

	SeF_6	TeF_6	SeF_4	TeF_4	Te_2F_{10}
Bp (°C)	−47 subl.	−39 subl.	101	–	59
Mp (°C)	−35	−38	−9.5	129	−34

Both tetrafluorides can be synthesized from the action of SF_4 on the dioxides. Selenium tetrafluoride is a white solid that melts to a colorless liquid. It can be handled in rigorously dried Pyrex, reacting slowly with glass but violently with H_2O. Selenium tetrafluoride can solvate many fluorides. Selenium tetrafluoride and other organic Se^{IV} fluorides have been utilized as fluorinating agents for alcohols and carbonyl compounds.

Tellurium tetrafluoride forms colorless sublimable crystals that exist as chains of *cis*-linked square-pyramidal TeF_5 groups (**1**). Its chemistry is similar to SeF_4, but is less useful for fluorination.



(**1**)

Both SeF_6 and TeF_6 may be prepared by the direct fluorination of the elements or by the reaction of BrF_3 with the dioxides. Both are toxic, colorless gases with offensive smells. The Se^{VI} and Te^{VI} fluorides are not as chemically inert as SF_6. Te_2F_{10} is a volatile liquid that can be synthesized from a mixture of F_2/O_2 and a mixture of Te/TeO_2 at 50–60 °C.

5.4.5 *Selenium[132] and Tellurium[133] Oxyfluorides*

Many compounds containing fluorine and oxygen are known for selenium and tellurium (Table 12). $SeOF_2$ is prepared by reaction of SeO_2 with SeF_4. SeO_2F_2 can be prepared from SeO_3 and SeF_4 in an analogous reaction or by reacting $SeOF_2$ with F_2. Reaction of SeO_2 with an F_2/N_2 mixture generates the hypofluorite SeF_5OF and the peroxide $F_5SeOOSeF_5$, depending on reaction conditions.

The two most important compounds for the synthesis of EF_5O derivatives (E = Se, Te) are the strong acids EF_5OH. TeF_5OH (bp 59.7 °C) is prepared in good yield by heating BaH_4TeO_6 with excess $HOSO_2F$. SeF_5OH (bp 47 °C) is prepared by reaction of SeO_2F_2 with a small excess of HF at 22 °C. These acids are used to prepare a variety of derivatives, including the important transfer agents $Hg(OEF_5)_2$ and $B(OTeF_5)_3$.

Both of the bispentafluoro peroxides can be prepared from $Xe(OMF_5)_2$ by UV irradiation of the melted xenon compound

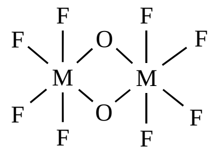
Table 12 Selenium and tellurium oxyfluorides

	$SeOF_2$	SeO_2F_2	$(SeF_5O)_2$	$(SeF_5)_2O$	$(SeF_4O)_2$	$(TeF_5O)_2$	$(TeF_5)_2O$	$(TeF_4O)_2$
Bp (°C)	126	−9.5	−61.5	53	65	81.5	59.8	77.5
Mp (°C)	15	−99.5	−62.8	−85	−12	−39	−36.6	28

(equation 81).

$$Xe(OMF_5)_2 \xrightarrow{h\nu} Xe + F_5MOOMF_5 \qquad (81)$$

Thermolysis of $B(OSeF_5)_3$ and $B(OTeF_5)_3$ yields the compounds $Se_2O_2F_8$ and $Te_2O_2F_8$, which are dimers of the simple OMF_4 structure containing bridging oxygens (**2**).



(**2**)

Some exotic structures have been made containing tellurium both as a central atom and as a fluorinated ligand. For example, the series of Te^{VI} octahedral compounds $F_4Te(OTeF_5)_2$ (cis and trans), $F_2Te(OTeF_5)_4$ (cis and trans), $FTe(OTeF_5)_5$, and $Te(OTeF_5)_6$ have been made via ligand exchange with $B(OTeF_5)_3$.

The $–OTeF_5$ group has been shown to provide a large nonbridging ligand with an electronegativity approaching that of fluorine. The ether $F_5Te–O–TeF_5$ was prepared by direct fluorination of TeO_2 with F_2/N_2.

5.5 Halogen Fluorides and Oxyfluorides

5.5.1 Halogen Fluorides[134,135]

Each of the halogens reacts exothermically with fluorine and, depending on stoichiometry and reaction conditions, generates compounds with four possible oxidation states. Stoichiometries of XF, XF_3, and XF_5 are known for Cl, Br, and I; IF_7 is also known (Table 13). All halogen fluorides are diamagnetic and have an even number of atoms. Their reaction chemistry is similar to that of fluorine, and they are extremely reactive fluorinating agents. They comprise one of the most reactive classes of compounds known. For a given stoichiometry XF_n, the following order of reactivity holds: $ClF_n > BrF_n > IF_n$. For a given halogen fluoride the reactivity generally decreases with the number of fluorine atoms. The sequence of reactivity for all the binary halogen fluorides usually quoted is as follows: $ClF_3 > ClF_5 > BrF_5 > IF_7 > ClF > BrF_3 > IF_5 > BrF > IF_3 > IF$. Under proper conditions, reactions with all organic materials, metals and nonmetals are known.

Table 13 Halogen fluorides[33]

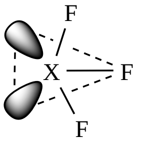
XF (bp/mp °C)	XF_3	XF_5	XF_7
ClF (−100.1/ −155.6)	ClF_3 (11.8/ −76.3)	ClF_5 (−13.1/ −103)	[d]
BrF (≈20[a]/ ≈−33[a])	BrF_3 (125.8/ 8.8)	BrF_5 (41.3/ −60.5)	[d]
IF[a]	IF_3 (−28[a])	IF_5 (104.5/9.4)	IF_7 (4.8[c]/6.5[b])

[a]Decomposes. [b]Triple point. [c]Sublimation. [d]Compound unknown.

Diatomic Halogen Fluorides. All three diatomic halogen fluorides (XF) exist, but only ClF is stable. BrF exists only in equilibrium with Br_2 and BrF_5, so it is impossible to isolate. Both IF and BrF disproportionate rapidly and irreversibly to higher fluorides and Br_2 or I_2.

Chlorine monofluoride is a colorless gas that condenses to a very pale yellow liquid. It is prepared by the interaction of chlorine trifluoride and chlorine or by heating chlorine and fluorine together in a 1:1 ratio. It can be used to saturate multiply bonded systems or oxidize coordinatively unsaturated central atoms. Scheme 8 illustrates some types of ClF reactivity.[136]

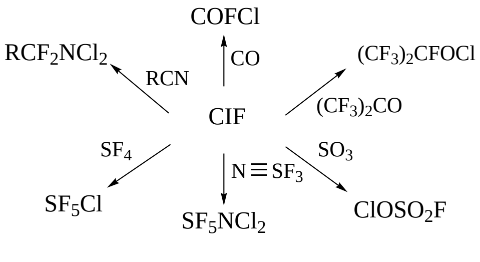
Halogen Trifluorides. All the trifluorides (XF_3) of the halogens can be synthesized by direct combination of the proper proportions of the halogens with fluorine. IF_3, which is unstable above −28 °C, can also be made by the action of XeF_2 on I_2. ClF_3 and BrF_3 have a T-shaped structure with a C_{2v} symmetry (**3**).



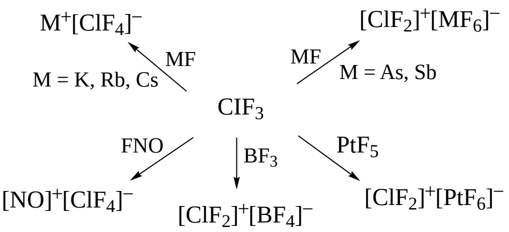
X = Cl, Br
(**3**)

Chlorine trifluoride, ClF_3, is violently reactive with many oxidizable substrates. It is available commercially and has been utilized to fluorinate uranium to UF_6 in the nuclear power industry. This is an important step in uranium enrichment because volatile UF_6 can be readily separated from the nonvolatile fluoride impurities.

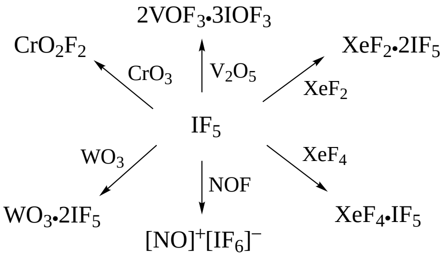
Chlorine trifluoride may serve as a fluoride donor or fluoride acceptor to give cations and anions, depending on the substrate employed (Scheme 9).



Scheme 8 Some reactions of ClF



Scheme 9 Some reactions of chlorine trifluoride



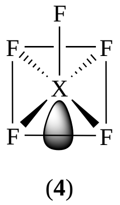
Scheme 10 Some reactions of iodine pentafluoride

Bromine trifluoride, BrF_3, is also commercially available and is used as a nonaqueous ionizing solvent. Its electrical conductivity is derived from a dissociative equilibrium (equation 82). It fluorinates most substrates that dissolve in it and typically gives fluorides in their highest valency state.

$$2BrF_3 \rightleftharpoons [BrF_2]^+ + [BrF_4]^- \quad (82)$$

5.5.2 *Halogen Pentafluorides*

The three pentafluorides (XF_5)[137] are conveniently made by direct fluorination of the halogens or a lower halogen fluoride. All can be used as fluorinating agents. Chlorine pentafluoride, ClF_5, and BrF_5 are considerably more vigorous than IF_5. All three pentafluorides react vigorously with H_2O. Bromine pentafluoride and iodine pentafluoride react in a 1:3 ratio with H_2O to yield a mixture of hydrofluoric acid and either bromic or iodic acid. The chlorine analog gives $FClO_2$ and HF upon reacting in a 1:2 ratio with H_2O. All the pentafluorides are colorless gases and condense to volatile colorless liquids. The molecular structure of XF_5 is square pyramidal (C_{4v}) with the central X atom slightly below the plane of the four base fluorine atoms (**4**).



(**4**)

All three pentafluorides form adducts with AsF_5 and SbF_5. ClF_5 and IF_5 form 1:1 adducts while the adduct with BrF_5 is 1:2, $[BrF_4]^+[Sb_2F_{11}]^-$. Conversely, these pentafluorides can behave as fluoride ion acceptors: both $CsBrF_6$ and KIF_6 can be isolated. Several hundred tons of IF_5 are manufactured in the United States each year because of its important reactions with perfluoroalkenes. In the presence of SbF_5 the reaction of IF_5 with alkenes gives the telomer in high yields. BrF_5 thermally decomposes above 559 °C to give BrF_3 and F_2. BrF_5 fluorinates Mg_2N_3 at room temperature to give N_2F_2.[138]

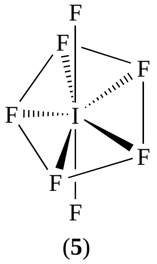
The cations $ClF_6{}^+$ and $BrF_6{}^+$ have been made by oxidation of the pentafluorides with extremely strong oxidizers such as PtF_6 or KrF^+ (equation 83).

$$ClF_5 + PtF_6 \longrightarrow [ClF_6]^+[PtF_6]^- + [ClF_4]^+[PtF_6]^- \quad (83)$$

Decomposition of the strongly oxidizing krypton fluorides in a solution of BrF_5 at ambient temperatures yields $BrF_6{}^+$ in small yields. The salt $[BrF_6{}^+][AsF_6{}^-]$ results when $Kr_2F_3AsF_6$ or $KrFAsF_6$ is decomposed in BrF_5.[139] The $[BrF_6{}^+][Sb_2F_{11}]$ salt is also known from the decomposition of $Kr_2F_3SbF_6$.

The chemistry of IF_5 has been extensively studied. It is easily handled in glass and less reactive than the other pentafluorides. Reaction of the pentafluoride frequently leads to partially fluorinated products (Scheme 10).

Iodine Heptafluoride. Iodine heptafluoride (IF_7) is the only known heptafluoride. Its structure is pentagonal bipyramidal (**5**). It is a stronger fluorinating agent than IF_5 and reacts with H_2O to give the oxyfluoride IOF_5 and HF. The oxyfluorides will be discussed in the following section as a separate class of compounds.



(**5**)

5.5.3 *Halogen Oxyfluorides*[140]

Five oxyfluorides of both chlorine[141,142] and iodine and three of bromine[143] have been characterized. They resemble the related halogen fluorides both structurally and chemically. They tend to be strong fluorinating and oxidizing agents. Many behave as both Lewis acids and bases, being able to donate

Table 14 Halogen oxyfluorides

	XO_2F (bp/mp °C)	XOF_3	XO_3F	XO_2F_3	XOF_5	XOF

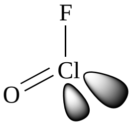
[a]Sublimes. [b]Decomposes without melting.[87] [c]Compound not known. [d]Decomposes before boiling point.

and accept fluoride ions. Table 14 gives the known halogen oxyfluorides.

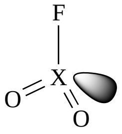
Chlorine Oxide Fluoride. The only member of the halogen oxide fluoride class is chlorine oxide fluoride (**6**). It forms a solid that melts to a red liquid at −70 °C. In the gaseous state, it is thermally unstable and decomposes to give $FClO_2$ and ClF. It can be made by the hydrolysis of ClF_3 with substoichiometric amounts of H_2O in a flow reactor. It is also produced by photolysis of a mixture of ClF and O_3 in Ar at 4−15 K.



(**6**)

Halogenyl Fluorides. All three halogenyl fluorides (XO_2F) are known though bromyl fluoride is unstable above its melting point. Both ClO_2F and BrO_2F are pyramidal and monomeric in the gas phase (**7**), whereas IO_2F is polymeric. All three can behave as Lewis acids and bases through donating or accepting a fluoride ion.

Chloryl fluoride can be prepared in high yield by the action of ClF_3 on $NaClO_3$. It is a colorless gas and a powerful oxidizing and fluorinating agent.[144] It is the most common chlorine oxyfluoride and is typically encountered in reactions between ClF_x and oxides or hydroxides.



X = Cl, Br

(**7**)

Bromyl fluoride can be made almost quantitatively by the hydrolysis of BrF_5 in a 5:1 molar ratio with H_2O. Solid BrO_2F may be stored indefinitely in quartz ampules. Liquid BrO_2F is stable at ambient temperatures when stored in Kel-F. Gaseous BrO_2F has a half-life near 30 min at 15 °C.

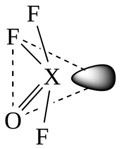
Iodyl fluoride can be prepared by fluorination of I_2O_5 at 20 °C in anhydrous HF. Lewis acids form complexes with $[IO_2]^+$ and Lewis bases form complexes involving $[IO_2F_2]^-$.

Perhalogenyl Fluorides (XO_3F)[145]. Perchloryl fluoride can be prepared by the action of F_2 on $KClO_3$ or by HSO_3F-SbF_5 on $KClO_4$. It is a colorless gas that is thermally stable to about 400 °C and reacts slowly with H_2O at 300 °C. Compared to other members of this class, $FClO_3$ is remarkably inert and shows no tendencies to form adducts with Lewis acids or bases. It has been widely used as an oxidant for rocket fuels because of its low reactivity and high specific impulse. It is a mild fluorinating agent that has shown some use in selective fluorination of steroids and acidic methylenes. Because of its extraordinary kinetic stability and excellent dielectric properties, perchloryl fluoride offers a higher resistance to dielectric breakdown than any other gas.

Perbromyl fluoride can be prepared in high yield by fluorination of $KBrO_4$ with SbF_5 in HF. It decomposes slowly at room temperature and is much more reactive than $FClO_3$, reacting rapidly with glass.

Periodyl fluoride is a white crystalline solid that can be prepared by direct fluorination of HIO_4 in HF. Unlike $FClO_3$, it forms adducts with BF_3 and AsF_5. It is stable in glass but decomposes to FIO_2 upon heating to 100 °C.

Halogen Oxide Trifluorides (XOF_3). Chlorine oxide trifluoride (**8**) can be synthesized by the reaction of ClF_3 with OF_2 in UV radiation. The best large-scale preparation is fluorination of $ClONO_2$ at −35 °C. It is a powerful fluorinating and oxidizing agent and has been used as an oxidant for rocket fuels. It can behave as Lewis acid and base. It sublimes at room temperature and can be handled in metal, Teflon, or Kel-F.



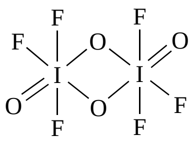
X = Cl, Br, I

(**8**)

Bromine oxide trifluoride can be prepared by the reaction of $KBrOF_4$ with HF. It decomposes slowly at room temperature to give O_2 and BrF_3.

Iodine oxide trifluoride, a colorless crystalline solid, is prepared by dissolving I_2O_5 in boiling IF_5 followed by cooling. Above 110 °C it thermally dismutates into FIO_2 and IF_5.

Halogen Dioxide Trifluorides (XO_2F_3). Both ClO_2F_3 and IO_2F_3 (**9**) are well known but attempts to make and isolate the



$(IO_2F_3)_2$, C_{2h}

(**9**)

bromine analog have been fruitless. ClO_2F_3 is a stable volatile gas prepared according to equation (84).

It can be purified by fractional distillation followed by complexing with BF_3. It is a strong oxidizing and fluorinating agent that forms stable adducts to some Lewis acids.

$$2FClO_2 + 2PtF_6 \longrightarrow [F_2ClO_2]^+[PtF_6]^- + [ClO_2]^+[PtF_6]^- \xrightarrow{2FNO_2} F_3ClO_2 + FClO_2 + 2[NO_2]^+[PtF_6]^- \quad (84)$$

Iodine dioxide trifluoride can be prepared by partial fluorination of $Ba_3H_4(IO_6)_2$ with HSO_3F. It decomposes upon heating (97 °C) to yield IOF_3 and O_2. It is highly associated under all conditions. It reacts with AsF_5, SbF_5, NbF_5, and TaF_5 to form oxygen-bridged polymers.

Halogen Oxide Pentafluorides (XOF_5). Only the iodine oxide pentafluoride is known (**10**). IOF_5 is a colorless liquid that can be made from the action of IF_7 and H_2O. IOF_5 is not easily hydrolyzed, and microwave spectroscopy yields a dipole moment of 1.08 D.

1 INTRODUCTION

The element gallium was predicted, as eka-aluminum, by Mendeleev in 1870, and subsequently discovered by Lecoq de Boisbaudran in 1875. The new element was named in honor of France (Latin *Gallia*). The chemistry of gallium was reviewed by Gmelin in 1936,[1] and in the following year by Einecke.[2] Several general but informative chemistry publications/books have appeared that deal with certain aspects of the history, occurrence, extraction, purification, analysis, physical, and chemical properties, toxicology, or uses of the element,[3–5] while the industrial application[6–8] and coordination chemistry[9,10] of gallium has been extensively reviewed. In addition, the area has generally been reviewed and published in annual reviews.[11–21]

2 THE ELEMENT

2.1 Abundance

Gallium is very much less abundant than aluminum and tends to occur at low concentrations in sulfide minerals rather than as oxides, although gallium is also found associated with aluminum in bauxite. At 19 ppm, gallium is about as abundant as nitrogen, lithium, and lead; it is twice as abundant as boron (9 ppm), but is more difficult to extract owing to the lack of any major gallium-containing ore. Gallium always occurs in association either with zinc or germanium, its neighbors in the periodic table, or with aluminum in the same group. Thus, the highest concentrations (0.1–1%) are in the rare mineral germanite (a complex sulfide of Zn, Cu, Ge, and As); concentrations in sphalerite (ZnS), bauxite, or coal are a hundredfold less.

2.2 Preparation and Use

Gallium was originally recovered from flue dusts emitted during sulfide roasting or coal burning (up to 1.5% Ga), but is now obtained as a by-product of the aluminum industry. The Bayer process for obtaining alumina from bauxite gradually enriches the alkaline solutions from an initial weight ratio Ga:Al of about 1:5000 to about 1:300; electrolysis of these extracts with an Hg electrode gives further concentration, and the solution of sodium gallate is then electrolyzed with a stainless steel cathode to give gallium metal. Ultra high-purity gallium for semiconductor growth is obtained by further chemical treatment with acids and oxygen at high temperatures followed by crystallization and zone refining. Since bauxite (Al_2O_3) contain 0.003–0.01% gallium, complete recovery would yield some 500–1000 tons per year; however, present consumption, though growing rapidly, is only a small fraction of this being of the order of 10 tons per annum. This can be compared with the estimate of 5 tons for the total of Ga metal in the 90 years following its discovery (1875–1965).

Gallium's main use is in semiconductor technology. For example, GaAs can convert electricity directly into coherent light (laser diodes) and convert sunlight into electricity (solar cells), is employed in electroluminescent light-emitting diodes (LEDs); it is also used for doping other semiconductors and in solid-state devices such as heterojunction bipolar transistors (HBTs). The compound $MgGa_2O_4$ is used in ultraviolet-activated powders as a brilliant green phosphor used in copying machines. Another very important application is to improve the sensitivity of various bands used in the spectroscopic analysis of uranium. Minor uses are as high-temperature liquid seals, manometric fluids, and heat-transfer media, and for low-temperature solders.

2.3 Properties

Gallium has a beautiful silvery-blue appearance; it wets glass, porcelain, and most other surfaces (except quartz, graphite, and Teflon) and forms a brilliant mirror when painted onto glass. Selected physical constants of gallium are summarized in Table 1. The atomic radius and first ionization potential of gallium are almost identical with those of aluminum and the two elements frequently resemble each

Table 1 Physical properties of gallium metal

Atomic number	31	Melting point (°C)	29.75
Atomic weight	69.72	Boiling point (°C)	2227
Atomic radius (Å)	1.245	d_4^{20} (solid) (g mL^{-1})	5.907
Ionic radius (Å)	0.62	$d_4^{29.8}$ (liquid) (g mL^{-1})	6.0948
Ionization potential (eV)	6.00	Atomic volume (29 °C) (mL)	11.81
Standard electrode potential (volts)	0.52	Atomic volume (30 °C) (mL)	11.44

other in chemical properties. Both are amphoteric, but gallium is less electropositive as indicated by its lower electrode potential. Differences in the chemistry of the two elements can be related to the presence of a filled set of 3d orbitals in gallium.

The unusual physical properties of metallic gallium arise from its unique crystal structure which consists of Ga_2 units arranged in deformed sets of hexagonal rings, Figure 1.[6] The orthorhombic unit cell has four Ga_2 units lying symmetrically in the *ac* plane at angles of 17° to the *c*-axis, the spacing of these molecular planes being *b*/2. Each gallium atom has seven Ga···Ga interactions, one nearest neighbor at 2.44 Å, and three sets of two each at 2.71, 2.74, and 2.80 Å. This rather open structure collapses to a more nearly close-packed arrangement in the liquid state, and melting is accompanied by a contraction of 3.1% in atomic volume and by a considerable increase in electrical conductivity. Here gallium resembles its neighbor germanium, as well as antimony and bismuth. The structure of a denser form of gallium (orthorhombic) has been obtained by supercooling the liquid to −16.3 °C.[22] In this arrangement, the gallium atoms form zigzag chains along the *c*-axis. In a chain, the Ga–Ga distance is 2.68 Å, and the Ga–Ga–Ga angle is 72.3°. Between the chains, the gallium atoms have four additional neighbors at 2.87 Å, and two at 2.90 Å, making a total of eight Ga···Ga interactions.

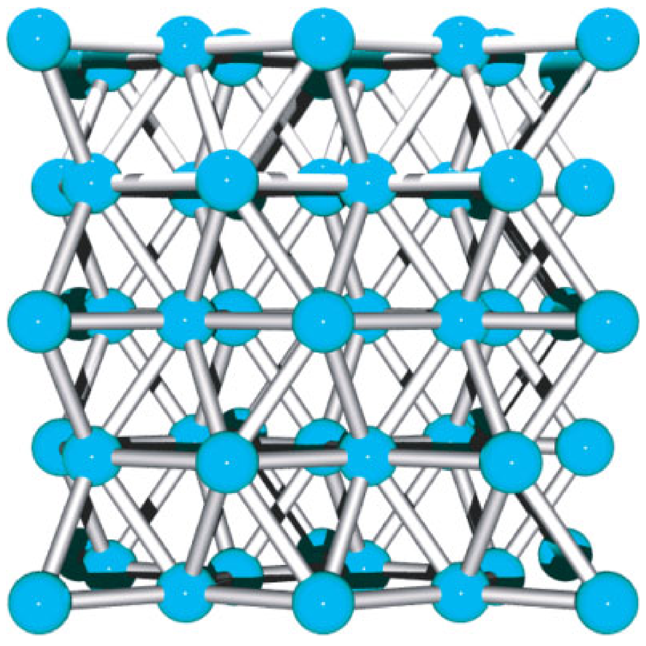

Figure 1 Unit cell of α-gallium metal

Elemental gallium has a very low-melting point, and an extraordinary low vapor pressure (less than 1 mmHg at 1300 °C). These factors combine to give gallium the longest liquid range of any known substance and form the basis of its (very limited) use in high-temperature thermometers.

3 SPECTROSCOPY

3.1 Gallium NMR

Gallium has two NMR-active isotopes (spin $I = 3/2$), ^{69}Ga and ^{71}Ga, with the latter possessing a higher receptivity in addition to narrower relative line width; however, NMR studies for both isotopes are equally reported and studied. Chemical shifts are generally reported with respect to either $Ga(NO_3)_3$ or $[Ga(H_2O)_6]^{3+}$ with the chemical shift window being approximately 1400 ppm (this follows suit with the corresponding Al compounds) (Table 2).

Ga NMR studies have received increased impetus as a viable probing tool for some key areas. ^{69}Ga NMR studies have been used to support and follow Ga antitumor agents and their mode of action and uptake into tumor cells. ^{71}Ga NMR has thus been used to study how various ligands may form complexes with the cation. In another area, the use of ^{69,71}Ga NMR has been used to examine defects in semiconductors, which can have a crucial influence on the semiconductors' electronic and optical properties.[23–25] In addition, a number of very useful web sites detailing Ga NMR related studies are available.[26–28]

3.2 Mass Spectroscopy

The two naturally occurring isotopes of Gallium Table 2 can be used as an aid in mass spectroscopic studies. Isotopic distribution patterns have been used to model the masses and abundances of the isotopes for a given formula, and as a 'fingerprinting' tool when used in a comparative analysis with the experimental data. This technique has recently been used for identifying the formation, mechanism, and the fragmentation pattern of Ga_n clusters (Figure 2),[29] and more recently to confirm the formation of the first Ga=As containing species.[30]

Table 2 Summary of properties for magnetically active quadruploar ga nuclei

Isotope	Spin	Natural abundance (%)	Quadrupole moment (10^{-28} m^2)	Relative sensitivity	Width Factor	Relative Intensity	Absolute sensitivity	NMR frequency (MHz)
^{69}Ga	3/2	60.4	0.178	6.91E-2	5.93	0.007	4.17E-2	24.003
^{71}Ga	3/2	39.6	0.112	0.14	2.34	0.024	5.62E-2	30.495

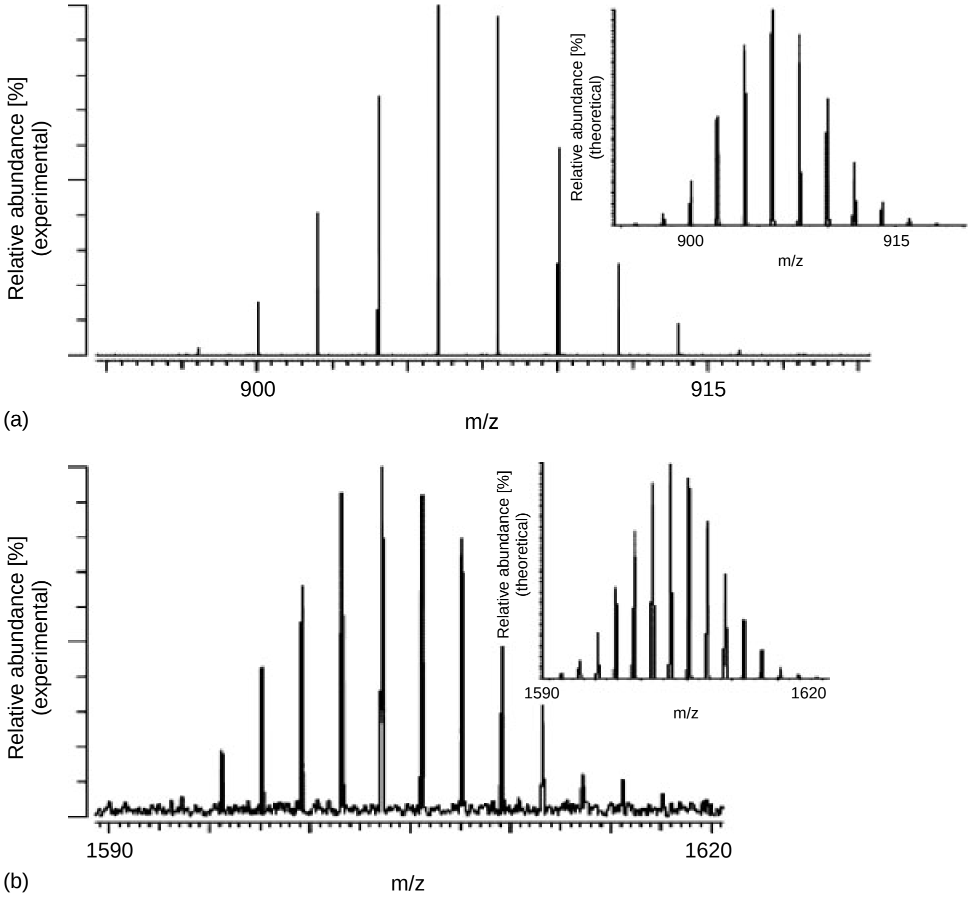

Figure 2 Mass spectra of the Ga_{13}^- cluster (a) and the Ga_{23}^- cluster (b) and the corresponding calculated spectra. (Reprinted from Ref. 29. © 2002, with permission from Elsevier)

4 BINARY COMPOUNDS

4.1 Gallium Pnictogens, (III-V)

Undoubtedly the binary compounds of gallium with the most industrial interest are those of the group 15 elements, GaE (E = N, P, As, Sb). The group 15 gallium alloys with nitrogen, phosphorus, arsenic, and antimony are isoelectronic with the group 14 elements. There has been considerable interest, particularly in the physical properties of these compounds, since 1952 when Welker first showed that they had semiconducting properties analogous to those of silicon and germanium.

4.1.1 Synthesis, Structure, and Physical Properties of Bulk Material

Gallium nitride is the only member of the group which cannot be prepared by direct reaction of the elements. It was first made by the reaction of gallium with ammonia at 1000 °C, but has also been prepared by the decomposition of either $[NH_4]_3[GaF_6]$ or the halide Lewis acid–base adduct $GaCl_3(NH_3)$. Gladfelter has shown that cubic GaN may be prepared by the low-temperature pyrolysis of the trimeric gallane compound $[H_2Ga(NH_2)]_3$ (equation 1).[31]

$$[H_2Ga(NH_2)]_3 \xrightarrow{\Delta} 3GaN + 6H_2 \quad (1)$$

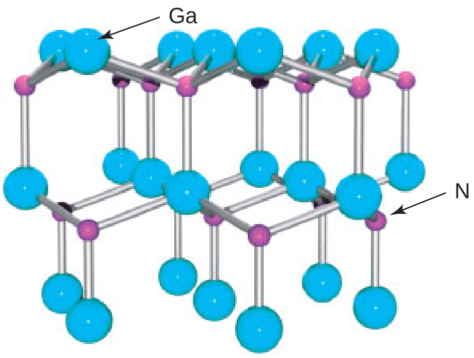

Figure 3 Lattice packing of würtzite GaN

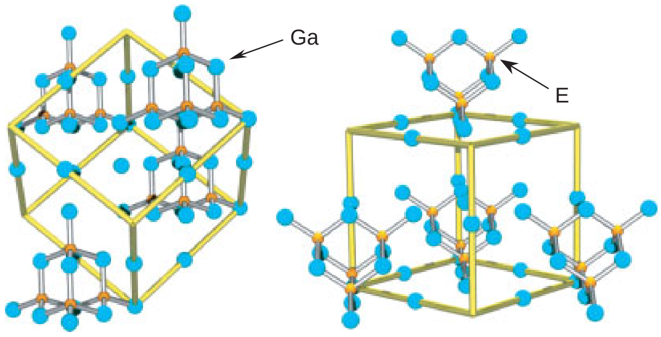

Figure 4 Unit cell structure of GaE (E = P, As, Sb); gallium atoms are cyan

Gallium nitride is commonly gray or yellow, diamagnetic, and crystallizes in the würtzite (ZnS) structure (Figure 3). Gallium nitride is not hydrolyzed by hot water or by acids such as dilute or concentrated hydrofluoric, hydrochloric, or nitric, or aqua regia. However, the compound dissolves slowly in hot concentrated sulfuric acid. With hot concentrated aqueous alkali, ammonia is evolved. There is no reaction with hydrogen at 800 °C but oxygen slowly reacts with gallium nitride at 900 °C over a period of days to give nitrogen and Ga_2O_3. The properties of GaN are summarized in Table 3.

Gallium phosphide, arsenide, and antimonide can all be prepared by direct reaction of the elements; this is normally done in sealed silica tubes or in a graphite crucible under hydrogen. Phase diagram data are hard to obtain in the gallium–phosphorus system because of loss of phosphorus from the bulk material at elevated temperatures. Thus, GaP has a vapor pressure of more than 13.5 atm at its melting point, compared to 0.89 atm for GaAs. The physical properties of these three compounds are compared with those of the nitride in Table 3. All three adopt the zinc blende crystal structure (Figure 4), and are more highly conducting than gallium nitride.

When considering the synthesis of group 13–15 compounds for electronic applications, the very nature of semiconductor behavior demands the use of high-purity single-crystal materials. The polycrystalline materials synthesized above are, therefore, of little use for 13–15 semiconductors but may, however, serve as the starting material for melt-grown single crystals. For gallium arsenide, undoubtedly the most important 13–15 semiconductor, melt-grown single crystals are achieved by one of two techniques: the Bridgman technique, and the Czochralski technique.

The Bridgman technique requires a two-zone furnace, of the type shown in Figure 5. The left-hand zone is maintained at a temperature of ca. 610 °C, allowing sufficient overpressure of arsenic within the sealed system to prevent arsenic loss from the gallium arsenide. The right-hand side of the furnace contains the polycrystalline GaAs raw material held at a temperature just above its melting point (ca. 1240 °C). As the furnace moves from left to right, the melt cools and solidifies. If a seed crystal is placed at the left-hand side of the melt (at a point where the temperature gradient is such that only the end melts), a specific orientation of the single crystal may be propagated at the liquid–solid interface eventually to produce a single crystal.

The Czochralski technique shown in Figure 6 relies on the controlled withdrawal of a seed crystal from a liquid melt. As the seed is lowered into the melt, partial melting of the tip occurs, creating the liquid–solid interface required for crystal growth. As the seed is withdrawn, solidification occurs and the seed orientation is propagated into the grown material. The

variable parameters of rate of withdrawal and rotation rate can control crystal diameter and purity. The gallium arsenide melt is capped by boron trioxide (B_2O_3). The capping layer, which is inert to gallium arsenide, prevents arsenic loss when the pressure on the surface is above atmospheric pressure. The growth of gallium arsenide by this technique is thus termed liquid encapsulated Czochralski (LEC) growth.

While the Bridgman technique is largely favored for GaAs growth, larger diameter wafers can be obtained by the Czochralski method. Both of these melt techniques produce materials heavily contaminated by the crucible, making them suitable almost exclusively as substrate material. The methods by which higher purity single crystal of epitaxial GaAs can be obtained are therefore discussed below.

Table 4 Comparison of physical and semiconductor properties of GaAs and Si

4.1.2 Electronic Applications of GaAs

Gallium arsenide is a compound semiconductor with a combination of physical properties that has made it an attractive candidate for many electronic applications. From a comparison of various physical and electronic properties of GaAs with those of Si (Table 4), the advantages of GaAs over Si can be readily ascertained.

1. The band gap of GaAs is 1.42 eV, resulting in photon emission in the infrared range. Alloying GaAs with Al to give $Al_xGa_{1-x}As$ can extend the band gap into the visible red range. Unlike Si, the band gap of GaAs is direct, that is, the transition between the valence band maximum and conduction band minimum involves no momentum change and hence does not require a collaborative particle interaction to occur. Photon generation by interband radiative recombination is therefore possible in GaAs, whereas for Si, with an indirect band gap, this process is too inefficient to be of use. The ability to convert electrical energy into light forms the basis of the use of GaAs, and its alloys, in optoelectronics, for example, in LEDs (Figure 7), solid-state LASERs (light amplification by the stimulated emission of radiation), and solar cells.
   A significant drawback of small band-gap semiconductors, such as Si, is that electrons may be thermally promoted from the valence band to the conduction band. Thus, with increasing temperature the thermal generation of carriers eventually becomes dominant over the intentionally doped level of carriers. The wider band gap of GaAs gives it the ability to remain 'intentionally' semiconducting at higher temperatures; GaAs devices are generally more stable to high temperatures than are similar Si devices.
2. The low intrinsic carrier density of GaAs in a pure (undoped) form indicates that GaAs is intrinsically a very poor conductor and is commonly referred to as being semi-insulating. This property allows many active

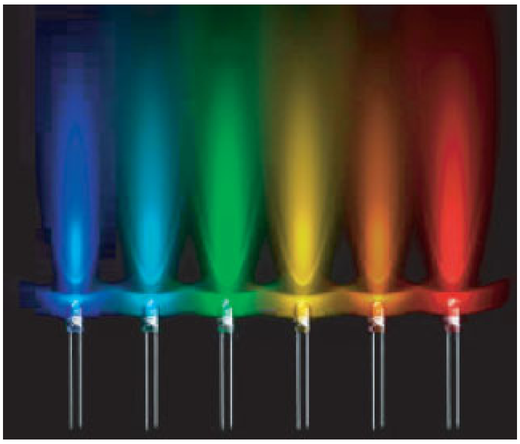

Figure 7 III-V based light-emitting diodes

devices to be grown on a single substrate, where the semi-insulating GaAs provides the electrical isolation of each device; this is an important feature in the miniaturization of electronic circuitry, that is, VLSI (very large-scale integration) involving over 100 000 components per chip (one chip is typically between 1 and 10 mm^2).

3. The higher electron mobility in GaAs than in Si potentially means that in devices where electron transit time is the critical performance parameter, GaAs devices will operate with higher response times than equivalent Si devices. However, the fact that hole mobility is similar for both GaAs and Si means that devices relying on cooperative electron and hole movement, or hole movement alone, show no improvement in response time when GaAs based.

The many desirable properties of gallium arsenide are offset to a great extent by a number of undesirable properties, which have limited the applications of GaAs-based devices to date.

1. The bulk crystal growth of GaAs (see Section 4.1.1) presents a problem of stoichiometric control owing to the loss, by evaporation, of arsenic both in the melt and the growing crystal (>ca. 600 °C). Melt-growth techniques are, therefore, designed to enable an overpressure of arsenic above the melt to be maintained, thus preventing evaporative losses. The loss of arsenic also negates diffusion techniques commonly used for wafer doping in Si technology, since the diffusion temperatures required exceed that of arsenic loss.
2. The thermal gradient and, hence, stress generated in melt-grown crystals have limited the maximum diameter of GaAs wafers (currently 3–4 inch diameter compared to over 12 inch for Si), because with increased wafer diameters the thermal stress-generated dislocation (crystal imperfection) densities eventually becomes unacceptable for device applications.
3. Gallium arsenide single crystals are very brittle, requiring considerably thicker substrates than those employed for Si devices.
4. Gallium arsenide's native oxide is found to be a mixture of nonstoichiometric gallium and arsenic oxides and elemental arsenic. Thus, the electronic band structure is found to be severely disrupted, causing a breakdown in 'normal' semiconductor behavior on the GaAs surface. As a consequence, the GaAs MISFET (metal–insulator semiconductor field-effect transistor) equivalent to the technologically important Si-based MOSFET (metal–oxide semiconductor field-effect transistor) is, therefore, presently unavailable.

4.1.3 Gallium Arsenide-Based Devices

The considerable difficulty of growing GaAs single crystals, added to the higher cost of the raw materials gallium and arsenic compared to silicon, has resulted in GaAs technology only being used where Si-based technology is impractical, that is, application areas utilize either the high-speed or light-emitting properties of GaAs. Two areas where GaAs-based devices display properties unobtainable in Si-based devices are in microwave and photonic devices. To illustrate the basic operating principles and complex structures involved in such devices, we can consider two currently operational devices.

1. The MESFET (metal–semiconductor field-effect transistor) is a GaAs device capable of operating at microwave frequencies (1–100 GHz) and in its simplest form is shown schematically (Figure 8). A lightly doped *n*-type (electrons as majority carriers) GaAs layer is grown on a semi-insulating (i.e. high purity) GaAs substrate. Source and drain contacts (Au/Ge alloy) are termed ohmic, that is, there is negligible contact resistance between metallization and semiconductor. The gate contact (Al) is rectifying and creates what is termed a Schottky diode with the *n*-type GaAs. Under appropriate applied voltage or biasing conditions, the gate contact can reduce or maintain conductance in the underlying layer between source and drain and can thus modulate current flow through the

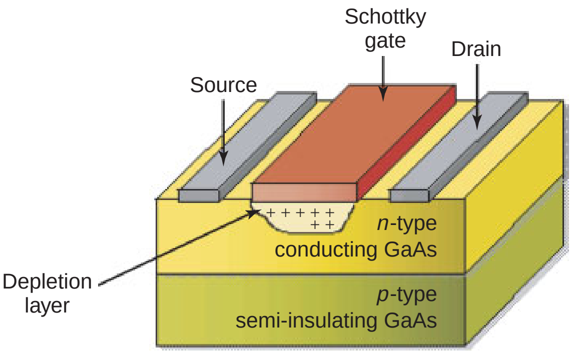

Figure 8 Schematic diagram of a GaAs-based MESFET device

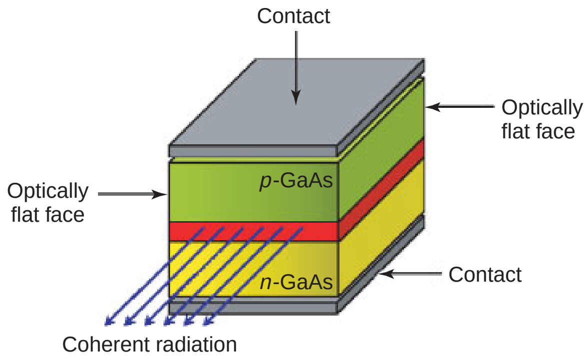

Figure 9 Schematic diagram of a GaAs-based solid-state laser

semiconducting layer. It is this high-speed switching that is utilized in microwave devices.

2. A schematic of a GaAs-based semiconductor laser structure is shown in Figure 9. The basic operating principle of this device is that a forward-biased p–n junction injects charged pairs (holes and electrons) into the ‘active’ region of the laser. Within this region, carrier recombination occurs, generating light. The injected charge carriers and generated light are confined within this active layer by the surrounding layer possessing both energy band discontinuities and high refractive indices. By this optical and carrier confinement method, stimulated emission of radiation can occur, that is, a generated photon can stimulate electron–hole recombination to produce a further photon in phase with the original. The laser structure thus generates a flux of coherent light. The absence of a direct band gap makes such a device impractical for silicon.

4.1.4 *Epitaxial Growth of GaAs*

The continuing drive for the scaling down of electronic device dimensions has necessitated the introduction of a new class of growth techniques where high-purity thin single-crystal layers are grown on a single-crystal substrate. The techniques of epitaxial growth (from the Greek *epi taxis* meaning *arrangement on*) are classified as either homo- or heteroepitaxy, depending on whether the base substrate is the same as or different from the growing film. The advantages of using epitaxial growth techniques include control of layer thicknesses, interfacial structure, material composition, and impurity concentration. Homoepitaxy, that is, GaAs on GaAs, is generally employed to provide either doping junctions, for example, *p*-type on *n*-type GaAs, or to allow low-impurity GaAs to be grown on considerably less pure substrates, whereby only the thin (high purity) epitaxial layer is electrically active in the device. Heteroepitaxy, that is, AlGaAs on GaAs, provides junctions with band discontinuities (conduction or valence) that can present either a barrier or enhancement to electron and hole mobility (and therefore current flow) depending on the appropriate doping and electronic biasing conditions. The techniques of epitaxy are discussed below.

4.1.5 *Liquid Phase Epitaxy (LPE)*

Liquid phase epitaxy (LPE) involves the growth of thin epitaxial layers on a crystalline substrate by direct precipitation from the liquid phase. The requirement for this process is that a suitable solvent for the film material can be obtained that provides a saturated melt solution at a temperature well below the melting point of the substrate. Gallium metal is used as the solvent for LPE of GaAs. A saturated solution of GaAs in gallium metal is introduced on to a substrate of GaAs and allowed to cool below the equilibrium saturation temperature. The melt solution becomes supersaturated, causing precipitation of GaAs on the GaAs substrate. As the melt temperature decreases, the precipitation reaction continues. Impurity additions can similarly be added to the melt to provide *n*- or *p*-type doping by segregation from the melt into the growing film.

4.1.6 *Metal-Organic Vapor-phase Epitaxy (MOVPE)*

Metal-organic Vapor-phase epitaxy (MOVPE) and what is commonly termed MOCVD (*metal–organic chemical vapor deposition*) are essentially the same technique whereby organometallic compounds, in the form of volatile liquids or sublimable solids, are transported via the vapor phase on to a heated substrate and decomposed alone or in combination with other vapors or gases to give the desired film (Figure 10). The vapor-phase techniques offer the advantages of low growth temperatures substantially below the melting point of the grown film, the ability to grow irregular shaped substrates with conformal, uniform growth, and in some instances the ability to selectively deposit only on desired areas of a substrate surface.

For the growth of group 13–15 compounds, the general embodiment of the vapor-phase process is that liquid

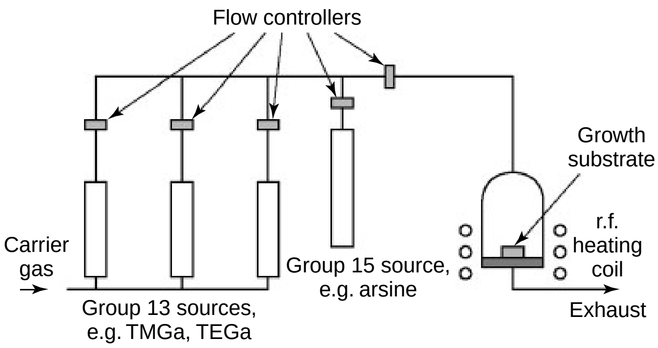

Figure 10 Schematic diagram of a typical MOVPE chamber

organometallic group 13 compounds react with group 15 hydrides at elevated temperatures (equation 2).

$$Me_3Ga + AsH_2 \xrightarrow{H_2} GaAs + 3MeH \qquad (2)$$

There are a number of properties required for compounds to be suitable as precursors for MOVPE; these include sufficient vapor pressure to allow suitable growth rates, ability to be highly purified, controllable deposition behavior, stability in storage, and stability with other species during vapor-phase transport.

Trimethylgallium is the most commonly used precursor owing to its relatively high vapor pressure (182 Torr at 20 °C) at both atmospheric and low pressure. Conversely, Et_3Ga, with both a lower vapor pressure (5.1 Torr at 20 °C) and lower thermal stability is used when higher purity films of GaAs are required. The increased purity of films grown from Et_3Ga, when compared to those grown from Me_3Ga, is a result of lower carbon incorporation (carbon is a *p*-dopant) in the growing film. Mechanistic studies reveal the differing carbon incorporation levels being due to

1. a decrease in Ga–C bond strength for Et_3Ga (52 kcal mol^{-1}) when compared to Me_3Ga (58 kcal mol^{-1}) allows for a lower temperature being required for the homolytic fission of the Ga–C bond in Et_3Ga
2. the ability of Et_3Ga to undergo a *β-Hydride Elimination* step involving the 'clean' elimination of an alkene also contributes to lower carbon incorporation (*see* ***Gallium: Organometallic Chemistry***).

The incorporation of a β-hydride elimination step into precursor pyrolysis has focused attention on alternative organometallic precursors for gallium. However, only limited success has been achieved. Other routes to 'clean' precursor decomposition include the pyrolysis of gallane adducts, that is, the gallane–trimethylamine adduct $H_3Ga(NMe_3)$; however, this and other related gallane compounds are thermally unstable and decompose at room temperature. Storage at low temperatures (−15 °C) and the difficulty of large-scale purification are some of the factors that limit the utility of such adducts. Several studies reported the presence of polymeric contaminant in MOVPE chambers in which the source vapors were allowed to react prior to the deposition zone. While this has now been circumvented by changes in reactor design, precursor compounds of the form $R_3Ga(AsR'_3)$ were found to provide a source of gallium alkyl without the unwanted prereaction with AsH_3. However, AsH_3 was still required as the arsenic source. Recently, many workers have focused on GaAs single-source precursors, with the general formula $[R_2Ga(\mu\text{-}AsR'_2)]_n$; however, the quality of films grown from these compounds still needs to be further improved for microelectronic applications.[9,10]

4.1.7 Molecular Beam Epitaxy

Molecular Beam Epitaxy (MBE) is essentially a modified and highly controllable form of vacuum evaporation, whereby elemental gallium and arsenic sources are held in effusion cells and heated in ultra-high vacuum (UHV) conditions to produce molecular fluxes. Under the UHV conditions, the molecular beams impinge on a heated rotating growth surface with no prior gas-phase collisions to produce precise epitaxial films. The advantages of MBE over vapor-phase techniques include the highly controlled growth that can be obtained, enabling structures of a few atomic layers to be grown, and with that multilayers and quantum-well structure where the layer thickness is less than the mean free path of an electron's travel. The UHV conditions (ca. 10^{-10} Torr) allow both films of the highest purity to be grown and also enable diagnostic and growth monitoring techniques to be employed in situ, that is, reflection high energy electron diffraction (RHEED), low-energy electron diffraction (LEED), and others.

A variation of MBE utilizes organometallic rather than elemental sources for the molecular beams and is termed metal–organic molecular beam epitaxy (MOMBE) or chemical beam epitaxy (CBE). The molecular sources are commonly those used in vapor-phase epitaxy, that is, R_3Ga and AsH_3, and are generally gaseous under UHV conditions. The MOMBE technique offers several advantages over conventional MBE, including lower growth temperatures with concomitant control of layer and doping profiles by lowering interdiffusion processes. The gaseous sources (in UHV) also mean that precursor reservoirs can be externally connected to the UHV chamber, providing 'constant' operational capability. The use of organometallics, however, inevitably introduces impurities (mainly carbon) into the growth system.

4.1.8 Passivation of GaAs

As discussed earlier, GaAs has the potential to be widely used in high-speed electronics and optoelectronics, but its implementation is somewhat hampered by difficulties in reproducibility controlling surface composition and electrical properties. From the earliest days of solid-state electronics, it has been recognized that the presence or absence of surface states plays a decisive role in the usefulness of any semiconductor material. It is desirable to covalently satisfy all surface bonds, thereby shifting the surface states out of the band gap and into the valence and conduction bands. Owing to the high surface-state density of GaAs, and its inability to form a stable native oxide overlayer (see above), there has been much work investigating the chemical passivation of the surface.

Oxide layers on GaAs have been grown by exposure of the GaAs surface to water,[9] or hydrogen peroxide,[32] aniodic oxidation,[33] and oxidation by high kinetic energy atomic oxygen beams.[34] The first effective passivation layer was reported in 1987 by Sandroff and coworkers.[35] They

discovered that a class of inorganic sulfides (Li_2S, $(NH_4)_2S$, $Na_2S{\cdot}9H_2O$, etc.) imparts excellent properties to GaAs surfaces. The surface recombination velocity (SRV) at the interface between $Na_2S{\cdot}9H_2O$ and GaAs begins to approach that of the nearly ideal AlGaAs/GaAs interface. These workers proposed, and this was confirmed by many subsequent studies, that a sulfide layer was covalently bonded to the GaAs surface. While these sulfide films result in a marked decrease in the SRV of GaAs, the effects are only temporary; after 18 h the SRV have returned to their pretreatment values. It is this lack of permanency that has prompted several groups to propose that MOCVD-grown films would make ideal passivation coatings.

The recently reported MOCVD-grown metastable cubic phase of gallium sulfide (GaS),[36] which forms a nearly lattice-matched layer on GaAs, shows promise as a stable commercially viable passivation layer for GaAs-based devices.[37,38] In addition, electrical characterization of the cubic GaS/GaAs interface shows that the Fermi level in both n- and p-type GaAs is completely unpinned, with the capacitance versus voltage curves showing well-defined accumulation and depletion regions.

4.2 Gallium Chalcogenides

4.2.1 Oxides and Hydroxides

The gallium oxide system is somewhat similar to that of aluminum, affording a high-temperature (α) and a low-temperature γ-Ga_2O_3, each having the same structure as their aluminum counterparts. β-Ga_2O_3 is the most stable crystalline modification (mp 1740 °C); it has a unique crystal structure with the oxide ions in distorted ccp and Ga^{III} in distorted tetrahedral and octahedral sites, with Ga-O distances of 1.83 and 2.00 Å, respectively (Figure 11).[39]

The structure appears to owe its stability to these distortions and, because of the lower coordination of half the Ga^{III}, the density is ca. 10% less than for the α (corundum-type) form. This preference of Ga^{III} for fourfold coordination, despite the fact that it is larger than Al^{III}, may indicate the polarizing

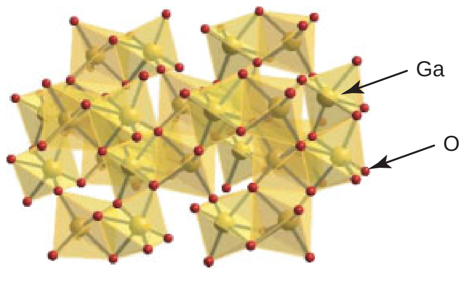

Figure 11 Structure of β-Ga_2O_3; oxygen atoms are shown red. (Ref. 27. Reproduced by permission from Dr Mark J Winter/WebElements. Source: WebElements [http://www.webelements.com/]; http://www.webelements.com/webelements/compounds/text/Ga/Ga2O3-12024214.html)

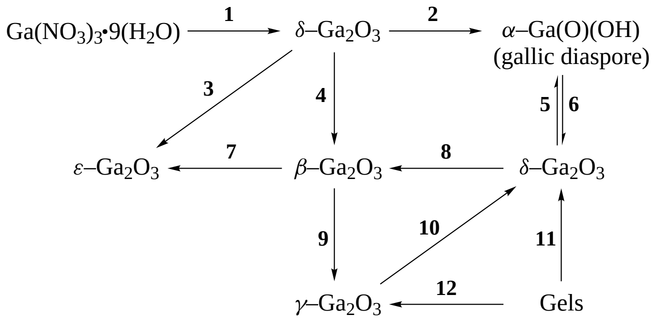

Scheme 1 Transformation relationships among the forms of gallium oxide and its hydrate. influence of the d^{10} core; a similar tetrahedral site preference is observed for Fe^{III}. The trioxide is formed by heating the nitrate, the sulfate, or the hydrous oxides that are precipitated from Ga^{III} solutions by the action of ammonia. A summary of the transformations in the gallium oxide (and hydroxide) system is given in Scheme 1.

β-Ga_2O_3 is classified as a transparent conducting oxide (TCO), that is, materials that, though having a wide band gap, are electrically conductive, and exhibits the largest band gap among TCOs with $E_g = 4.8\,eV$.[40] Consequently, it has a unique transparency from the visible into the UV wavelength region and is a viable candidate for the next generation of optoelectronic devices operating at shorter wavelengths. Large-size single crystals of high quality β-Ga_2O_3 (>2 cm diam.) have been grown by the floating zone technique.[41] Processed, cut, and polished wafers were found to be highly transparent in the visible and near UV, as well as electrically conductive, hence supporting its potential as a substrate for optoelectronic devices operating in the visible/near UV and with vertical current flow. Additionally, investigation into the formation of β-Ga_2O_3 nanocrystals has also been pursued.

A departure from the similarity of gallium oxides with those of aluminum is the stability of the gallium(I) oxide, which is made by high-temperature reactions (e.g. equations 3–5).

$$Ga_2O_3 + 4Ga \xrightarrow{700\,°C} 3Ga_2O \quad (3)$$

$$2Ga + CO_2 \rightleftharpoons Ga_2O + CO \quad (4)$$

$$4Ga + SiO_2 \rightleftharpoons Si/Ga + 2Ga_2O \quad (5)$$

The dark brown, diamagnetic powder is stable in dry air and may be purified by vacuum sublimation at 500 °C, but undergoes surface oxidation at higher temperatures. Above 800 °C it disproportionates according to the reverse of equation (3). The hydrous oxides Ga(O)OH and $Ga(OH)_3$ are similar to their aluminum analogs. Thus gallium hydroxide

is amphoteric, but a much stronger acid than aluminum hydroxide; for $Ga(OH)_3$ the first acid dissociation constant is 1.4×10^{-7}, while for $Al(OH)_3$ the value is 2×10^{-11}.

On heating with other metal oxides, gallium oxide forms gallates M^IGaO_2, $M^{II}Ga_2O_4$ (spinels), and $M^{III}GaO_3$. The latter include the solid solutions $M^{III}_{2-x}Ga_xO_3$ (M = Al, In). Mixed oxide stoichiometries other than 1:1 (O^{2-}; Ga_2O_3) are quite common. With sodium, there are complex gallates: $NaGaO_2$, Na_3GaO_3, $Na_8Ga_2O_7$, and Na_5GaO_4. The structures of these last two are built up from effectively isolated $[Ga_2O_7]^{8-}$ and $[GaO_4]^{5-}$ units. Some hydrated forms have also been studied, for example, $LiGaO_2{\cdot}6H_2O$, effectively $[Li(OH_2)_4][GaO_2(OH_2)_2]$. The compound $NaGa_{11}O_{16}(OH)_2$ has a complicated structure in which both GaO_4 tetrahedra and GaO_6 octahedra are present. Structures based on GaO_4 tetrahedra prevail among gallates of the divalent metals, for example, $SrGa_2O_4$, $CaGa_2O_4$, $Ca_3Ga_4O_9$, and $Pb_9Ga_8O_{21}$.

4.2.2 *Sulfides and Selenides*

Although not as extensively studied as the group 13–15 compound semiconductors, there has been increasing interest in the heavier gallium chalcogenides because of their possible application as semiconductors,[39] semimetals, photoconductors, and light emitters.[42,43] The gallium sulfides, GaS and Ga_2S_3, are wide band-gap semiconductors (3.05 and 2.85 eV respectively), and are, therefore, considered to hold promise as optoelectronic and photovoltaic materials. Additional work on gallium sulfide has been prompted by its application as passivation layers on GaAs. The chalcogenides of Ga are much more numerous than that of aluminum,[44] and are listed in Table 5.

The hexagonal α- and β-forms of Ga_2S_3 are isostructural with the aluminum analog, having a würtzite structure, while γ-Ga_2S_3 adopts the defect sphalerite structure derived from cubic ZnS (zinc blende). This latter structure is the only type found for Ga_2Se_3 and Ga_2Te_3. It is the isomorphism of γ-Ga_2S_3 with ZnS that is believed to account for the specific enrichment of gallium in sphalerite minerals. All three chalcogenides, Ga_2E_3, are readily prepared from the direct reaction of the elements at high temperature. In addition, Ga_2S_3 can be prepared by the solid-state reaction of $GaCl_3$ and sodium sulfide (equation 6).[45,46] Ga_2S_3 disproportionates at high temperatures to give a nonstoichiometric sulfide, $Ga_4S_{4.8-5.2}$ (equation 7).

Table 5 Stoichiometries and structures of the crystalline chalcogenides of gallium

Sulfide	Selenide	Telluride
Ga_2S green prisms	Ga_2Se	
GaS hexagonal layered structure, Ga–Ga bonds	GaSe like GaS	GaTe like GaS
GaS cubic (ZnS)		
Ga_4S_5		Ga_3Te_2
α-Ga_2S_3 würtzite (ZnS)		
β-Ga_2S_3 defect würtzite		
γ-Ga_2S_3 defect sphalerite	Ga_2Se_3 defect sphalerite	Ga_2Te_3 defect sphalerite
		Ga_2Te_5 chains of $GaTe_4$ plus Te atoms

$$2GaCl_3 + 3Na_2S \longrightarrow Ga_2S_3 + 6NaCl \quad (6)$$

$$2Ga_2S_3 \rightleftharpoons Ga_4S_5 + \tfrac{1}{2}S_2 \quad (7)$$

Unlike the chalcogenides of aluminum, those of gallium form subvalent compounds (i.e. those in which the metal is formally of an oxidation state less than +3). Of these subchalcogenides, the (formally) divalent compounds are of the most interest. The thermodynamic phase of GaS has a hexagonal layer structure (Figure 12) with Ga-Ga bonds (2.48 Å).[47] Each Ga is coordinated by 3 S and 1 Ga, and the sequence of layers along the z-axis is ···SGaGaS, SGaGaS···. The compound can therefore be considered as an example of Ga^{II}, while the presence of Ga-Ga bonding accounts for the diamagnetism of the compound.

Two other phases of GaS are known. The first is a rhombohedral phase,[48] similar in structure to the hexagonal phase, found as an impurity in Ga_2S_3. The second is a metastable fcc phase prepared by MOCVD from the cubane precursor $[(t\text{-Bu})GaS]_4$.[36] The latter phase does not contain any Ga–Ga interactions and is therefore most probably a mixed valence Ga^I/Ga^{III} compound. However, while the electronic structure of the cubic phase is not fully understood, it does have significant applications as a passivation layer on GaAs and other group 13–15 materials. The structures of GaSe and GaTe are similar to the hexagonal phase of the sulfide.

Gallium(I) sulfide cannot be prepared directly from the elements, but is obtained from the thermal decomposition of the higher sulfides. Thus when gallium(II) sulfide is heated at 1100 °C for several hours in a stream of nitrogen, Ga_2S sublimes quantitatively as green hexagonal prisms or yellow–green plates. The compound is in fact a phase of variable composition, $Ga_2S_{0.8-1.1}$, and has a hexagonal lattice similar to that of gallium(II) sulfide (see above). Above

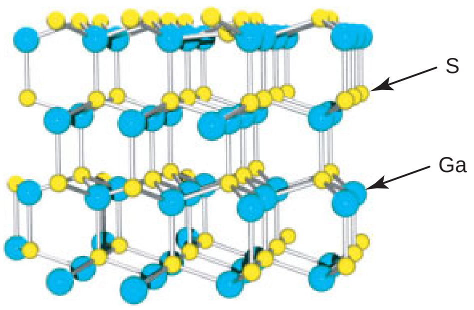

Figure 12 Lattice structure for hexagonal GaS

950 °C, pure Ga_2S decomposes to a liquid mixture of GaS and metallic gallium which becomes homogeneous above 1150 °C (equation 8).

$$Ga_2S(s) \longrightarrow GaS(l) + Ga(l) \rightleftharpoons Ga_2S(g) \qquad (8)$$

Gallium(I) selenide and gallium(I) telluride can be made by melting the elements together in evacuated quartz tubes for prolonged periods; their X-ray powder diffraction patterns have been recorded and indexed.

4.2.3 Chalcogenide Salts

Gallium forms a variety of ternary sulfides and selenides. Common types are $M^{I}GaS_2$, $M^{II}Ga_2S_4$, and $M^{III}GaS_3$; examples of each are $CuGaS_2$, $CdGa_2S_4$, and $LaGaS_3$, respectively. Owing to the unusual electrical properties of these and the corresponding indium compounds, there is an extensive literature concerned with their preparation, physical properties, growth as single crystals, and X-ray studies. Compounds of other stoichiometries occur in mixed sulfide systems involving gallium, for example, $Pb_2Ga_2S_4$ (or $2PbS{\cdot}Ga_2S_3$). All of these compounds have the common structural feature of extended lattices composed of linked GaS_4 tetrahedra, with Ga–S bond distances in the range 2.18−2.36 Å. The tetragallium anion $[Ga_4S_{10}]^{8-}$ has been isolated from the reaction of Ga_2S_3 with aqueous metal sulfides (e.g. equation 9).

$$2Ga_2S_3 + 4K_2S \longrightarrow K_8GaS_{10} \qquad (9)$$

The structure of the hydrated salt, $K_8Ga_4S_{10}{\cdot}14H_2O$, has been determined by X-ray crystallography (Figure 13).[49] The analogous seleno compound has been synthesized, as have the indium species, and all the structures have high thermal and solvolytic stability. Layers of isostructural Ga_4Se_{10} groups, linked through corners, comprise the structure of the ternary selenide $TlGaSe_2$.

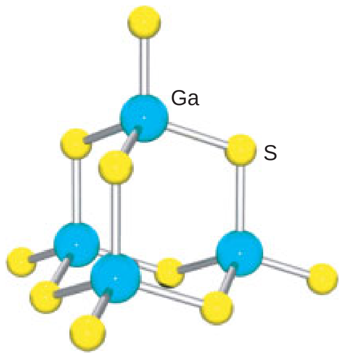

Figure 13 $[Ga_4S_{10}]^{8-}$ anion; Ga–S distances are 2.28 Å (bridging) and 2.25 Å (terminal)

Other gallium−chalcogenide anions are observed in the solid state, that is, discrete $[Ga_6Se_{10}]^{8-}$ anions occur in $Cs_5Ga_3Se_7$, while $Cs_6Ga_2Se_6$, obtained as moisture-sensitive crystals by the reaction of Cs_2Se with Ga_2Se_3, contains the $[Ga_2Se_6]^{6-}$ anion.

5 I-III-VI$_2$ TERNARY COMPOUNDS

The crystal structure of I-III-VI$_2$ ternary materials is common to the cubic zinc blende structure of II-VI material's (i.e. ZnS), but differs by group I and III atoms occupying the Zn sites alternatively. Consequently, each group I or III atom has a connectivity of four bonds to the group VI atom, hence each VI atom has two VI-I and two VI-III bonds (Figure 14). Owing to the different bond lengths of I & III with the group VI, atom lattice distortion is evident.

The most prevalent ternary chalcopyrite materials are *p*-type Cu(In:Ga)(S:Se)$_2$ (CIGS), which crystallize in the tetragonal chalcopyrite structure and are used in the photovoltaic modules. The complexity of the phase diagrams for Cu-III-VI materials results in a large number of intrinsic

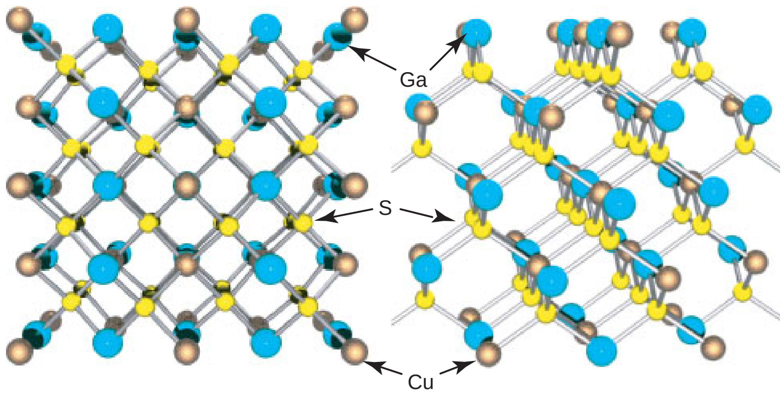

Figure 14 Structural representation of lattice packing for I-III-VI$_2$ materials

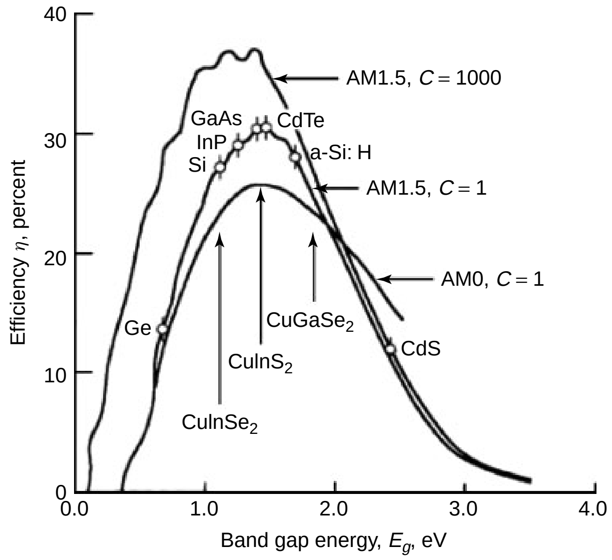

Figure 15 Predicted efficiency versus band gap for thin-film photovoltaic materials for solar spectra in space (AM0) and on the surface of the Earth (AM1.5) at 300 K compared with bandgaps of other PV materials with unconcentrated (C = 1) and high concentration (C = 1000) sunlight

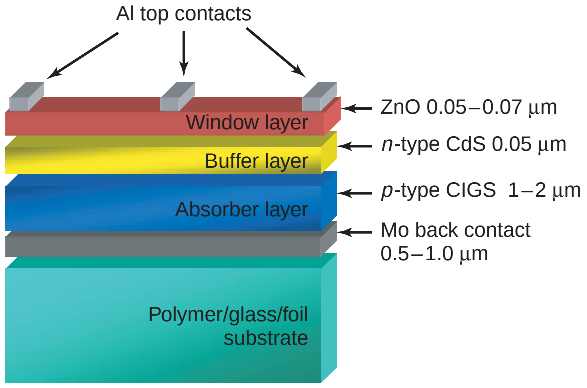

Figure 16 Schematic representation of a typical CIGS solar cell

defects in the semiconductor, which can influence the doping of the alloy and has been recently studied by Burgelman and Zhang.[50–53] The conductivity of the *p*-type CIGS is mainly due to copper atoms residing on indium vacant sites, whilst a deficiency in group VI atoms is considered to contribute to *n*-type doping. The use of a chalcopyrite semiconducting material is highly appealing since the band gap correlate well to the maximum photon power density in the solar spectrum for both terrestrial (AM 1.5), and space applications (AM0) (Figure 15), while displaying long-term stability and excellent radiation tolerance.[54] Furthermore, the band gap can be tuned from 1.0 eV to 2.4 eV, by adjusting the percent atomic composition of either Ga for In and S for Se.[55] The schematic of typical CIGS solar cell is shown in Figure 16.

Current methods for depositing ternary crystallite compounds include coevaporation of elements,[56] or alloys,[57] electrodeposition,[58] reactive-sintering,[59] and flash evaporation,[60] which are often followed by sulphurization/selenization steps, at elevated temperatures. The current world record cell has been reported by NREL with an efficiency of 19.2% based on their patented three-stage process.[55]

A more chemistry-based route to I-III-VI alloys is one that encompasses the design of molecular 'single-source precursors'. Two such routes are those involving the codeposition of two binary single-source precursors, namely, metal dithiocarbamates, and more recently the use of ternary single-source precursors. The first example of a ternary $CuGaS_2$ single-source precursor was recently reported, and although the exact molecular structure of the ternary precursor could not determined, well adhering stoichiometric thin films of $CuGaS_2$ were successfully deposited in an Aerosol Assisted CVD process.[61] Additionally, codeposition of Ga and In ternary single-source precursor to CIGS was also realized. Ternary single-source precursors of the form $[M^{(I)}(ER)_2Ga^{(III)}(ER)_2]$ ($M^{(I)}$ = Cu, Ag), to afford the semiconductor $CuGaS_2$ $AgGaS_2$ have also been designed, and their molecular structure have been elucidated[62] (Figure 17).

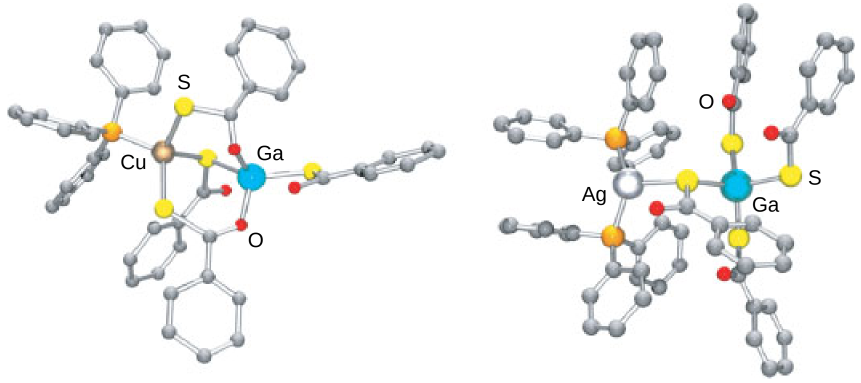

Figure 17 Molecular structure of $[\{PPh_3\}Cu(\mu\text{-}SC\{O\}Ph)_4Ga(SC\{O\}Ph)_2]$, $[\{PPh_3\}_2Ag(\mu\text{-}SC\{O\}Ph)_4Ga(SC\{O\}Ph)_2]$

Thermogravimetry and pyrolysis studies at 300 °C, (0.5 mmHg) for 30 min revealed that these compounds decompose to give the corresponding ternary metal sulfide materials, but thin-film deposition studies for the Ga derivatives are yet to be studied.

A series of trialkylammonium salts of indium and gallium thiocarboxylates, $[Et_3NH][M(SC\{O\}Ph)_4]\cdot H_2O$ (M = In, Ga) were synthesized and characterized for their use as precursors to metal chalcopyrite structures.[63] Thermogravimetric and pyrolysis experiments of these compounds showed the formation of tetragonal β-In_2S_3 and poorly crystalline monoclinic Ga_2S_3, respectively. In similar MOCVD studies, deposition on a nickel substrate gave thin films of cubic γ-Ga_2S_3 and hexagonal $Ni_{0.96}S$. Whereas deposition onto a Cu coated Si substrate afforded thin films of tetragonal $CuInS_2$, the gallium derivative furnished a mixture of tetragonal $Cu_{1.96}S$ and $CuGaS_2$. The composition of the thin films was found to be temperature-dependent during the growth process and the formation of $Cu_{1.96}S$ and $CuGaS_2$ results by the reaction of the group III compounds with the copper substrate to form the metal sulfide thin films.

6 GALLIUM NANOCRYSTALLITES

6.1 Introduction

Over the decade, there has been an immense drive to develop synthetic processes, and characterize binary nanocrystalline semiconducting material. The size dependent luminescence of these materials is a result of quantum confinement within the nanosized particulate resulting in an engineered band gap (eV) through the formation of discreet bonding/antibonding orbitals. As discussed earlier, many of the III-V materials are direct band-gap semiconductors, which have led to their increased use in optoelectronics and telecommunications. Consequently, it is the most frequently studied group of Ga nanocrystallites, but still falls well short of the number of studies for its Indium analogs. A few detailed reviews[9,64,65] and book chapters[66,67] have recently covered this area in depth.

6.2 III-V

Unlike the synthetic procedure established for fabricating II-VI semiconducting nanocrystallites, the use of a similar synthetic procedure cannot be directly translated for the synthesis of gallium pnictogens nanocrystallites, but requires modification. This is attributed to the reactivity of the gallium reagents, the greater covalent bonding nature of III-V material and the higher energetic barriers in the formation of the semiconductor from suitable precursors. The current reported methods that have been used are shown in equations (10–13).

$$GaCl_3 + As(SiMe_3)_3 \longrightarrow GaAs + 3ClSiMe_3 \quad (10)$$

$$Ga(CH_3(CO)CH(CO)CH_3)_3 + As(SiMe_3)_3 \xrightarrow{\text{triglyme}} GaAs \quad (11)$$

$$GaCl_3 + M_3E \xrightarrow[\text{M=K, Na; E=P, As}]{\text{glymes}} GaE + 3ClSiMe_3 \quad (12)$$

$$2GaCl_3 + 2InCl_3 + P(SiMe_3)_3 \xrightarrow{\text{TOPO}} GaInP_2 + 3ClSiMe_3 \quad (13)$$

GaAs nanocrystals have been prepared by dehalosilyation reaction (equation 10), with the driving force being the high propensity for the formation of the Si–Cl bond.[68–70] In order to limit nucleation and particle growth via Ostwald ripening, coordinating ligands are used, which are commonly referred to a capping or passivating group/ligand. Initial studies using the dehalosilyation route where quinoline was used as both the solvent and capping ligand afforded 3–4 nm sized nanocrystals. However, optical interference from by-products during the synthesis was prevalent. Alternatively, the use of coordinating compounds such $Ga(acac)_3$ (acac = $CH_3(CO)CH(CO)CH_3$) has been studied (equation 11). However, size distribution control of the GaAs nanocrystals was not achievable owing to the large number of nucleation centers formed.[71] In the presence of a trioctylphosphine oxide (TOPO), which serves to passivate dangling surface bonds, nanocrystals of GaP and $GaInP_2$ were realized with good size distribution and optical properties.[64,72] In the continued pursuit of greater size distribution control and crystal quality, a polymeric Ga imide precursor $[Ga(NH_3)_{3/2}]_n$ heated in trioctylamine at 360 °C for one day was investigated.[73] The purified GaN particles, when partially dispersed in a nonpolar solvent, yielded transparent colloidal solution that consisted of individual spherical GaN particles (3 nm). The photoluminescence spectrum at 10 K (excited at 310 nm) showed a band edge emission with several emission peaks at 3.2–3.8 eV, while the photoluminescence excitation spectrum studies showed two excited-state transitions at higher energies.

A thermal reaction preparative route reacting Li_3N and $GaCl_3$ in benzene under pressure was successfully demonstrated to afford GaN 30 nm particles at low temperatures (280 °C) in high bulk yields of approximately 80%. Structural characterization revealed the sample was mainly hexagonal-phase GaN with a small fraction of rocksalt-phase GaN, which has a lattice constant of 4.100 Å. This rocksalt structure has been observed previously only under high pressure (>37 gigapascals).[74]

An interesting variation to this benzene thermal route is the preparation of GaN nanoparticles from the conversion of Ga_2S_3, as shown in equation (14). At 180 °C, a size distribution of 10–15 nm is achieved, whereas at 230 °C, a size distribution of 15–25 is achieved; however, crystal quality is poor at best or amorphous at the lower temperatures.[75]

$$Ga_2S_3 + 2Na_3N \xrightarrow{\text{benzene}} 2GaN + 3Na_2S \quad (14)$$

A novel method receiving great interest is the use of binary III-V single-source precursors, for example, the controlled pyrolysis of the inorganic polymer $[(Cl_3Ga_2P)]_n$ or $[X_2GaP(SiMe_3)_2]_2$ at reduced temperatures and pressures affords GaP nanocrystallites.[65] Additionally, the hydride analog $[H_2GaE(SiMe_3)_2]_2$ (E = As, P) was also successfully decomposed in xylenes (450 °C) to form III-V particles (5 nm).[76] Thermolysis of $M(PBu^t_2)_3$ (M = Ga, In) in hot 4-ethylpyridine afforded InP and GaP nanocrystals.[65] Investigations into the thermal decomposition mechanisms have suggested three major processes, two of which are temperature dependent; reductive elimination and β-hydrogen elimination, and the third a minor pathway involving free-radical formation. Attempts to prepare III-V nanocrystallites from either $Ga(PBu^t_2)_3$ and $In(PBu^t_2)_3$ in TOPO failed to yield the desired product. The fabrication of nanoparticles using this method has been recently been published.[77]

A non-chemical solution route for nanocrystallites formation is via Stranski-Krastinow Epitaxial Growth.[78] The nanocrystallites are formed by epitaxial growth by either MBE or MOCVD. The principle behind the formation of nanocrystallites is the controlled deposition onto a semiconducting substrate with a differing lattice constant, then the III-V material being deposited. When the lattice mismatch is sufficiently high, after the deposition of the first few monolayers, small islands of nanocrystallites are formed. This technique has focused primarily on Ga_xInAs_{1-x} grown on GaAs. A number of reports have focused on the preparation of β-Ga_2O_3 nano derivatives. A patented high-temperature method involves heating (1600 °C), a mixture of boron powder and bulk Ga_2O_3 in a 2:1 ratio in an inert atmosphere to yield Ga_2O_3 nanowires with a diameter of 15–100 nm, coated with 3–5 nm of BN layer.[79] In a similar process, substituting activated carbon for boron affords β-Ga_2O_3 nanowhiskers ($\leq$50-mm length, diameter 10–100 nm).[80]

Nanocrystal shape engineering has been demonstrated via a novel technique for the preparation of α-Ga_2O_3 nanoparticles, nano-hollow-particles, or nanorods and nanotubes via oxidation of nanocrystalline GaP at 400 °C for 30 min in dry O_2.[81] Additionally, a chemical vapor deposition process has been used to fabricate β-Ga_2O_3 from a gallium/gallium oxide mixture and oxygen. The diameter of the single-crystalline monoclinic nanowires were 30–80 nm with an average value of 50 nm. Nanowires grown without catalyst exhibited a significant planar defect, whereas the nanowires grown with nickel catalytic nanoparticles were reported to be almost defect-free.[82]

6.3 III-VI & I-III-VI$_2$

Binary III-VI alloys crystallize in a variety of forms such as defect wurtzite (Ga_2E_3), layered structures GaE, and a novel cubic form, whereas α, β, and $\gamma - Ga_2S_3$ are reported to have a wurtzite, hexagonal, and monoclinic phase respectively.[83] The two predominant binary stoichiometries are AB and A_2B_3, and these are categorized as mentioned earlier as mid to wide band-gap semiconductors. In comparison with II-VI and III-V nanocrystallites, there is a paucity of reports on preparation of III-VI and I-III-VI$_2$ nano derivatives, and of those they mostly focus on Indium derivatives (*see* ***Indium: Inorganic Chemistry***). The most widely used methods are pyrolysis of single-source precursors such as carbamate coordination compounds, selenolate thiolate complexes, and solvothermal high-temperature procedures of metal salts.

Although there are a limited number of reports for the preparation of InS and InSe nanoparticles via the use of single-source precursors such as $[In(S_2CNEt_2)_3]$ and $[In(Se_2CNEt_2)_3]$ respectively, there are no reported studies for their Gallium counterparts. However, decomposition of $[Bu^tGaSe]_4$ clusters under CVD condition has been shown to afford GaSe pseudo-spherical nanoparticles with a mean diameter of 42 ± 13 nm.[84] In addition, the use of ternary single-source precursors such as $[(PPh_3)_2CuIn(SEt)_4]$ and $[(PPh_3)_2CuIn(SePh)_4]$ have been successfully shown to yield I-III-VI$_2$ nanoparticles via pyrolysis in dioctyl phthalate at 200–300 °C (forming aggregated cluster with nanoparticles of size from 3 to 30 nm);[85,86] however, similar gallium derivatives remain to be studied for their potential use for the formation of Ga based I-III-IV$_2$ nanoparticles via this route.

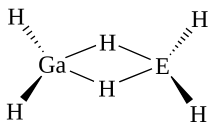
Solvothermal routes have been used to realize the formation of I-III-VI$_2$ nanoparticles.[87–89] Aqueous and nonaqueous colloids, $CuInS_2$, $CuInSe_2$, $CuGaS_2$, $CuFeS_2$, $AgInS_2$, were prepared by the reaction of the respective metal salts in either water or $CNMe_3$ that has been saturated with H_2E, (E = S, Se) and stabilized with polyvinylalcohol (1%). For the formation of nanoparticle $CuGaS_2$ clusters, these were synthesized exclusively from a CuI solution in acetonitrile (0.01 mol/l and below) and gallium nitrate. Spherical $CuGaS_2$ particles (35-nm diameter) have been synthesized by adapting a low-temperature autoclave method used for preparing III-V nanoparticles. The reaction of CuCl with elemental Ga with excess sulfur at 200 °C for 12 h affords the crude product. Treatment of the precipitate, by washing with dilute acid, distilled water, and absolute ethanol, respectively, and drying under vacuum at 50 °C for 4 h gave the final nanocrystalline semiconductor. The synthesis of a number of analogous Ga-containing clusters has been reported, with the potential to afford ternary semiconducting alloys.[90]

7 HYDRIDES AND HYDRIDE COMPLEXES

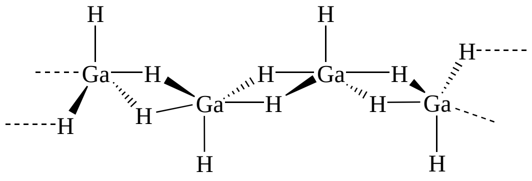
The chemistry of the group 13 hydrides originated in 1912 with Alfred Stock's classic investigations into the synthesis and characterization of numerous boron hydrides (boranes) including the parent diborane, B_2H_6 (*see* ***Boron Hydrides***). Unlike boron, aluminum does not form a low-molecular weight hydride analogous to diborane, but a polymeric species $[AlH_3]_x$, in which each aluminum is surrounded octahedrally

by six hydrogens. As early as 1941, the isolation of both $[GaH_3]_x$[91] and Ga_2H_6[92] was claimed, but failure to repeat this work and the anomalously high thermal stability of the compounds caused researchers to question the existence of these compounds. However, a recent series of definitive studies not only showed that gallane does indeed exist in both oligomeric, $[GaH_3]_x$, and dimeric, Ga_2H_6, forms, but also confirms that the previous synthetic claims were incorrect. The low thermal stability ($<-20\,°C$) of gallane is consistent, however, with the periodic decrease in the M–H bond strength.

The presence of a stable diborane-like molecule $[H_2Ga(\mu\text{-}H)]_2$ in both solution and the vapor phase suggests that the chemistry of gallane has a marked similarity to that of diborane, that is, (**1**). The analogy between the gallium and boron hydrides is extended by the synthesis and structural characterization of the mixed gallaborane, $GaBH_6$ (**1**).



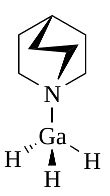
(**1**) E = B, Ga



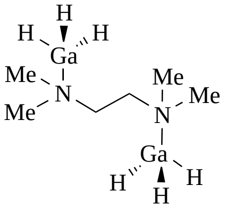
(**2**)

Although no structural details have been reported for the oligomeric form of gallane, $[GaH_3]_x$, IR spectroscopic evidence suggests the retention of terminal Ga–H bonds. This is unlike the all-bridging hydride six-coordinate structure of $[AlH_3]_x$, suggesting the gallium in $[GaH_3]_x$ is perhaps five-coordinate with a single terminal Ga–H bond along with doubly hydride-bridged $Ga(\mu\text{-}H)_2Ga$ units (**2**), similar to that observed in the structure of $HGa(BH_4)_2$.[93]

The adduct $[GaH_3(NMe_3)]$ is a colorless, crystalline compound (mp 70.5 °C), which is formed quantitatively by the reaction of ethereal solutions of $Li[GaH_4]$ and $[NHMe_3]Cl$; like the aluminum analog, it takes up a further mole of ligand to give the trigonal bipyramidal $[GaH_3(NMe_3)_2]$. Numerous complexes with other Lewis base ligands may be prepared from $[GaH_3(NMe_3)]$, and the structures of some of these have been determined by X-ray crystallography, for example, (**3**) and (**4**).[94] The stabilities of the 1:1 adducts have been determined to decrease in the sequences: $NHMe_2 > NMe_3 >$ pyridine $> NEt_3 > NMe_2Ph > NPh_3$; $NMe_3 \sim PMe_3 > PHMe_2$; $PPh_3 > NPh_3 > AsPh_3$; NR_3 or $PR_3 > OR_2$ or SR_2.



(**3**)



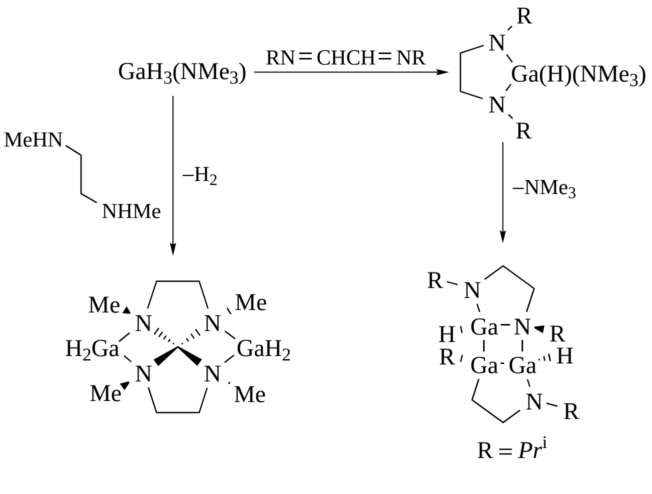
(**4**)

Gallane and its Lewis base complexes react readily with protic acids to eliminate hydrogen. Thus complexes of the type $GaH_2X(NMe_3)$ and $GaHX_2(NMe_3)$ (X = Cl, Br) are readily prepared by reaction of HX on the gallane complex at low temperatures. The reactions shown in Scheme 2[94] are examples of an elimination–condensation reaction with a secondary amine and the reduction of an imine; both reaction types have been observed for aluminum hydrides.

Gallium hydride complexes have also been studied for their use in fabricating binary thin films. $[H_3Ga(HNMe_2)]$ has been used in the growth of GaAs and AlGaAs film in low-pressure CVD type processes, which demonstrates reduced carbon contamination in the III-V films.[95] Unfortunately, as like most amine adducts of gallane they are very labile and require storage at low temperatures, therefore these GaAs films grown from $[H_3Ga(HNMe_2)]$ with AsH_3 or H_2AsBu^t have *p*-type behavior.[95]

Dichlorogallane $(HGaCl_2)_2$ was recently readily prepared from $GaCl_3$ and triethylsilane in high yields. Single-crystal X-ray diffraction revealed the Cl-bridged dimers as having C_{2h} symmetry, with the terminal H atoms in trans geometry. In the reaction of dichlorogallane with 2 equivalents of triethylphosphine, mononuclear $[(Et_3P)GaHCl_2]$ is formed.[96]

The reactions of trichlorogermane $HGeCl_3$ and dichlorogallane $HGaCl_2$ with pyridine donors has been recently studied. Pyridine was found to deprotonate $HGeCl_3$ to afford pyridinium trichlorogermanate(II), $PyH^+[GeCl_3]^-$.



Scheme 2

This course of the reaction was examined and supports the assignment of an inverse polarization (−)Ge-H(+) of the bond in $HGeCl_3$ as compared to the (+)Si-H(−) bond in trichlorosilane $HSiCl_3$, which is known to form a 1:2 adduct with pyridine instead. Dichlorogallane was found to form 1:1 coordination compounds ($HGaCl_2L$), where L = pyridine, 4-dimethylaminopyridine, 4-cyanopyridine, and 3,5-dimethylpyridine.[97]

Dialkylgallium hydrides $[R_2GaH]_n$ (R = Me, Et, $CHMe_2$, CH_2CHMe_2, CH_2CMe_3) have been readily prepared by two different synthetic routes. The methyl and ethyl derivatives were formed by the reaction of LiH with the corresponding dialkylgallium chlorides via lithium dialkyldihydrogallate intermediates; however, they were not isolated in a pure form. In the second route, the trialkylgallium compound was treated with $[H_3Ga(NMe_2Et)]$ to yield the dialkylgallium hydrides by a substituent exchange reaction. The trimeric structure with inner Ga_3H_3-heterocycle was verified for R = $CHMe_2$ by a single-crystal structure determination, whereas for R = CH_2CMe_3, a dimeric structure both in solution and solid state is noted.[98]

The synthesis and structural characterization of a thermally stable group 13 hydride complexes derived from a gallium(I) carbene analog was achieved.[99] The reactivity of $[Ga\{NC(R)C(H)\}_2]^-$ (R = $C_6H_3(Pr^i)_2$) with $[AlH_3(NMe_3)]$ in an ethereal solution yielded $[Ga\{[NC(R)C(H)]_2\}_2][K(DME)_4]$. In addition, the reaction with tertiary amine adducts of GaH_3 and InH_3 in a 2:1 stoichiometry were found to give the respective salt complexes.

The first gallane-coordinated metal complex, $[(OC)5W(\eta^1\text{-}GaH_3\cdot\text{quinuclidine})]$, was synthesized by photolysis of a near 1:1 mixture of $W(CO)_6$ and H_3Ga·(quinuclidine), in toluene and THF.[100] X-ray crystal-structure analysis revealed that product is bound to the W fragment via a W–H–Ga three-center-two-electron bond. Controlled test reactions indicated that the gallane ligand complex is inert toward direct substitution reactions and decomposes without releasing free H_3Ga·(quinuclidine). The synthesis of Lewis acid/base-stabilized phosphanylgallanes $[(CO)_5WPH_2MH_2(NMe_3)]$ (M = Al, Ga) has been obtained via H_2 elimination reactions between $[(CO)_5WPH_3]$ and H_3MNMe_3. Crystal structures were determined for both complexes and comprehensive density functional theory (DFT) calculations on the aluminum systems were used to verify the high stability of the complexes.[101] In addition, a complete series of intermetallic gallane hydrides has been synthesized and studied with their potential aspect for depositing mixed metal gallium films.[102]

The preparation of $[Bu^t(H)Ga(\mu\text{-}NEt_2)]_2$ was accomplished by the metathesis reaction between Bu^tLi with $[Cl_2Ga(\mu\text{-}NEt_2)]_2$. Evidence suggests that two Bu^t groups are lost as isobutylene and result in Ga–H bond formation. The gallium hydride demonstrates high stability toward ambient air, oxygen, photolysis, and moderate heating; however, in $CHCl_3$ the hydride is replaced by chloride, producing $[Bu^t(Cl)Ga(\mu\text{-}NEt_2)]_2$. $[Bu^t(H)Ga(\mu\text{-}NEt_2)]_2$ was also synthesized by sequential additions of Bu^tLi to $[Cl_2Ga(\mu\text{-}NEt_2)]_2$. A singly substituted *tert*-Bu dimer, $[Bu^t(Cl)Ga(\mu\text{-}NEt_2)_2GaCl_2]$, was also isolated, and interconversions between three gallium hydrides were reported as was its utility in fabricating GaN. However, it was found to yield nitrogen deficient films as a consequence of facile Et_2NH elimination.[103]

8 GROUP 14, 15, AND 16 DONOR LIGANDS

8.1 Introduction

The majority of compounds reported in the literature containing ligands with either a group 15 or 16 donor atom are derived from a gallium alkyl, and as such they are covered in (*see* ***Gallium: Organometallic Chemistry***). However, a number of purely inorganic compounds and complexes are relevant to the present discussion. Where compounds contain both a group 15 or 16 donor ligand and either a hydride or halide ligand, they (and any relevant references) are included in the appropriate section depending on the ligand type of primary importance.

8.2 Silyl Gallium Compounds

Clearly, alkyl (and aryl) groups make up the largest contingent of group 14 ligands; however, surprisingly little work has been reported on compounds of gallium with silicon containing ligands, and no nonalkyl-based compounds with germanium or tin ligands are known. Tris(trimethylsilyl)gallium is produced by treating $GaCl_3$ and three equivalents of Me_3SiCl in the presence of lithium metal in THF. The initial solvated adduct, $Ga(SiMe_3)_3$·THF, is converted to $Ga(SiMe_3)_3$ by vacuum sublimation. $Ga(SiMe_3)_3$ is monomeric, with a planar $GaSi_3$ framework, characterized by vibrational bands $\nu(\text{Ga–Si})_{sym} = 312\,\text{cm}^{-1}$ (Raman) and $\nu(\text{Ga–Si})_{deg} = 349\,\text{cm}^{-1}$. The area of Si gallium chemistry that has been explored thoroughly is the use of bulky silane groups to encourage cluster formation, and as such is reported in detail in ***Electronic Structure of Clusters***; ***Silicon: Inorganic Chemistry***; ***Silicon: Organosilicon Chemistry***.

Recently the first compounds containing Si=Ga or Si=In double bonds, 1,3-disila-2-gallata- and -indataallenic anions respectively, were obtained in the form of lithium salts as dark red crystals by the reaction of *bis*(di-*tert*-butylmethylsilyl)dilithiosilane, with the respective M(III) halide (Figure 18).[104] X-ray crystallographic analysis of gallium and indium salt derivatives showed that the >SiMSi< frameworks (M = Ga, In) are not linear and the two Si=M

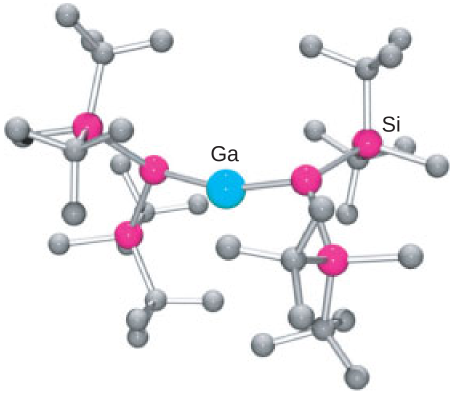


Figure 18 $Li[(Bu^t_2MeSi)_2SiGaSi(Bu^t_2MeSi)_2]$: hydrogen atoms and the cationic fragment $[Li(thf)_4]^+$ are omitted for clarity: Si-Ga-Si = 161.61(3) deg

bond lengths are about 9% shorter than typical Si–M single bonds (Figure 18). The ^{29}Si NMR spectra show the signals of the terminal Si atoms in both compounds are greatly shifted upfield (Ga: −79.9; In: −77.6 ppm). In addition, the gallium salt was found to react with MeI to give the corresponding iodogallane in nearly quantitative yield, thus confirming that the allenic $[>SiMSi<]^-$ fragments are highly polarized.

8.3 Nitrogen Derivatives

8.3.1 Amine and Amido Ligands

As discussed earlier, gallane and the trihalides all form Lewis acid–base complexes with amines and N-heterocyclic ligands. While the majority of these compounds are neutral and have a general formula of $GaX_3(L)_n$ ($n = 1, 2$), complexes formed with bidentate ligands such as 1,10-phenanthroline and 2,2′-bipyridyl are typically ionic. A common feature of these complexes is the presence of a gallium cation, for example, $[Ga(bipy)_3]^{3+}$ or $[GaCl_2(bipy)_2]^+$. Thus the crystal structure of '$GaCl_3$(bipy)' shows it to be *cis*-$[GaCl_2(bipy)_2]^+[GaCl_4]^-$.[4]

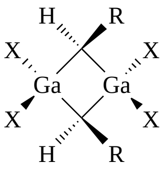
Potassium amidogallate, $K[Ga(NH_2)_4]$, is prepared by dissolving gallium in a solution of KOH in liquid ammonia. Heating this compound to 300 °C under vacuum removes two moles of ammonia, forming the imido complex $K[Ga(NH)_2]$, while partial neutralization of the ammonia solution of $K[Ga(NH_2)_4]$ with NH_4Cl yields $Ga(NH_2)_3$. The anion $[Ga(NH_2)_4]^-$ has tetrahedral symmetry, according to the single-crystal Raman spectrum in which ν(Ga–N) appears near 550 cm^{-1}. $NaGa(NH_2)_4$ crystallizes isotypic in space group P21/c was obtained by the reaction of the metals with NH_3 in autoclaves at 100 °C and $P(NH_3) = 60$ bar within 7 days.[105] A more highly coordinated complex, $Na_2[Ga(NH_2)_5]$, has also been prepared. From evidence of IR spectra, this contains six-coordinate gallium, with a structure based on linked $Ga(NH_2)_6$ octahedra with both bridging and nonbridging NH_2 groups.[4]

Dialkylamido compounds, $GaX_2(NR_2)$, $GaX(NR_2)_2$ (X = halide), and $Ga(NR_2)_3$, are obtained from the reaction of GaX_3 with the appropriate equivalents of $LiNR_2$; unless precluded owing to steric hindrance, an excess yields $Li[Ga(NR_2)_4]$. Hydrido-substituted amido compounds, $[H_2Ga(NXR)]_n$ (X = H or R, $n = 2$ or 3), may be prepared from the reaction of primary or secondary amines with $GaH_3(NMe_3)$. In the absence of steric hindrance, gallium amido compounds oligomerize as a result of the amido ligands bridging ability.[4] Thus for $Ga(NR_2)_3$ when R = Me, a dimerization through bridging dimethylamido ligands occurs, while in the case of R = $SiMe_3$ a monomeric structure is observed.

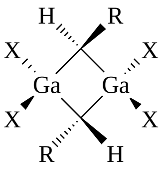
Gallane complexes with amido-amine ligands $–N(R)CH_2CMe_2CH_2NMe_2$ [R = H or $SiMe_3$ (TMS)], (**5**) $\{H_2Ga[N(H)CH_2CMe_2CH_2NMe_2]\}_2$, (**6**) $H_2Ga[N(TMS)CH_2CMe_2CH_2NMe_2]$, (**7**) $\{H(Cl)Ga[N(H)CH_2CMe_2CH_2NMe_2]\}_2$, (**8**) $\{[(TMS)_2N](H)Ga[N(H)CH_2CMe_2CH_2NMe_2]\}_2$, (**9**) and $HGa[N(TMS)CH_2CMe_2CH_2NMe_2]_2$, (**10**) were synthesized from the reactions of the quinuclidine adducts of mono- and dichlorogallane with the corresponding lithium amides. Structural determinations of compounds (**5**), (**7**), (**8**) showed they were dimeric with bridging amido groups. The tertiary amine groups in (**5**) and (**8**) were hydrogen-bonded to the amido N–H rather than being bonded directly to gallium center. In the structure of compound (**7**), the amine group was found to occupy an axial position in the trigonal bipyramidal geometry of the five-coordinate gallium. These results were rationalized in terms of the steric and electronic properties of respective gallium ligands.[106]

Base-free tris(primary amido) compounds of the type $M[N(H)Mes^*]_3$ (M = Al, Ga, In; Mes* = 2,4,6-tri-*tert*-butylphenyl) have been synthesized via the salt elimination reaction of Mes*N(H)Li with the respective MCl_3. Whereas the singly base-stabilized *tris*(primary amido) derivatives, $[M\{N(H)Dipp\}_3(py)]$ (Dipp = 2,6-diisopropylphenyl), have been prepared via an amine elimination reaction of H_2NDipp with $[E(NMe_2)_3]_2$. These derivatives were also to be examined for their potential as III-V precursors.[107]

In compounds where oligomerization occurs, the formation of dimeric versus trimeric species, as well as *cis* (**11**) and *trans* (**12**) isomers for compounds derived from primary (or asymmetric secondary) amines, is governed by the steric hindrance at both nitrogen and gallium.



(**11**)



(**12**)

For example, an equilibrium mixture of the *trans* trimer, and the *cis* and *trans* dimers of $GaCl_2[NH(SiMe_3)]$, has been observed in toluene solution. When a methyl group is

substituted for the hydrogen atom on the nitrogen, only the *cis* and *trans* dimers of $GaCl_2[NMe(SiMe_3)]$ were found in solution.[108] Substituted aminogallanes exhibit a similar trend. $GaH_2(NHMe)$ is trimeric in solution while $GaH_2(NMe_2)$ exists as a dimer. Apparently the introduction of a second substituent on the nitrogen atom creates sufficient steric strain to prohibit the formation of the trimer. The effect of the substituents bonded to the nitrogen on the degree of association and the conformational properties of aminogallanes has been examined extensively; however, the manner in which the substituents on the gallium atom influence the trimer–dimer equilibrium and the isomerization of the dimer has only been recently explored. One such study showed that the trimer–dimer equilibrium present for $GaCl_2[NH(SiMe_3)]$ is absent for $GaBr_2[NH(SiMe_3)]$, *cis* and *trans* isomers of the dimer being the only species observed.[109] Although the van der Waals radii of the chlorine and bromine atoms (1.70–1.90 and 1.80–2.00 Å) differ only slightly, the increase in the steric requirements of the bromide atoms compared with the chloride atoms is clearly sufficient to prohibit the formation of the trimer, leading to the exclusive formation of $[Br_3Ga(NHSiMe_3)]_2$.

8.3.2 Miscellaneous

While the transition metal chemistry of the pyrazolylborate ligands, $[H_xB(pz)_{4-x}]^-$ ($x = 0-2$, pz = pyrazolyl) has been extensively studied, it is only recently that the first gallium compounds have been reported. Reaction of $GaCl_3$ with the bis(pyrazolyl)borato ligands (equation 15) yields a five-coordinate complex (Figure 19).[110]

$$2K[H_2B(pz)_2] + GaCl_3 \longrightarrow [H_2B(pz)_2]_2GaCl + 2KCl \quad (15)$$

In contrast, the substituted tris(pyrazolyl)borate ligand allows for the formation of the six-coordinate complex cation (**13**) (equation 16).[111] The 3,5-dimethylpyrazolate analog has

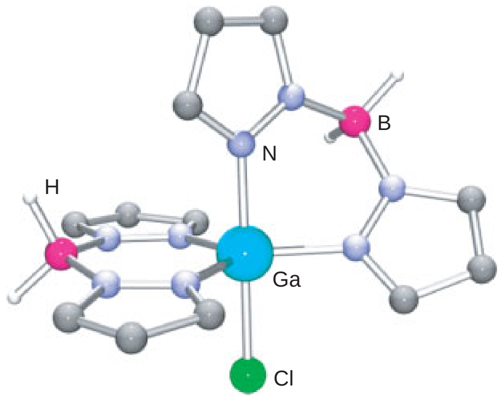


Figure 19 Molecular structure of $[H_2B(pz)_2]_2GaCl$

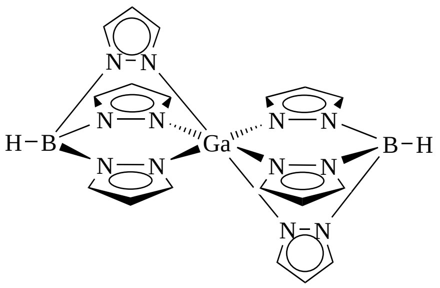
also been reported.

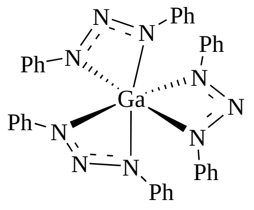
$$2K[HB(pz)_3] + 2GaCl_3 \longrightarrow [GaH\{(pz)_3BH\}_2]^+ + [GaCl_4]^- + 2KCl \quad (16)$$



(**13**)

$[GaCl_2(pyrazole)_4]Cl$ and $[GaCl_2(pyrazole)_4]GaCl_4$ are formed in the reaction of pyrazole and anhydrous $GaCl_3$ in toluene/Et_2O solution. The crystal structure of the chloride salt shows the cations in a trans-configuration which are associated with the chloride counterions through N-H–Cl H bonds.

The triazenide anion, $RN{=}N{-}NR^-$, is formally isolobal with the carboxylate anion. However, while there are no well-characterized examples of gallium tris-carboxylates (see Section 8.7), the *tris*(1,3-diphenyltriazenide) complex $Ga(dpt)_3$ (**14**) has been isolated and fully characterized.[112]



(**14**)

A number of simple N-donor ligand complexes are known; for example, azide, $[Ga(N_3)]$, thiocyanate, $[Ga(NCS)_4]^-$, and selenocyanate, $[Ga(NCSe)_4]^-$. However, spectroscopic evidence suggests that the cyanate anions coordinate via the oxygen.[5] The gallium secondary amines adducts $TMPH{\cdot}GaCl_3$ and $Pr^i_2NH{\cdot}GaCl_3$ (TMPH = tetramethylpiperidine) were achieved through synthesis from the respective reagents in toluene at −78 °C in very high yields of 80%. Characterization via single-crystal determinations revealed $TMPH{\cdot}GaCl_3$ having short Ga···H–N distances (2.28(9) Å).[113]

A series of group 13 metal complexes featuring the β-diketiminate ligand $[\{(C_6H_3\text{-}2,6\text{-}Pr^i_2)NC(Me)\}_2CH]^-$ (i.e. $[Dipp_2nacnac]^-$, Dipp = C_6H_3-2,6-i-Pr^i_2) have been prepared and fully characterized. The chloride derivative $Dipp_2nacnacGaCl_2$ was isolated by the reaction of 1 equivalent of $Dipp_2nacnacLi{\cdot}Et_2O$ and the respective metal halides. The iodide derivatives $Dipp_2nacnacGaI_2$, which are useful for

reduction to afford M(I) species, were made by a variety of routes. Their X-ray crystal structures feature nearly planar C_3N_2 arrays in the $Dipp_2$nacnac ligand backbone with short C–C and C–N distances that are consistent with a delocalized structure. However, there are large dihedral angles between the C_3N_2 plane and the N_2Ga metal coordination plane, which have been attributed mainly to steric effects. The relatively short Ga–N distances are consistent with the coordination numbers of the metals and the normal/dative character of the nitrogen ligands.[114]

8.4 Phosphines and Arsines

While there are a large number of phosphines and arsine adducts of GaX_3, the number of nonorganometallic phosphide and arsenide compounds are few, and of those the steric bulk of the group 15 substitutes is of critical importance in controlling their isolation. Reaction of $GaCl_3$ with three equivalents of lithium dimesitylarsenide yields the monomeric triarsenide compound $Ga[As(Mes_2)]_3$,[115] whose structure has been shown by X-ray crystallography (Figure 20) to consist of a gallium atom bonded to three arsenic atoms in a trigonal-planar configuration. The Ga–As distances [2.470(1)–2.508(1) Å] are significantly shorter than those observed for four-coordinate gallium (below). A monomeric gallium phosphide, $Ga[P(t\text{-}Bu)_2]_3$, has also been reported but no structural elucidation presented.

Reaction of four equivalents of $LiEPh_2$ (E = P, As) with $GaCl_3$ in THF yields the anionic perphosphido and perarsenido complexes $[Li(THF)_4][Ga(EPPh_2)_4]$. While the gallium atoms are in a tetrahedral GaE_4 coordination environment, analogous to those in the binary compounds GaP and GaAs, the bond lengths are slightly longer in the anions than the binary compounds (e.g. Ga–As, 2.497(4) vs. 2.448 Å). However, these small differences are presumably due to the steric repulsion between the phenyl rings in the anions as opposed to any significant electronic interactions.

The coordination of pnictogen ligands to gallium alkyl compounds has also been used in purification techniques similar to those implemented for its indium analogs (*see* ***Indium: Organometallic Chemistry***). For example, $[R_yGa_xL]$ where L = PPh_3, dppe, triphos ($Ph_2P(CH_2)_2P(Ph)(CH_2)_2PPh_2$), tetraphos ($Ph_2P(CH_2)_2P(Ph)(CH_2)_2P(Ph)(CH_2)_2PPh_2$), and MBDA 4,4′-methylene-bis(N,N'-dimethylaniline).[9] Subsequent controlled heating liberates the highly pure metal derivative, which is used for fabricating high quality Ga alloy thin films. It is commonplace to also use gallium pnictogen coordination complexes for III-V film growth. The adduct $[ClEt_2Ga(AsEt_3)]$ has been used in conjunction with $HPEt_2$, for epitaxial growth of $GaAs_{1-x}P_x$ at 500–650 °C, whereas GaAs thin films have been grown from the halide derivatives, $[(C_6F_5)Me_2Ga(AsEt_3)]$ and $[\{ClEt_2Ga(AsEt_2)\}_2CH_2]$ at 600–700 °C and 500–625 °C, respectively.[9]

The metathesis reaction of potassium (tris(*tert*-butyl)silyl) phosphanide with $GaCl_3$ in a 1:1 affords $[Cl_2GaP(H)SiBu^t_3]_2$ as a mixture of *cis* and *trans*. The molecular structure reveals a Ga_2P_2 moiety cycle with nearly planar coordinated phosphorus atoms neglecting hydrogen atoms and Ga–P distances of 2.39 Å. The reaction of $GaCl_3$ with 3 equivilents of potassium (tris(*tert*-butyl)silyl)phosphanide as well as the reaction of 1 with 2 equiv of $KP(H)SiBu^t_3$ yields $[Bu^t_3SiP(H)Ga(\text{-}PSiBu^t_3)]_2$. The central moiety comprises a four-membered Ga_2P_2 cycle with one planar P atom and extremely short Ga–P bonds of approximately 2.26 Å. The structure of $[Bu^t_3SiP(H)Ga(\text{-}PSiBu^t_3)]_2$ is described as a GaPGa heteroallyl system which is bonded to a phosphanidyl substituent.[116]

The gallium chloro complex $[GaCl\{Fe(CO)_2Cp\}_2]$ (Cp = η^5-C_5H_5) was reacted with $MP(SiMe_3)_2$, (M = K, Li) under special conditions to yield the complexes $[\{CpFe(CO)\}_2\{\text{-}(CO)\}[\text{-}Ga\{CpFe(CO)_2\}]]$ and $[\{CpFe(CO)_2\}GaP(SiMe_3)]_4$, whereas $[[\{CpFe(CO)_2\}ClGa](\text{-}PPh_2)_2FeCpCO]$ was obtained by the reaction of $[GaCl\{Fe(CO)_2Cp\}_2]$ with $LiPPh_2$. Complex $[\{CpFe(CO)_2\}GaP(SiMe_3)]_4$ represents an ideal Ga_4P_4-heterocubane, the first Ga-containing example of this structural type with organometallic substituted group 13 elements. In addition, in the solid state, $[[\{CpFe(CO)_2\}ClGa](\text{-}PPh_2)_2FeCpCO]$ possesses a near planar GaPFeP four-membered ring, which is a novel structural motif in mixed group 13/15 chemistry (Scheme 3).[117]

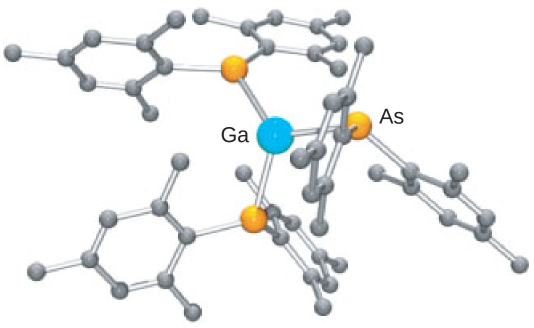


Figure 20 Molecular structure of $Ga[As(Mes_2)]_3$

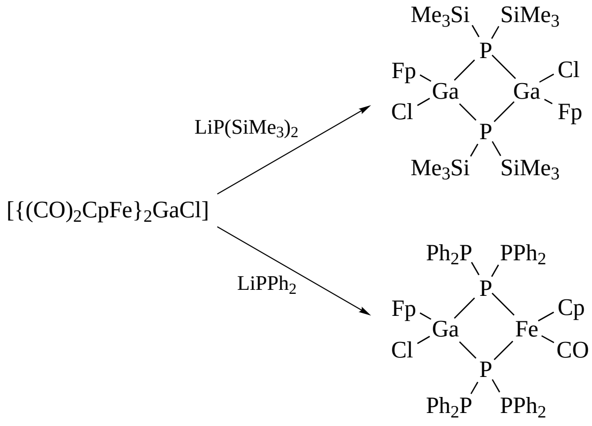


Scheme 3 Formation of mixed group 13/15 Fe derivatives

Examples of Ga derivatives with double bond character to group 15 centers have attracted much attention and review.[118–124] Power and coworkers recently published compounds with gallium–nitrogen multiple bonds,[125] and the first example of a Ga=As derivative, $[\{Li(THF)_3\}_2Ga_2\{As(SiPr^i_3)\}_4]$, has recently been synthesized and contains two As=Ga double bonds from the reaction of $GaCl_3$ with $Li_2AsSiPr^i_3$.[126]

8.5 Aqua ions and related

In acidic solutions, gallium exists as the hexaaqua cation $[Ga(H_2O)_6]^{3+}$ which, based on ^{17}O NMR studies, occurs in the hydrated crystals of oxyanion salts, for example, $Ga(X)_3{\cdot}xH_2O$ ($X = NO_3$, $x = 9$; $X = SO_4$, $x = 18$; $X = ClO_4$; $x = 6$).[5] Ligand exchange at 25 °C ($k_1 = 0.17\,s^{-1}$) is much faster in $[Ga(H_2O)_6]^{3+}$ than the associated exchange in $[Al(H_2O)_6]^{3+}$ ($k_1 = 1.8 \times 10^3\,s^{-1}$), thus reflecting the lesser affinity for oxygen donor ligands of Ga^{3+} versus Al^{3+}. A S_N2 type of mechanism, involving $[Ga(H_2O)_n]^{3+}$, has been suggested for ligand exchange. The gallium cation $[Ga(H_2O)_6]^{3+}$, with K_a of 2.5×10^{-3}, is a stronger acid than $[Al(H_2O)_6]^{3+}$ ($K_a = 1.1 \times 10^{-5}$).[5]

8.6 Alkoxides

Gallium alkoxides can be prepared by the methods employed for aluminum (*see* ***Aluminum: Inorganic Chemistry***). $Ga(OMe)_3$, a polymeric material, decomposes without melting but can be sublimed under vacuum. $Ga(OEt)_3$, $Ga(O\text{-}n\text{-}Pr)_3$, and $Ga(O\text{-}n\text{-}Bu)_3$ are more volatile than $Ga(OMe)_3$ and are tetrameric in solution. According to NMR studies, $Ga(O\text{-}i\text{-}Pr)_3$ and $Ga(O\text{-}t\text{-}Bu)_3$ have dimeric structures bridged by alkoxide ligands. The bulky trimethylsilyl ligand results in $Ga(OSiMe_3)_3$ being monomeric, but does not prevent the formation of a complex anion, $[Ga(OSiMe_3)_4]^-$. Aryloxides, for example, $Ga(OPh)_3$, are obtained by prolonged heating of Ga metal with the phenol at 180–220 °C. Like group 13 alkoxides generally, these compounds are Lewis acids and form 1:1 adducts with ammonia, pyridine, and other bases.

$$Ga_2X_4 + 3EtOH \xrightarrow{0\,°C} [GaX(OEt)_2] + [GaX_3(HOEt)] + H_2 \quad (17)$$

Reaction of gallium trihalides, GaX_3 ($X = Cl$ or Br), with less than three moles of alcohol initially gives the Lewis acid–base adducts $GaX_3(HOR)$. However, these are readily converted into oligomeric halide–alkoxide compounds, $GaX_n(OR)_{3-n}$ ($n = 1$ or 2), in which the alkoxide ligands are bridging. Alcoholysis of the mixed valent dihalides, Ga_2X_4, involves oxidation of the Ga^+ by the alcohol (equations 17 and 18).

$$Ga_2X_4 + 2EtOH \xrightarrow{25\,°C} 2[GaX_2(OEt)] + H_2 \quad (18)$$

Like their aluminum counterparts, gallium alkoxides are susceptible to hydrolysis, giving ill-defined products. Methanolysis of hydrated Ga^{3+} ions produces $Ga(OMe)^{2+}$ and $Ga(OMe)_2{}^+$ in solvated forms, as well as polymeric complexes. $Ga(OPh)_3$ reacts with boiling MeOH or EtOH to form the corresponding alkoxide. Reaction of the trialkoxide compounds with other metal alkoxides, for example, LiOR, results in the formation of four-coordinate complex anions of the type $[Ga(OR)_4]^-$.[5] A recent review of sesquihalides/oxides of group 13 derivatives has been published. The review covers the major synthetic routes and the structures of the corresponding products, and also reactions with compounds having sesquialkoxides as educts.[127]

Owing to the importance of Ga_2O_3 thin films, Ga alkoxides have also been examined as viable compounds to Ga_2O_3 materials. A general synthetic route to Ga alkoxide complexes involving reactions between Ga *tris*(dimethylamide) with alcohols has been developed. Their utility in a CVD process to deposit Ga oxide films was demonstrated.[128] $[Ga(NMe_2)_3]_2$ reacted with i-BuOH and i-PrOH to yield the tetramers $Ga[(\mu\text{-}OR)_2Ga(OR)_2]_3$ ($R = i$-Bu, i-Pr). In contrast to the results obtained using i-BuOH and i-PrOH, the bulkier alcohols t-BuOH and $EtMe_2COH$ reacted with $[Ga(NMe_2)_3]_2$ at room temperature to yield mixtures of the dimer $[Ga(\mu\text{-}OR)(OR)_2]_2$ and the amine adduct $[Ga(OR)_3(HNMe_2)]$, while $i\text{-}PrMe_2COH$ and Et_2MeCOH gave $[Ga(OR)_3(HNMe_2)]$ derivatives exclusively. The amine could be removed from the $[Ga(OR)_3(HNMe_2)]$ compound to yield the corresponding homoleptic alkoxide dimers. Low-pressure CVD using $[Ga(\text{-}OBu^t)(OBu^t)]$ and O precursors gave GaO films at substrate temperature between 300–700 °C, which were carbon-free, amorphous, and highly transparent in the 350–800-nm region.[129,130]

8.7 Carboxylates

A number of patents and publications have addressed the synthesis, properties, and application of gallium carboxylates.[10,131,132] Gallium carboxylates, $Ga(O_2CR)_3$, may be prepared by a variety of synthetic methods, including the reaction of the carboxylic acid with Ga_2O_3 (equation 19), $GaCl_3$ (equation 20), or directly with the metal (equation 21).[5] Basic carboxylates result if aqueous acids are employed (see below).

$$Ga_2O_3 + 3HO_2CR \longrightarrow [Ga(O_2CR)_3] + 3H_2O \quad (19)$$

$$GaCl_3 + 3HO_2CR \longrightarrow [Ga(O_2CR)_3] + 3HCl \quad (20)$$

$$Ga + 3HO_2CR \longrightarrow [Ga(O_2CR)_3] + 1.5H_2 \quad (21)$$

However, the gallium oxalate system has also been examined. $Ga(C_2O_4)_3{\cdot}4H_2O$ crystallizes from hot aqueous $Ga(NO_3)_3$ solution containing oxalic acid. On heating (>140 °C), a dihydrate and then anhydrous $Ga_2(C_2O_4)_3$

are produced. The latter decomposes to Ga_2O_3 at 200 °C. Complex salts containing $[Ga(C_2O_4)_2]^-$ and $[Ga(C_2O_4)_3]^{3-}$ anions have been prepared and the formation of these and the cation $[Ga(C_2O_4)]^+$, presumably hydrated, have been studied to obtain stability constants. It is thought that basic complexes are probably present in these aqueous solutions (see below). Raman spectra of gallium oxalate solutions confirm the presence of $[Ga(C_2O_4)_3]^{3-}$: $\nu(M\text{–}O)_{sym} = 573\,cm^{-1}$ compared to $585\,cm^{-1}$ in $[Al(C_2O_4)_3]^{3-}$.[5]

While no crystallographic data have been obtained for a gallium tricarboxylate, Hepp, Duraj and co-workers have reported the synthesis and structural characterization of an oxo-centered trinuclear carboxylate, of the well-established class of complexes commonly referred to as 'basic carboxylates', $[M_3(O)(O_2CR)_6(L)_3]^+$.[133] The reaction of Ga_2Cl_4 with sodium benzoate in the presence of 4-methylpyridine (4-Mepy) allows the isolation of $[Ga_3(O)(O_2CPh)_6$(4-Mepy)$_3$][$GaCl_4$] in high yield. The solid-state structure of the cation, $[Ga_3(O)(O_2CPh)_6$(4-Mepy)$_3$] consists of a planar oxo-centered Ga_3O core; each edge is bridged by two benzoate ligands, and the sixth coordination site of each gallium is occupied by a terminal pyridine ligand.

There are many reports of complexes between gallium and hydroxy acids (including those derived from carboxylic acids) and other related organic chelating agents. The lactate, tartrate, and citrate have all been used in physiological studies involving gallium radioisotopes. According to NMR studies (^1H, ^{13}C, and ^{71}Ga), the 1:1 Ga/citrate complex predominates at low pH (<2), while oligomeric species exist in the range pH 2–6, unlike the aluminum citrate system.[134] The structural characterization for the gallium citrate complex has recently been realized; the gallium citrate complex $(NH_4)_3[Ga(C_6H_5O_7)_2]\cdot 4H_2O$ hydrate has been prepared from the reaction of gallium nitrate with citric acid. The X-ray crystal structure of the complex revealed it to exist as discrete ions, with the 6-coordinate gallium center bonded to two deprotonated carboxylate groups and one alcoholate group from each citrate ligand leaving one protonated pendent carboxy group.[135]

A range of other systems of Ga^{3+} with chelating organic acids has been studied and solution equilibria data have been obtained.[5] Based on these investigations it is clear that in all cases basic complexes (i.e. those containing oxo or hydroxo ligands) are involved, and the hydrated hydroxide cation $[Ga(OH)]^{2+}$ shows greater reactivity compared with the hydrated ion of Ga^{3+}.

8.8 β-Diketonates

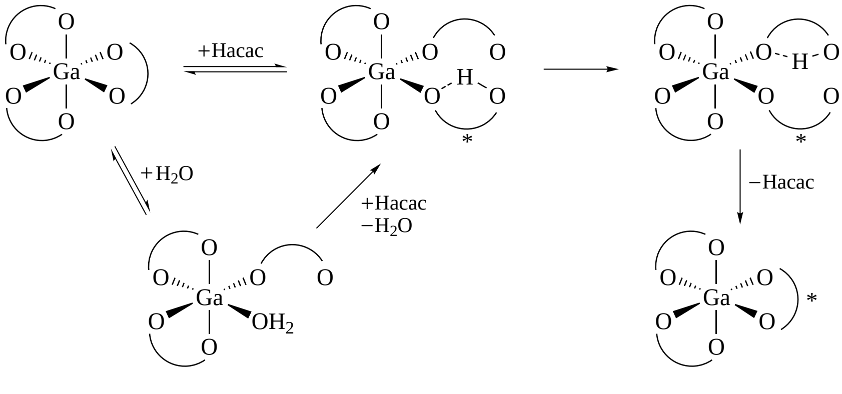
Gallium tris-β-diketonate complexes are formed by the addition of acetylacetonate ions to aqueous solutions of Ga^{3+} (e.g. equation 22). However, at β-diketonate to gallium ratios less than three, basic hydroxo complexes are also formed.

$$Ga_2(SO_4)_3 + 3Hacac \xrightarrow{[NH_4][OH]aq.} [Ga(acac)_3] + 3[NH_4]_2[SO_4] \quad (22)$$

Rates of ligand exchange have been measured for some β-diketonate complexes.[136] Exchange between $Ga(acac)_3$ and ^{14}C-labeled Hacac in THF solution is much faster than in the case of $Al(acac)_3$. A dissociative mechanism proceeds via a five-coordinate transition state in which one ligand is unidentate (Scheme 4). In addition, activation energies for cis–trans ligand rearrangements have been determined from NMR measurements. As expected, these studies place gallium between aluminum and indium in the order of decreasing bond strength, that is, Al–O > Ga–O > In–O. This result is consistent with Raman studies of $M(acac)_3$.[5] When $Ga(acac)_3$ is added to a solution of $Ga(ClO_4)_3$ in DMF, the NMR spectrum shows new signals attributable to $[Ga(acac)(DMF)_4]^{2+}$ and $[Ga(acac)_2(DMF)_2]^+$.

Tris(acetylacetonato)gallium(III) exists in two crystallographic modifications, differing slightly in density. The X-ray crystal-structure determination shows the central GaO_6 core to be close to octahedral, with an average Ga–O distance of 1.95 Å.

The dichlorogallium(III) β-diketonato derivatives of the type $GaCl_2L$ [L = acac (2,4-pentanedionato) and tmhd



Scheme 4 Proposed mechanism for the ligand exchange of [Ga{acac}$_3$] with excess acac ligand, in THF solution, (*14-C labeled)

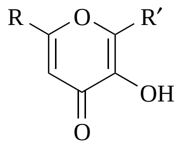
(2,2,6,6-tetramethylheptanedionato)] were prepared and characterized by a variety of spectroscopic techniques. The four-coordinate Ga compounds were found to react with THF to form $GaCl_2L\cdot THF$ derivatives. Single-crystal X-ray diffraction study identified [$GaCl_2$(acac)·THF] to be the ion-pair [*trans*-Ga(acac)$_2$(THF)$_2$]$^+$ [$GaCl_4$]$^-$. The Ga atom in the cation is six-coordinate, whereas in the anion it is four-coordinate. Variable-temperature ^{1}H NMR spectral studies suggest that multiple processes including (i) a stereochemical rearrangement, (ii) THF exchange, and (iii) equilibria between [$GaL_2(THF)_2$]$^+$[$GaCl_4$]$^-$, [$GaCl_2L$], and other species such as [GaL_2(THF)]$^+$[$GaCl_4$]$^-$ occur in solution. In contrast, the fluorinated derivatives GaX_2(hfac) (X = Cl, Br; hfac = 1,1,1,5,5,5-hexafluoro-2,4-pentanedionato) cannot be isolated since they undergo ligand redistribution reactions to form [Ga(hfac)$_3$].[137]

The gallium(II) derivatives [GaCl(acac)]$_2$, and [GaCl(tmhd)]$_2$ were prepared and characterized by X-ray structural studies.[138] Both compounds have direct gallium–gallium bonds between two tetracoordinated gallium atoms with each in the +2 oxidation state and each gallium bonded to a chloride and chelated to a β-diketonate ligand. Metal–metal bond lengths are Ga(1)-Ga(1a) = 2.396(3) Å. for the acac derivative, which has crystallographic imposed C2 symmetry and Ga(1)-Ga(2) = 2.391(2) Å. for the tmhd derivative.[138]

8.9 Pyridinones

The discovery that ^{67}Ga administered as the citrate localized in soft tumor tissue[139] initiated considerable clinical interest in gallium coordination chemistry. In fact the citrate complex is now widely used in oncological nuclear medicine for tumor detection; however, the mechanism of uptake is still to be determined. Despite this early success and the ready availability of both ^{67}Ga and ^{68}Ga, the application of gallium in medicine has been limited. One of the reasons for this is the complex hydrolysis chemistry of gallium compounds, and the majority of studies have been performed under acidic conditions. Clearly if the coordination chemistry of gallium is to be understood *in vivo*, then complexes stable at pH 7.4 are of great interest. While some researchers have concentrated on polydentate ligands, such as cryptands, others have investigated bidentate chelating ligands of biological relevance. The most successful work in this area is by Orvig and coworkers on complexes of gallium with hydroxypyrones and hydroxypyridinones.[140–142]

A series of tris(3-hydroxy-4-pyranato)gallium(III) complexes has been prepared by the neutralization of solutions of $GaCl_3$ and substituted pyrones (**15a–d**). The complexes of larixinic acid (**15b**) and kojic acid (**15c**) are water soluble but retain their neutral charge.



(**15a**) R = R′ = H; pyromeconic acid
(**15b**) R = H, R′ = Me; maltol (larixinic acid)
(**15c**) R = CH_2OH, R′ = H; kojic acid
(**15d**) R = CH_2Cl, R′ = H; chlorokojic acid

The known sequestering ability of various hydroxypyridinones for iron(III) prompted investigation of the gallium complexes. The tris complexes have been prepared with a wide range of substituted hydroxypyridinones (**16**).[140] The molecular structure of one such compound is shown in Figure 21. All the complexes form a rigid *fac* geometry, are water soluble, and have a wide window of stability to hydrolysis. Their lipophilicity is increased by the substitution of an aryl group at the nitrogen (see **17**).[141]

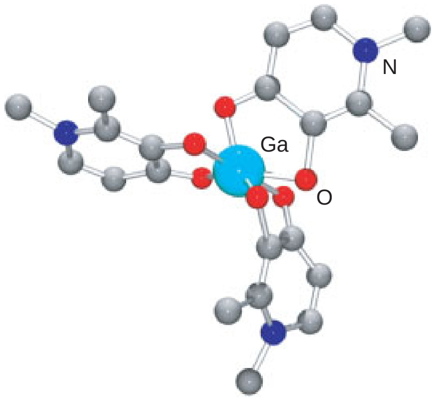


Figure 21 Molecular structure of Ga(dpp)$_3$; Hdpp = 3-hydroxy-1, 2-dimethyl-4-pyridinonate

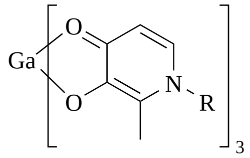
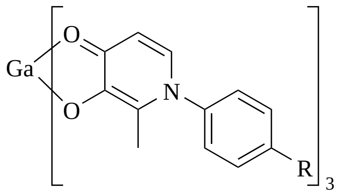


(**16**) R = H, Me, *n*-C_6H_{13}



(**17**) R = H, Me, OMe, NO_2

Aqueous solution stability constants for the aryl substituted complexes have been determined. The ML_3 complexes are highly stable; at 25 °C the overall stability constant (β_3) for the parent complex (**17**); R = H is $10^{36.3}$. At ligand to metal ratios ≥ 1, the ligands prevent gallium hydrolysis even at millimolar concentrations and under slightly basic conditions; the effective formation constant (β_{3eff}) for ML_3 at physiological pH is $10^{30.3}$. As a practical application of these data, comparative metal binding in a simple blood plasma model has been simulated, which in turn allowed for the design of biodistribution experiments in mice. The

concentration of ligand required to inhibit removal of gallium from the GaL_3 complexes and the excretion pathway have been determined.[142]

8.10 Chalcogen Donor Ligands

While the donor chemistry for the heavier chalcogens with group 13 elements is generally poorly developed in comparison to the lighter chalcogen oxygen donor ligand chemistry, in the case of gallium there has been significant interest in non-oxide chalcogen-containing compounds with chalcogenide, and in particular sulfur, donor ligands for III-VI binary alloy formation. This anomaly for gallium is as a function of the similarities in its coordination chemistry to that of high-spin iron(III), and the biological importance of iron–sulfur proteins (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***; ***Iron: Heme Proteins & Electron Transport***; ***Iron: Heme Proteins, Mono- & Dioxygenases***; ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). The anionic gallium tetrathiolate complexes, $[Ga(SR)_4]^-$, may be prepared by the reaction of either $GaCl_3$ or $[GaCl_4]^-$ with five equivalents of LiSR, where R = Me, Et, *i*-Pr, Ph, 2,3,5,6-Me_4C_6H, or 2,4,6-*i*-$Pr_3C_6H_2$.[143] Because of the inaccessibility of the +2 oxidation state of gallium, the tetrathiolate complexes do not undergo the redox reaction (equation 23) that is responsible for the instability of many of the iron analogs.

$$2M^{3+} + 2RS^- \longrightarrow 2M^{2+} + RSSR \tag{23}$$

The structure of $[(n\text{-}Pr)_4N][Ga(SEt)_4]$ has been determined by X-ray crystallography to be isomorphous to the iron analog; however, although isostructural, $[Et_4N][Ga(SPh)_4]$ is not isomorphous with its iron analog. This difference has been rationalized with regard to the presence of steric interactions between the *ortho* hydrogens of two of the phenyl rings and the GaS_4 core. Although no examples of neutral three-coordinate gallium alkoxides have been reported, thiolate and selenolate derivatives, $Ga[E(2,4,6\text{-}t\text{-}Bu_3C_6H_2)]_3$ (E = S, Se), have been crystallographically characterized,[144] and the thiolate compound is shown in Figure 22. Structural data show that the gallium centers are three coordinate and almost planar. The slight distortion from idealized trigonal-planar coordination has been explained on the basis of ionic M–S bonding character and some agostic Ga···H interactions involving the *ortho* *t*-butyl groups of the ligand.

In addition to a variety of organometallic gallium thiolates (*see* ***Gallium: Organometallic Chemistry***), there are a number of mixed thiolate compounds, for example, the halide–thiolate dimers $[I_2Ga(SMe)]_2$ and $[I_2Ga(S\text{-}i\text{-}Pr)]_2$. The latter compound has the unusual feature of having a butterfly Ga_2S_2 core.[145] The first gallium thiolato compound to be structurally characterized was the adamantane cluster $Ga_4I_4(SMe)_4S_2$ (Figure 23), prepared from the reaction of Me_2S_2 with Ga_2I_4.[146] The Ga–S distances fall into two groups, those to the sulfide (average = 2.20 Å) and those to the methylthiolate ligands (average = 2.33 Å). The $[Ga_2S_2(SPh)_4]^{2-}$ anion has been prepared and structurally characterized (Figure 24). The structure is that of a centrosymmetric dimer consisting of two edge-sharing tetrahedra.

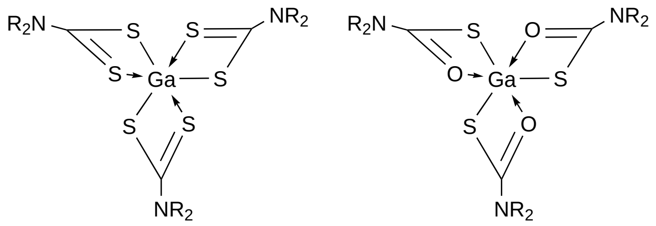

Figure 25 Schematic of [Ga(S_2CNR_2)$_3$] & [Ga($SOCNR_2$)$_3$] derivatives

A number of gallium dithiocarbamate coordination complexes have been investigated for their potential suitability as single-source III-VI precursors. These type of compounds are often referred to as Mitsubishi™ compounds owing to their structural resemblance to the respective company logo (Figure 25). Additionally this area has recently been reviewed.[145]

The gallium *tris*-dialkyldithiocarbamates are monomeric solids that possess relatively low volatility. Improved volatility is achieved with asymmetric secondary amines derivatives; for example, the use of [Ga{S_2CN(Me)Hex}$_3$] in a LP-MOCVD affords α-Ga_2S_3 thin films at 500 °C on GaAs(111).[147] Whereas the monothiocarbamato coordination complex [Ga($SOCNEt_2$)$_3$] affords thin films of GaS at 450 °C.[148] Again a more comprehensive array of the analogous indium derivatives has been synthesized and studied in comparison to gallium. The ^{71}Ga NMR studies have been preformed on a number of Mitsubishi™ complexes of the type [Ga{S_2CNR}$_3$], [Ga{S_2CNR}{(SCH_2CH_2)$_2$O}], where R=$CH_2CH_2OCH_2CH_2$, CH_2CH_2N(Me)CH_2CH_2, and [GaCl_2{S_2CN(CH_2CH_2)$_2$O}], [GaCl{S_2CN(CH_2CH_2)$_2$O}$_2$], and [Ga{S_2CN(CH_2CH_2)$_2$O}{S_2P(OR)$_2$}$_2$] where R = Et, Pr^i have been investigated. The ^{71}Ga NMR chemical shifts and half line widths were found to be influenced by the coordination number of gallium and the substituents on the ligand moiety; additionally, an in-depth study of their spectroscopic properties has been reported.[149]

Dithiophosphinato complexes have found application as solvent extraction reagents for metals, insecticides, and pesticides, flotation agents for mineral ores, and additives to lubricant oils and can be used as precursors in metal-organic chemical vapor deposition (MOCVD).[150] The related indium compounds [In(S_2PR)$_3$] (R = Me, Et, OEt, Ph) are monomeric in the solid state in contrast to the dinuclear species seen for the related group 12 zinc and cadmium species. The analogous group 13 derivatives [In(S_2PBu$^i_2$)$_3$] and [Ga(S_2PBu$^i_2$)$_3$] were prepared and characterized. Whereas the In metal center was found to be six-coordinate, the Ga metal center is four-coordinate, being bound to only one chelating and two pendant diisobutyldithiophosphinate ligands in a distorted tetrahedral geometry.

The sterically encumbering β-diketiminate ligand [{HC (MeCDippN)$_2$Ga}] (Dipp = C_6H_3-2,6-Pr$^i_2$) has been used to stabilize the first dimeric galloxane derivative [{HC(MeCDippN)$_2$}GaO]$_2$, as well as its S analog [{HC(MeCDippN)$_2$}GaS]$_2$. Treatment of {HC(MeCDippN)$_2$}Ga with N_2O or S_8 in a toluene solution at room temperature produced the respective compounds as colorless crystals. The Ga_2S_2 core is planar and has an average Ga–S bond length of 2.26(1) Å, which is just within the currently known range (2.20–2.27 Å) for low-coordinate Ga-S species.[151]

The reactions of Ga(CH_2CH_3)$_3$ with variable amounts of elemental sulfur, S_8, in toluene or benzene at different temperatures results in the insertion of sulfur into the Ga–C bonds to form the Ga[(S-S)CH_2CH_3]$_3$ and Ga[(S-S-S)CH_2CH_3]$_3$. Even when the reactions were carried out with more than 9.0 equiv of sulfur, the maximum extent of sulfur insertion was found to be three S units. However, the reactions of Ga(CH_3)$_3$ with various molar ratios of S in toluene or benzene only gave Ga[(S-S)CH_3]$_3$. In pyridine at −30 °C, deinsertion of the sulfur atoms from Ga-S-S-C bonds was noted for the first time from Ga[(S-S)CH_2CH_3]$_3$ and Ga[(S-S-S)CH_2CH_3]$_3$, resulting in formation of the six-membered Ga–S ring compounds [PyEtGaS]$_3$ and [PyMeGaS]$_3$ respectively.[152]

9 HALIDES

9.1 Ga(III) Halides

9.1.1 Synthesis and Structure

The halides (especially the chloride) are the most commonly employed synthons in the chemistry of gallium. This is undoubtedly due to their ease of synthesis and high reactivity. While the trihalides have been traditionally the most extensively studied, the mono- and dihalides have come under recent scrutiny.

Gallium fluoride differs markedly from the other halides of gallium and in this it resembles the fluorides of aluminum and indium. For example, the melting points of the fluorides are several hundred degrees above those of the chlorides, though this difference decreases from 1097 °C for aluminum, to 872 °C for gallium, to 584 °C for indium. The compound GaF_3 is produced by the thermal decomposition of either [NH_4]$_3$[GaF]$_6$ or GaF_3(NH_3)$_3$ in the absence of moisture; the latter brings about the formation of (NH_4)$_2GaF_3$(OH)$_2$. The GaF_3 molecule is planar with a Ga–F distance of 1.88 Å. This species and the dimer Ga_2F_6 have been examined in the vapor phase by mass spectrometry.[5]

The trihalides $GaCl_3$ and $GaBr_3$ are usually prepared directly from the elements, by burning the metal in a stream of Cl_2 (or Br_2) in an apparatus that uses all-glass, or greaseless, connections. GaI_3 can be obtained by dissolving

Table 6 Physical properties of gallium trihalides

Property	$GaCl_3$	$GaBr_3$	GaI_3
Mp (°C)	77.75 ± 0.05	122.3 ± 0.05	211.5 ± 0.1
Bp (°C)	201.2	279	346
Vapor pressure (mm Hg)	10.4 (at 78 °C)	4.7 (at 125 °C)	19.2 (at 215 °C)
Density ($g\,cm^{-3}$)	2.47	3.69	4.15
$\Delta H°_f$ ($kJ\,mol^{-1}$)	523	386	255
ΔH_{dimer} ($kJ\,mol^{-1}$)	87 (per Ga_2Cl_6)	77 (per Ga_2Br_6)	46 (per Ga_2I_6)

Ga in a refluxing solution of I_2 in CS_2. The trichloride and tribromide of gallium have some advantages over $AlCl_3$ as Friedel–Crafts catalysts, in particular, their high solubility in organic solvents.[4] All three halides are colorless, deliquescent, low-melting solids, whose physical properties are shown in Table 6. In solid and liquid states, and in noncoordinating solvents, the GaX_3 (X = Cl, Br, I) molecules are dimeric with bridging ligands spanning four-coordinate gallium atoms. In the vapor, there is increasing dissociation of Ga_2X_6 to GaX_3 for X = Cl (0.4%), Br (14%), or I (96%), in accord with the decreased ΔH of dimer formation (see Table 6). Molecular dimensions are known for the monomers $GaBr_3$ and GaI_3, and the dimers Ga_2Cl_6 and Ga_2I_6, but precise values are lacking for $GaCl_3$ and Ga_2Br_6. Vibrational assignments are available for the GaX_3 monomers (from gas-phase and matrix-isolation studies) and the Ga_2X_6 dimers.[4]

9.1.2 Complexes

The trihalides (except the fluorides) all function as Lewis acids, forming 1:1 adducts with a great variety of Lewis bases. This is one of the most important aspects of the chemistry of the gallium halides. The Lewis acidity of the GaX_3 groups has been extensively studied thermodynamically, and basicity sequences for a variety of donors have been established.

Neutral Adducts. Being powerful acceptors, the gallium trihalides react with donor molecules L to form the adducts $GaX_3(L)$, and in some instances $GaX_3(L)_2$. In the trigonal bipyramidal 2:1 complexes, the halogen atoms are usually equatorial. The 1:1 complexes of trimethylamine with gallium trichloride and tribromide are solids, stable above 200 °C, while the complexes with two moles of trimethylamine decompose above −48 °C to give the 1:1 complex. Pyridine and piperidine form 1:1 and 2:1 adducts with $GaCl_3$, but only the 1:1 complex with $GaBr_3$.[4,5] Ethers form stable complexes with GaX_3, and there seems to be less tendency than with the aluminum analogs for thermal elimination of alkyl halides. However, caution should be observed when dissolving $GaCl_3$ in coordinating ether solvents, for example, Et_2O or THF, since the formation of the $GaCl_3(L)$ complex is sufficiently exothermic to boil the solvent. While the donor atom is generally from group 15 or 16, several examples of neutral complexes between $GaCl_3$ and alkyl halides have been reported.[4]

Anionic Complexes. Gallium, like aluminum, forms tetrahedral tetrahalide ions, $[GaX_4]^-$. Crystalline salts can be obtained, for example, by the action of alkali metal halides or ammonium halides on Ga_2Cl_6. However, oxonium salts, for example, $[(Et_2O)_nH][GaCl_4]$, isolated from the reaction of $GaCl_3$ with HCl in ether, are viscous oils.[4] That the tetrahalogallates can be regarded as typical Lewis acid–base complexes is seen by the ease with which the halide is replaced by neutral donor ligands (e.g. equation 24).

$$M[GaCl_4] + L \xrightarrow[M = Li,\ NH_4;\ L = NR_3,\ py]{} GaCl_3(L) + MCl \qquad (24)$$

While the tetrahaloaluminates are unstable under acid conditions, the gallium analogs are readily extracted from aqueous solutions of gallium salts, into ethers, by 8 M HCl; the resulting ether phase contains $[GaCl_4]^-$ ions. This suggests the presence of a series of equilibria (equation 25):

$$[Ga(H_2O)_6]^{3+} \xrightarrow{+n\mathrm{HCl}} [GaCl_n(H_2O)_m]^{3-n} \xrightarrow{+m\mathrm{HCl}} [GaCl_4]^- \qquad (25)$$

In addition to crystallographic data for solids containing the $[GaX_4]^-$ ion, characteristic absorption spectra, vibrational frequencies, NMR chemical shifts, and NQR parameters are well established. These properties can be used to study effects such as ligand exchange processes of $[GaX_4]^-$ with Cl^-, ion pairing in nonaqueous solutions of alkylammonium chlorogallates, polymorphism of $K[GaCl_4]$, and solid-state interactions in the crystalline solids $[NO][GaCl_4]$ and $[Ga][GaCl_4]$. Bond dissociation energies $\Delta(X_3Ga–X)$ are 364 and 314 $kJ\,mol^{-1}$ for X = Cl and Br, respectively.

[GaSBr] and [GaSeBr] have been synthesized from $Ga[GaBr_4]$ and elemental S/Se in toluene or THF, respectively, with the formation of the by-product $GaBr_3(THF)_2$. The two ternary Ga bromides are insoluble in most common organic solvents, but are readily dissolved in pyridine and substituted pyridines (L) to give trinuclear $[GaSBr(L)]_3$

with L = 3,5-dimethylpyridine, 4-*tert*-butylpyridine, and 4-dimethylaminopyridine, and $[GaSeBr(L)]_3$ with L = 3,5-dimethylpyridine, respectively. The core units are six-membered rings with different substitution patterns and were found to depend largely on the steric requirements of the ligands L, and on the mode of crystallization undertaken. Similar studies have been preformed for the chloride analog.[153]

Cationic Complexes. Apart from the aqua ions and partially substituted species such as $[GaCl(H_2O)_5]^{2+}$, cationic complexes of gallium halides with pyridine, bipyridine, or phenanthroline are known, for example, $[GaCl_2(phen)_2]^+$ and $[Ga(phen)_3]^+$. Furthermore, given the steric hindrance about the gallium center in complexes formulated as $GaX_3(NH_3)_n$ (X = Cl, n = 1, 3, 5, 6, 7, 14; X = Br, n = 1, 5, 7, 9, 14; X = I, n = 1, 5, 6, 7, 9, 13, 20), it is likely that where n is greater than 3 these are also cationic solvates.[154]

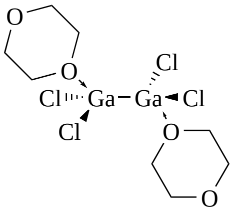
9.2 Lower Oxidation State (I) & (II) halides

All four halides GaX (X = F, Cl, Br or I) are known as vapor-phase species, but tend to disproportionate when condensed, producing elementary gallium. The solid once thought to be GaI has been shown to be Ga_2I_3. Gallium forms a number of mixed valence halides containing gallium(I) cations. In these compounds, the Ga^+ cation is stabilized by the presence of the anion formed when the strong Lewis acid GaX_3 combines with halide ligands. Examples are the so-called 'dihalides' $[Ga][GaX_4]$ and the compounds Ga_3X_7, that is, $[Ga][Ga_2X_7]$ (X = Cl, Br, I). In the subhalides, Ga_2X_3, the stabilizing anion is $[Ga_2X_6]^{2-}$, the constitution being $[Ga]_2[Ga_2X_6]$ (X = Cl, Br, I).

The crystal structure of Ga_2Cl_4 shows each of the Ga^+ cations surrounded by eight chlorides of the $[GaCl_4]^-$ counterions. The gallium(I) chloride distance is more than 3.00 Å, to be compared with the Ga–Cl bond length of 2.19 Å in $[GaCl_4]^-$, and implies that the Ga^+ cation is not coordinated but 'solvated'. However, when Ga_2Cl_4 is vaporized, the vapor consists solely of GaCl and $GaCl_3$ molecules. Recent structural analyses of Ga_2I_4 and Ga_2I_3 have directed attention to the influence on these structures of the $4s^2$ electron pair of the Ga^+ ion, and confirm that in the case of the iodide no coordination is observed to the lower oxidation state center.

The halides Ga_2X_4 combine with various donor ligands to give products since shown to be molecular adducts of the metal–metal bonded Ga^{II} state. For example, the treatment of Ga_2Cl_4 with dioxane gives a crystalline solvate (**18**), in which each Ga atom has a distorted tetrahedral configuration and the Ga–Ga distance is 2.406(1) Å.

There are reports of reactions of the halides Ga_2X_4 with alcohols, water, aqueous NaOH, HCl or HF, and H_2S gas. Oxidative addition usually occurs, although there is evidence of the initial precipitation of Ga^I containing solids in the reactions of Ga_2Cl_4 in benzene solution with H_2O or H_2S.



(**18**)

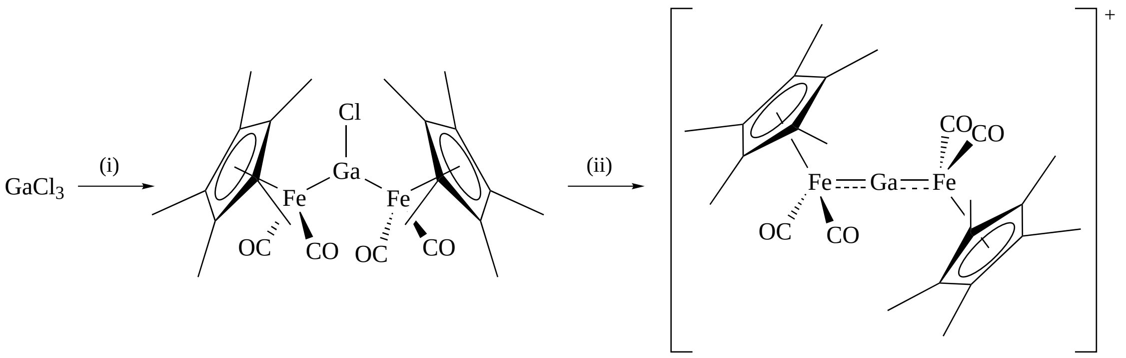
The crystalline solid Ga_2Cl_4 is soluble in benzene. Under regulated conditions this solution yields crystals that prove to contain the complex $[Ga(C_6H_6)_2][GaCl_4]$, and X-ray studies show the cation to be the η^6-bis(benzene) complex of Ga^I (*see* ***Gallium: Organometallic Chemistry***). The $[GaCl_4]^-$ ions interact weakly with Ga^+ to provide bridging chlorine atoms between the Ga^I centers. The anodic dissolution of gallium in 6 M HCl or HBr at 0 °C followed by addition of $[Me_4N]X$ precipitates white crystalline salts of the ion $[Ga_2X_6]^{2-}$ that are stable and diamagnetic owing to the presence of a Ga–Ga bond (2.39 Å for X = Cl and 2.41 Å when X = Br).[155]

Mixed metal derivatives of gallium have become novel target compounds for investigation. [Tetra(n-ethyl)-1,1′-diphosphaferrocene $GaCl_2]^+$ $[GaCl_4]^-$ was prepared by the reaction of the ferrocene derivative and $GaCl_3$ at room temperature. The synthesis of the corresponding complex incorporating octa(n-propyl)-1,1′-diphosphaferrocene was carried out to try an ascertain the bonding structure in these molecules the [octa(n-propyl)-1,1′-diphosphaferrocene-$GaCl_2]^+$ $[GaCl_4]^-$ complex, which was successfully characterized by X-ray crystallography. In octa derivative, the diphosphaferrocene ligand acts as a chelate and the overall geometry around the gallium is tetrahedral. Theoretical calculations indicated that the bonding of the diphosphaferrocene ligand to the $[GaCl_2]^+$ fragment involves the lone pairs on the phosphorus atoms and a contribution of the P–Fe bond.[156]

$[[(\eta5\text{-Cp}^*)Fe(CO)_2]_2GaCl]$ is a useful reagent that is readily prepared by a metathesis reaction with 2 equivalents of $Na[(\eta5\text{-Cp}^*)Fe(CO)_2]$ with $GaCl_3$ at room temperature. Treatment of the aforementioned with a boron anion allows for the formation of the unique cationic Fe complex $[[(\eta5\text{-Cp}^*)Fe(CO)_2]_2Ga]^+$ $[BAr^f_4]^-$ (Ar^f = $C_6H_3(CF_3)_2$-3,5) (Scheme 5), which contains a symmetrically bridging two-coordinate Ga atom and a delocalized Fe-Ga-Fe π system having partial Fe–Ga multiple bond character. DFT (BLYP/TZP) computational analysis showed that the fully optimized geometry is consistent with that for the crystallographically solved structure.[157]

10 POLYDENTATE LIGANDS

Kinetically stable complexes of gallium are being examined for use as imaging agents in diagnostic nuclear medicine



Scheme 5 Syntheses of [[(η5-Cp*)Fe(CO)$_2$]$_2$GaCl] and [[(η5-Cp*)Fe(CO)$_2$]$_2$Ga]$^+$ [BAr$^f{}_4$]$^-$. Reagents and conditions: (i) Na[(η5-Cp*)Fe (CO)$_2$] 2 equiv., toluene, 20 °C, 12 h; (ii) Na[BAr$^f{}_4$] 1 equiv., dichloromethane, 278 °C to 20 °C, 30 min

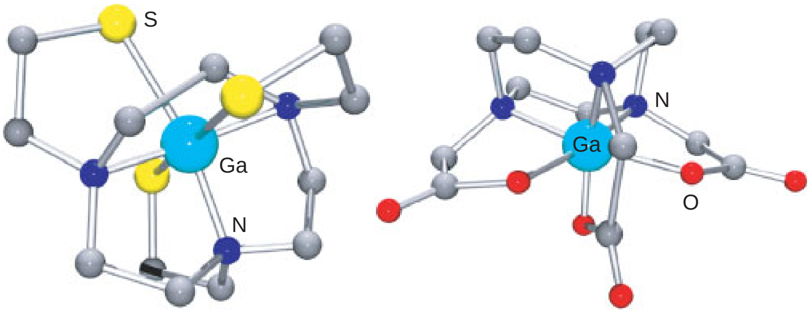


Figure 26 Molecular structure of Ga(TS-TACN); H$_3$TS-TACN = 1,4,7-tris(2-mercaptoethyl)-1,4,7-triazacyclononane and Ga(NOTA) (NOTAH$_3$ = 1,4,7-triazacyclononante-1,4,7-trisacetic acid)

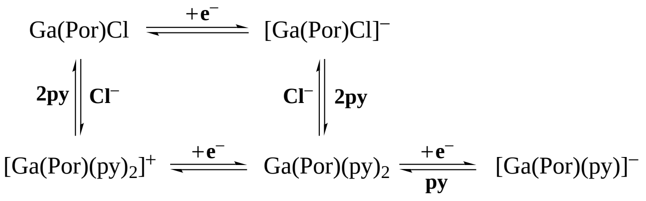
(^{67}Ga, γ, $t_{1/2} = 3.25$ days; ^{68}Ga, β^+, $t_{1/2} = 68$ min). In order for these complexes to be used in vivo, they should resist acid (or cation) mediated decomplexation in the pH range 2–8. The synthesis of oxygen, nitrogen, and recently sulfur functionalized polydentate ligands, especially those that may be attached to tumor-localizing antibodies, has been investigated.

10.1 Cryptand Ligands

The development of new metal-chelating agents for medical applications is an actively growing area of research in gallium coordination chemistry. While much effort has been put into the synthesis and determination of stability constants of ethylenediamine derivatives, these ligands yield a potential coordination sphere consisting of an $[N_2O_4]^{4-}$ core, which produces an anionic complex when bound to gallium(III).[158,159] Accordingly, these complexes are not very lipophilic. Hydrophilicity may be the principal reason that some radio-labeled complexes of Ga^{3+} are unable to cross the blood–brain barrier. Research has therefore been directed toward the development of cryptand ligands that possess a potential coordination sphere consisting of an $[N_3O_3]^{3-}$ core, thereby producing neutral, highly lipophilic complexes of Ga^{3+}. Several groups have reported a variety of triprotic ligands with $[O_6]^{3-}$, $[N_3O_3]^{3-}$, and $[N_3S_3]^{3-}$ cores,[160–162] examples are shown in Figure 26.

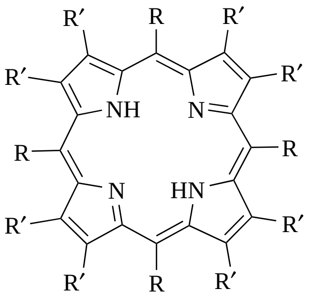
10.2 Porphyrin and Related Ligands

Chlorogallium(III) porphyrins, Ga(Por)Cl, are obtained in good yield by treating the corresponding free bases with gallium trichloride. The action of the hydrogen halides HX (X = F or I) on the chloro derivatives Ga(Por)Cl led to the corresponding halogeno complexes Ga(Por)X. The crystal structure of the tetraphenylporphyrin derivative has been determined by X-ray diffraction methods and shows a square pyramidal coordination for the gallium.[163] The reactions of the Lewis bases (L) *N*-methylimidazole and pyridine with Ga(Por)X [H$_2$Por = octaethylporphyrin (OEP, (**19b**)), tetraphenylporphyrin (TPP, (**19a**)); X = Cl^-, OAc^-, OH^-, F^-] have been investigated, and demonstrated the stepwise formation of hexacoordinate gallium porphyrin species of the type [Ga(Por)(X)(L)] and $[Ga(Por)(L)_2]^+$ (Scheme 6).[164] These compounds represent the first monomeric, hexacoordinated gallium(III) porphyrins to be reported. Equilibrium constants for ligand binding by Ga(Por)X and Ga(Por)(X)(L) were calculated from the electronic absorption spectra.

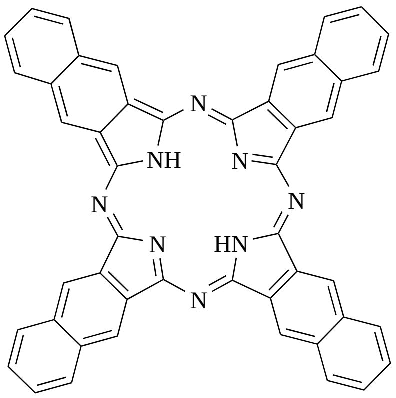


Scheme 6 Electrochemical reactions of gallium porphyrin complexes

The synthesis, spectroscopic, and structural characterization of the stable Ga hydride porphyrin [Ga(TPP)H] (TPP = 5,10,15,20-tetraphenylporphyrinato) was synthesized in high yield (85%) by reducing [Ga(TPP)Cl] with $NaBH_4$ in DMF. Infrared (IR) studies determined the Ga–H stretch at $1864\,cm^{-1}$, and the hydride ^1H NMR resonance located at -6.47 ppm. The Ga–H distance is 1.48(4) Å, whereas the Ga atom lies 0.46(1) Å from the perfect porphyrin plane.[165]



(**19a**) TPP; R = Ph, R′ = H
(**19b**) OEP; R = H, R′ = Et

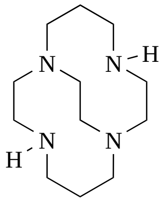


(**20**) H_2Nc

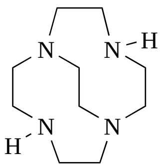
Gallium complexes of naphalocyanine (H_2Nc, (**20**)) have been investigated with respect to their application in photodynamic therapy agents for neoplastic disease. Compounds of the general formula Ga(Nc)X were prepared for X = F, Cl, OH, or $OSi(n\text{-}C_6H_{13})_3$.

Corroles are tetrapyrrole macrocycles that are closely related to porphyrins, with one carbon atom less in the outer periphery and one NH proton more in their inner core. They may also be considered as the aromatic version (identical skeleton) of the only partially conjugated corrin, the cobalt-coordinating ligand in Vitamin B_{12}. Two potential application of corroles are in tumor detection and their use in photovoltaic devices. Selective substitution of corroles via nitration, hydroformylation, and chlorosulfonation for the gallium were studied in detail and the respective mechanistic pathways and spectroscopic data were reported, (an example is shown in Figure 27). Overall, over 139 various corroles were synthesized and the effect of various metal complexation pertaining to their selective reactivity examined.[166,167]

The first highly characterized Ga and In halide complexes of tetraazamacrocycles have been reported. Gallium(III) and indium(III) complexes of cross-bridged cyclam and cyclen tetraaza macrocyclic ligands have been prepared and structurally characterized. In the crystalline state, both the $GaCl_3$ (cross-bridged cyclam) (**21**) and $InBr_3$ (cross-bridged cyclen) (**22**) complexes feature hexacoordinate cations in cis-folded tetradentate ligand clefts with ancillary cis-dihalides.[168]



(**21**)



(**22**)

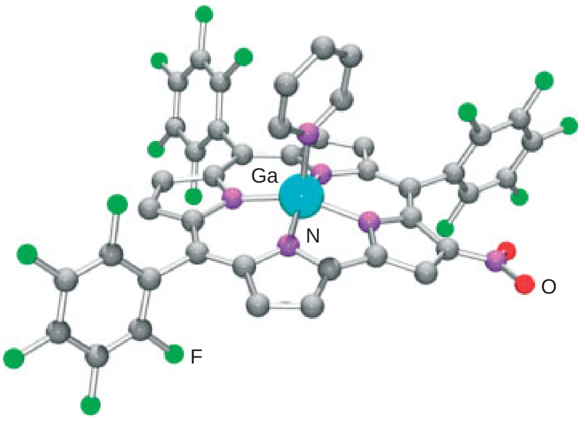


Figure 27 $C_{42}H_{12}F_{15}GaN_6O_2\cdot(C_6H_6)$, $M = 1065.4$, orthorhombic, space group $P2_12_12_1$, $a = 12.0410(2)$, $b = 18.2040(3)$, $c = 18.5900(3)$ Å, $V = 4074.8(1)$ Å^3, $D_c = 1.737\,g\,cm^{-3}$, μ(Mo Kα) = $0.80\,mm^{-1}$. The observed Ga–N coordination distances to the four pyrrole and the pyridyl nitrogens are 1.972, 1.926, 1.942, 1.938, and 2.039(4) Å, respectively

Three hexadentate, asymmetric pendent arm macrocycles containing a 1,4,7-triazacyclononane-1,4-diacetate backbone and a third, *N*-bound phenolate or thiophenolate arm have been synthesized. In $[L^1]^{3-}$ the third arm is 3,5-di-*tert*-butyl-2-hydroxybenzyl, in $[L^2]^{3-}$ it is 2-mercaptobenzyl, and in $[L^3]^{3-}$ it is 3,5-di-*tert*-butyl-2-mercaptobenzyl. With trivalent metal ions these ligands form very stable neutral mononuclear complexes $[Ga^{III}L^{1to3}]$ where the gallium complexes possess an $S = 0$ ground state. Cyclic voltammetry studies revealed that all three $[Ga^{III}L^1]$ complexes undergo a reversible, ligand-based, one-electron oxidation generating the monocations $[GaL^1]^+$, which contain a coordinated phenoxyl radical as was unambiguously established by their electronic absorption, EPR, and Mössbauer spectra. In contrast, $[Ga^{III}L^2]$ complexes in CH_3CN solution undergo an irreversible one-electron oxidation where the putative thiyl radical monocationic intermediates dimerize with S–S bond formation yielding dinuclear disulfide species $[Ga^{III}L^2\text{-}L^2Ga^{III}]^{2+}$. $[GaL^3]$ behaves similarly despite the steric bulk of two tertiary butyl groups at the 3,5-positions of the thiophenolate.[169] Similar work has been performed on various gallium triazacyclononane with modified pendent arms and their crystal structures have been elucidated.[170]

11 Ga(III): A DIAMAGNETIC MIMIC OF IRON(III)

The hydrolytic behavior and aqueous chemistry of the Ga^{3+} ion is similar to that of the Fe^{3+} ion. In fact, useful extrapolations of properties have been made between the two. For instance, diamagnetic gallium analogs of the microbial iron chelates (siderophores) have been useful in NMR studies,[171] since the native Fe^{3+} ion complexes are paramagnetic. In reverse, the knowledge gained from studies of Fe^{3+} ion transport has been applied to the development of ^{67}Ga radiopharmaceuticals.[172] The basis for this replacement of Fe^{3+} by Ga^{3+} lies in the physical and chemical similarities of the two ions. Both have the same charge and similar ionic radii in six-coordinate complexes (0.620 Å for Ga^{3+} compared to 0.645 Å for Fe^{3+}). Neither ion is perturbed by crystal field effects. The Fe^{3+} ion configuration is high-spin d^5 while the gallium is diamagnetic d^{10}. Moreover, since neither have any crystal field stabilization and both have similar ionic radii, they are similar in many of their ligand exchange rates. However, there are some significant differences in the stabilities of Ga^{3+} and Fe^{3+} complexes. The formation constants of a series of catecholate complexes have been determined and the gallium complexes are found to be consistently less stable than the analogous iron complexes. The stabilities of the benzohydroxamate complexes show a similar disparity.

One notable difference in the properties of Ga^{3+} and Fe^{3+} is that while the Fe^{3+}/Fe^{2+} redox system is very important in biological systems, the absence of a stable divalent state for gallium removes from consideration any processes that involve one-electron reduction of Ga^{3+}.

1 INTRODUCTION

The organometallic chemistry of gallium has experienced substantial growth in the intervening decade since publication of the first edition of the *Encyclopedia of Inorganic Chemistry*. One could legitimately argue that the organometallic chemistry of gallium has only just begun to be studied with a critical hand and vigilant eye in the last two decades. It seems that much of the activity in the organometallic chemistry of gallium during this period was driven by the quest for single-source molecular precursors to advanced materials (e.g. semiconductors) and the utilization of organogallium compounds in *Metal-Organic Chemical Vapor Deposition* (MOCVD) procedures.[1] Although it is evident that the breadth of the organometallic chemistry of gallium is as wide as it is varied, fundamental issues relating to structure and bonding have been a substantial driving force in this field much of the past decade. Perhaps more than could ever have been imagined when Paul-E'mile Lecoq de Boisbaudran discovered this rare and oddly mercurial element in 1875, the organometallic chemistry of gallium has been proven to be engaging and exciting. This contribution does not seek to cover the same fundamental material so eloquently presented in the original chapter, *Gallium: Organometallic Chemistry*, authored by A.R. Barron. Rather, this contribution seeks to utilize the original chapter as a template and bring sharper focus to some of the more noteworthy advances in the organometallic chemistry of gallium of the past decade. Specifically, this contribution seeks to highlight two prominent areas: (1) Organogallium compounds utilizing sterically demanding ligands; and (2) Organogallium cluster compounds. However, for historical perspective it is important to first contrast the synthesis of sterically demanding organogallium compounds with that of simple trialkyl and triaryl organogallium compounds.

2 SIMPLE TRIALKYL AND TRIARYL ORGANOGALLIUM COMPOUNDS

2.1 Syntheses

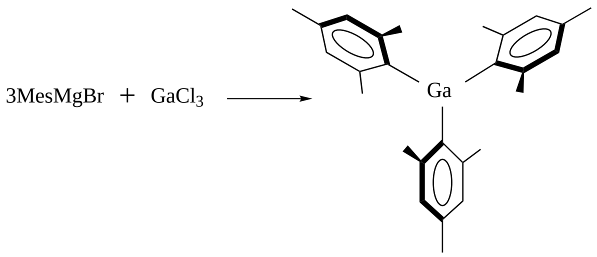
Triethylgallium monoetherate, $Et_3Ga{\cdot}(Et_2O)$, the first reported organometallic compound of gallium, was isolated from reaction of ethylmagnesium bromide with gallium bromide in 1932 (equation 1).[2]

$$3EtMgBr + GaBr_3 \xrightarrow[Et_2O]{} Et_3Ga{\cdot}(Et_2O) \qquad (1)$$

Triethylgallium monoetherate was isolated as a colorless, moderately viscous, pyrophoric liquid. The workers also reported that ether-free triethylgallium, Et_3Ga, could be prepared from reaction of gallium metal with diethylmercury. These two synthetic methods – reaction of a gallium halide with a Grignard Reagent and reaction of metallic gallium with a dialkylmercury reagent – are indicative of the often straightforward manner in which simple gallium alkyls and aryls may be prepared. Generally, simple gallium alkyls and gallium aryls may be approached synthetically by variations of these methods. However, some methods are significantly more effective than others.

2.1.1 *Grignard Reagents*

The utilization of Grignard Reagents, RMgX, with gallium halides, GaX_3, is perhaps the most versatile synthetic method to approach simple gallium alkyls and aryls. Indeed, not only was this the preparative method of choice for triethylgallium[2] in 1932, but it was also used to prepare trimesitylgallium, Mes_3Ga (Mesityl = 1,3,5-trimethylphenyl) – arguably the first sterically demanding organogallium compound – more than five decades later (equation 2).[3]



(2)

Mesitylmagnesium bromide was also utilized to prepare dichloromesitylgallium derivatives, which were reported as an inorganic polymer.[4] The following sterically demanding

organogallium compounds, R_3Ga, have been prepared (where R =: -neopentyl[5] and $–CH_2CMe_2Ph$).[6] One of the more recent sterically demanding organogallium species to be prepared by this route is the bis(adamantyl)-based gallate anions, $[Ada_2GaMe_2]^-$ and $[Ada_2GaBr_2]^-$ (Ada = adamantyl).[7] As is widely known, diethyl ether is often present in the organogallium products of such reaction products. However, it is often possible to obtain the ether-free moiety after prolonged exposure to vacuum. In addition, if the ligand is sufficiently sterically demanding, such as (Me_5C_6) Ga, ether complexation with the metal center is often prevented.

2.1.2 Lithium Reagents

The utilization of organolithium reagents, RLi (R = alkyl or aryl), with gallium halides is also a fruitful route to organogallium compounds. The overall reaction is quite similar to that of the Grignard Reagents: for example, reaction of phenyllithium with gallium chloride readily yields triphenylgallium, Ph_3Ga (equation 3).

$3(C_6H_5)Li + GaCl_3 \longrightarrow$  (3)

This method bears some similarities to the Grignard Reagent method in that product formation is often accomplished with solvent association. In particular, this method has been useful in preparing sterically demanding organogallium compounds, $(Aryl)_3Ga$ (vide infra).

2.1.3 Organomercury Reagents

Although organomercury reagents such as dimethylmercury, Me_2Hg, present significant toxicity concerns, these compounds offer a straightforward route to simple organogallium compounds. As demonstrated by the reaction of dimethylmercury with gallium metal, these reactions may be regarded as organometallic redox systems: the gallium metal is oxidized to R_3Ga while the mercury in Me_2Hg is reduced to elemental mercury (equation 4).

$$3Me_2Hg + 2Ga \longrightarrow 2Me_3Ga + 3Hg \qquad (4)$$

This method can also be utilized to prepare trimethylindium. It should be noted, however, that this preparative method is quite limited, being restricted to the simplest of alkyls.

2.1.4 Ligand Redistribution

Preparation of organogallium compounds by ligand redistribution between gallium halides and alkyls of metals such as zinc and mercury is severely limited. A noteworthy example is the preparation of $(CF_3)_3Ga$, isolated from reaction of $GaCl_3$ with $(CF_3)_2Cd$.[8,9] It should be noted that a potentially important class of organogallium compounds is the mixed trialkyls, $R_2R'Ga$. For example, ligand redistribution reactions involving Cp_3Ga and Me_3Ga, to give Me_2GaCp and $MeGaCp_2$, have been examined.[10]

2.2 Structural Characterization

In one sense, the coordination chemistry of simple gallium alkyls and aryls is rather restricted to three-coordinate trigonal planar. Although single-crystal X-ray diffraction remains the most important structural technique in the organometallic chemistry realm, gas-phase electron diffraction data of Me_3Ga unambiguously confirms a monomeric species with the gallium center residing in a trigonal planar environment.[11] While single-crystal X-ray diffraction data confirms the coordination of the gallium center in triphenylgallium, Ph_3Ga, as trigonal planar (Figure 1),[12] it is interesting to note one phenyl ring is observed to be coplanar with the GaC_3 plane while a second phenyl ring resides slightly out of the GaC_3 plane at 13°. In contrast, the third phenyl ring is found to reside considerably out of plane at 31°. Indeed, a more expansive view of the unit cell reveals significant secondary interactions of each gallium center with meta carbon atoms of other Ph_3Ga units (3.42 Å). This effectively results in the coordination approaching five-coordinate trigonal bipyramidal.

A similar intermolecular stabilization has also been observed in $(t\text{-Bu})_2Ga(OCPh_3)$[13] wherein the carbon atom of one of the phenyl rings approaches the gallium center offering

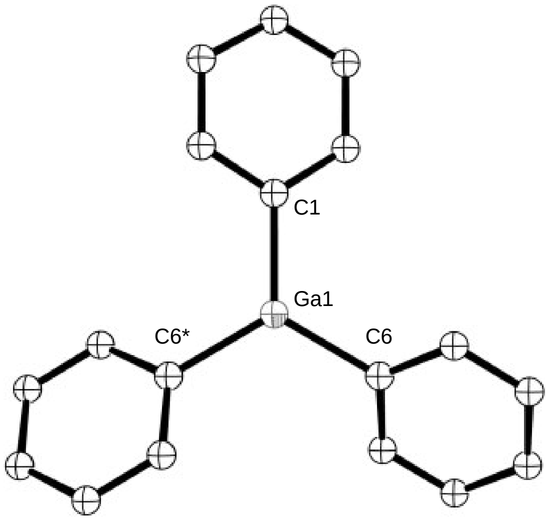


Figure 1 Solid-state structure of Ph_3Ga

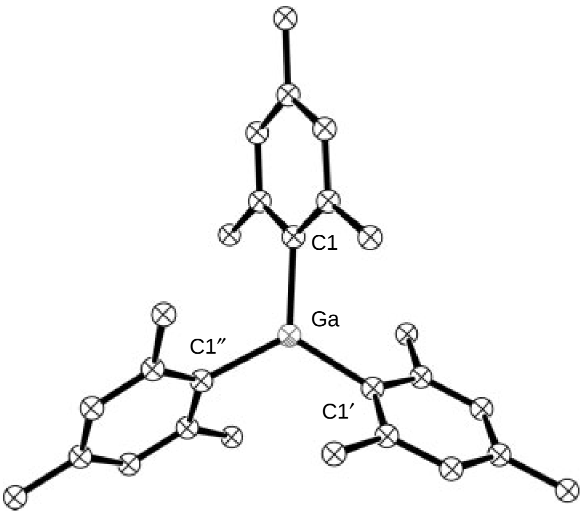

Figure 2 Solid-state structure of Mes_3Ga

additional electron density. Effectively, the coordination of the gallium center may be described as 'trigonal pyramidal': the gallium atom resides in a normal trigonal planar environment with further stabilization from one of the carbon atoms of a phenyl ring.

The solid-state structure of Mes_3Ga stands as a benchmark in organogallium chemistry.[3] The structure reveals the gallium atom in an almost idealized trigonal planar environment (C–Ga–C bond angle: 120°) (Figure 2). While the Ga–C bond distances are unremarkable (Ga–C: 1.968 Å), the mesityl rings of Mes_3Ga reside in a propeller arrangement at angles of 55.9° relative to the GaC_3 basal plane. Unlike Ph_3Ga, the steric bulk of the mesityl groups in Mes_3Ga preclude any significant secondary interaction from neighboring molecules in the unit cell or solvent donor interactions.

In notable contrast to Mes_3Ga, the solid-state structure of mesitylgallium dichloride, $MesGaCl_2$, reveals a one-dimensional polymer.[14]

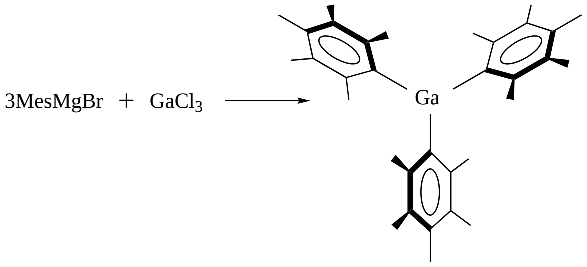
3 STERICALLY DEMANDING ORGANOGALLIUM COMPOUNDS

3.1 Syntheses

Considerable activity in the synthesis of sterically demanding organogallium compounds has taken place in the past decade. In particular, there has been significant activity concerning sterically demanding *m*-terphenyl ligands. The synthesis of such organogallium compounds has predominantly been accomplished *via* the lithium reagent route. In particular, the lithium reagent method is often preferred to the Grignard reagent route by workers as it frequently provides uncomplicated reaction products. For example, the Grignard reagent method often yields ionic salts accompanied by $[Mg(Et_2O)_x]^+$ cations. Nonetheless, both Grignard reagents and lithium reagents have greatly contributed to the synthesis of sterically demanding organogallium compounds.

3.1.1 *Grignard Reagents and Lithium Reagents*

It is interesting that, arguably, the ligand most similar to mesityl, pentamethylphenyl, has only recently been utilized in organogallium chemistry. The synthesis of tris(pentamethylphenyl)gallium, $(C_6Me_5)_3Ga$, is cleanly achieved by reaction of the pentamethylphenylmagnesium bromide Grignard reagent with $GaCl_3$ in diethyl ether (equation 5).[15] Tris(pentamethylphenyl)gallium was isolated as colorless, needle crystals in modest yield.



(5)

A particularly intriguing aryllithium reagent is the bis(etherate) of 2,6-diphenylphenyllithium, $(2,6\text{-}Ph_2C_6H_3)Li(Et_2O)_2$. This reagent, readily prepared by reaction of (2,6-diphenyl)-1-iodobenzene with *n*-butyllithium, is isolated as a white crystalline solid (equation 6).[16]

$$(2,6\text{-}Ph_2C_6H_3)I + n\text{-}BuLi \xrightarrow[Et_2O]{} (2,6\text{-}Ph_2C_6H_3)Li(Et_2O)_2 \qquad (6)$$

The solid-state structure of $(2,6\text{-}Ph_2C_6H_3)Li(Et_2O)_2$ reveals the lithium atom in a trigonal planar environment with the Li–C bond (2.106(9) Å) being complemented by two Li–O interactions (1.943(5) Å). Reaction of $(2,6\text{-}Ph_2C_6H_3)Li$ with GaI_3 gives the neutral trigonal planar complex bis(2,6-diphenylphenyl)gallium iodide, $(2,6\text{-}Ph_2C_6H_3)_2GaI$ (equation 7).[16]

$$2(2,6\text{-}Ph_2C_6H_3)Li(Et_2O)_2 + GaI_3 \longrightarrow (2,6\text{-}Ph_2C_6H_3)_2GaI \qquad (7)$$

It is noteworthy that when gallium(III) chloride, $GaCl_3$, instead of GaI_3, is allowed to react with $(2,6\text{-}Ph_2C_6H_3)Li(Et_2O)_2$, the ionic complex $[Li(Et_2O)_2][(2,6\text{-}Ph_2C_6H_3)GaCl_3]$ is obtained (instead of the neutral chloride analog of $(2,6\text{-}Ph_2C_6H_3)_2GaI$).[16] Indeed, the analogous ionic compound, $[Li(Et_2O)_2][(1,3,5\text{-}Ph_3C_6H_3)GaCl_3]$, is also isolated from reaction of the related lithium aryl 1,3,5-triphenylphenyllithium, $(1,3,5\text{-}Ph_3C_6H_2)Li$, with $GaCl_3$.[16] Thus, it appears that the propensity to obtain the neutral trigonal planar diarylgallium halide is enhanced when iodide is used instead of chloride.

Arguably, the most prominent aryllithium reagent in organogallium chemistry of the past decade is 2,6-dimesitylphenyllithium, (2,6-$Mes_2C_6H_3$)Li. The previous statement is justifiable owing to the significant organogallium compounds prepared using this sterically demanding *m*-terphenyl ligand. This reagent is conveniently prepared in a straightforward fashion from reaction of 2,6-dimesityl-1-iodobenzene[17] with *n*-butyllithium.[18] Reaction of 2,6-dimesitylphenyllithium with gallium chloride readily affords bis(2,6-dimesitylphenyl)gallium chloride, (2,6-$Mes_2C_6H_3)_2$GaCl, (equation 8) in high yield.[19]

$$2(2,6\text{-}Mes_2C_6H_3)Li + GaCl_3 \longrightarrow (2,6\text{-}Mes_2C_6H_3)_2GaCl \quad (8)$$

This compound was noteworthy for two reasons: (1) The isolation of (2,6-$Mes_2C_6H_3)_2$GaCl demonstrated that it was possible to affix two of these large *m*-terphenyl ligands about a gallium center; and (2) The T-shaped coordination geometry about the gallium center in (2,6-$Mes_2C_6H_3)_2$GaCl was the first reported for a gallium center. Notably, both the corresponding bis(2,6-dimesitylphenyl)gallium bromide, (2,6-$Mes_2C_6H_3)_2$GaBr, and the dimeric (2,6-dimesitylphenyl)gallium dichloride complex, [(2,6-$MesC_6H_3$)$GaCl_2]_2$, have also been prepared and their solid-state structures determined.[20]

A variation on this method produces perhaps the most sterically protected gallium center reported in dimesityl-(2,6-dimesitylphenyl)gallium, $(Mes)_2$(2,6-$Mes_2C_6H_3$) Ga.[20] This compound was prepared by reaction of (2,6-$Mes_2C_6H_3$)Li with $GaCl_3$ followed by the in situ reaction with mesityllithium.

3.2 Structural Characterization

The structural characterization of sterically demanding organogallium compounds is arguably the most significant development in this area of the past decade. The fact that gallium atoms have been observed in a variety of coordination environments over the past decade underscores the fact that the organometallic chemistry of gallium is as varied as it is exciting.

It is perhaps expected that the pentamethylphenyl ligand has received considerably less attention than the closely related mesityl ligand. Indeed, the addition of two additional methyl groups in the two meta positions of a mesityl moiety would hardly be expected to result in any significant structural changes. The facts, however, bespeak as to why experiments are necessary. The coordination of the gallium center in $(C_6Me_5)_3$Ga is almost idealized trigonal planar with a C–Ga–C bond angle of 120.1(2)°. The structure of $(C_6Me_5)_3$Ga (Figure 3) is most easily compared to that of Mes_3Ga. Both $(C_6Me_5)_3$Ga and Mes_3Ga approximate D_3 symmetry. It is surprising that the mean Ga–C bond distance of 1.981 Å in $(C_6Me_5)_3$Ga is considerably longer than the reported values for either Ph_3Ga (1.957 Å) or Mes_3Ga (1.968 Å). The mesityl rings

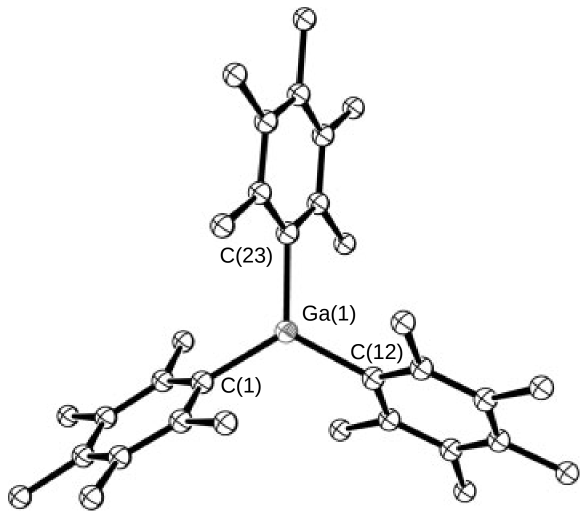


Figure 3 Solid-state structure of $(C_6Me_5)_3$Ga

of Mes_3Ga reside in a propeller arrangement at angles of 55.9°. However, the angles of the (C_6Me_5)-rings in $(C_6Me_5)_3$Ga are 67.3°, 62.3°, and 60.9°. Contributing factors to this may be a weak aromatic–aromatic interaction, at a distance of 4.1 Å, between parallel rings of two molecules in the unit cell.

The solid-state structure of bis(2,6-diphenylphenyl)gallium iodide, (2,6-$Ph_2C_6H_3)_2$GaI,[16] displays the gallium atom in a somewhat distorted trigonal planar environment (C–Ga–C: 134.3(3)°). The Ga–I bond distance of 2.550(1) Å is unremarkable (Figure 4).

Perhaps the most telling comparison of (2,6-$Ph_2C_6H_3$)- is with the closely related, but even more sterically demanding ligand system of 2,6-dimesitylphenyl, (2,6-$Mes_2C_6H_3$)-. The solid-state structures of both bis(2,6-dimesitylphenyl)gallium

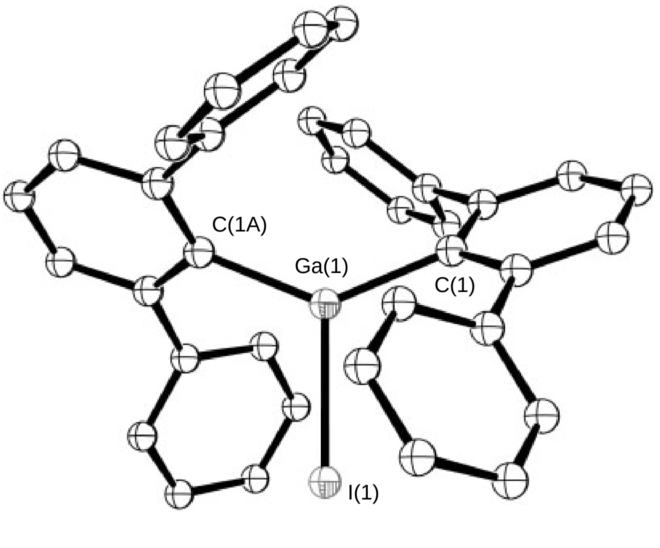

Figure 4 Solid-state structure of (2,6-$Ph_2C_6H_3)_2$GaI

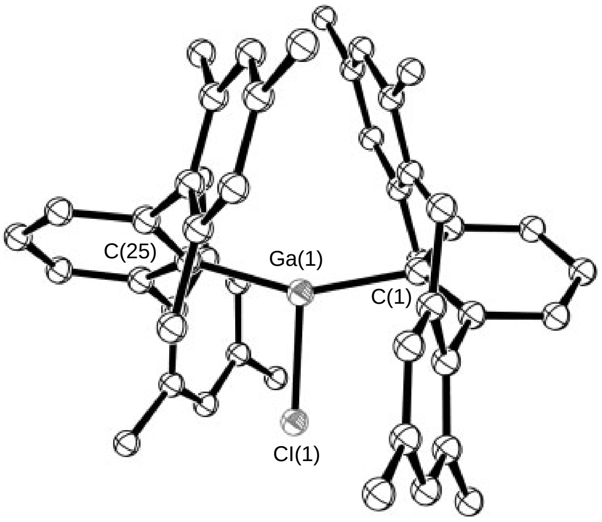

Figure 5 Solid-state structure of $(2,6\text{-}Mes_2C_6H_3)_2GaCl$

chloride, $(2,6\text{-}Mes_2C_6H_3)_2GaCl$ (Figure 5),[19] and bis(2,6-dimesitylphenyl)gallium bromide, $(2,6\text{-}Mes_2C_6H_3)_2GaBr$,[20] have been determined. They are isostructural. Although the Ga–X bond distances are rather long (X = Cl: 2.177(5) Å; X = Br: 2.3183(1) Å), the singular most striking feature of these compounds is the C–Ga–C bond angles of 153.5(5)°. The normal coordination for three-coordinate gallium is trigonal planar with bond angles about the metallic center approximating 120°. However, the C–Ga–C bond angles in these two compounds substantially exceed the 120° benchmark sufficiently to justify the T-shaped description. The T-shaped structure is almost exclusively reserved for interhalogen compounds such as ClF_3 and BrF_3 wherein the coordination is facilitated by the steric repulsion of the two lone pairs of electrons about the central halide ion. Thus, $(2,6\text{-}Mes_2C_6H_3)_2GaCl$ and $(2,6\text{-}Mes_2C_6H_3)_2GaBr$ are significant in that they represent rare examples of three-coordinate gallium atoms assuming the uncommon T-shaped coordination environment through sheer ligand steric repulsion (*without* the aid of lone pair–lone pair repulsion).

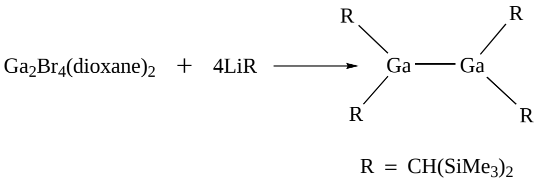
4 ORGANOMETALLIC COMPOUNDS CONTAINING GALLIUM–GALLIUM BONDS

The stabilization of the Ga–Ga bond is, arguably, the most important development of the past decade in the organometallic chemistry of gallium. Perhaps the most significant factor in the stabilization of these compounds is the utilization of sterically demanding ligands. Such ligands are necessary as they provide kinetic stabilization. It is anticipated that this field will only continue to grow as workers realize the variety of compounds that may be isolated.

4.1 Synthesis

4.1.1 Gallium Dimers and Tetrahedra

A notable difference between gallium and aluminum lies in the 2+ oxidation state: while aluminum(II) halides are not known, those of gallium are stable and well known. Indeed, the solid-state structures of bis-dioxane adducts of both gallium(II) chloride[21] and gallium(II) bromide[22] have been shown to reside about Ga–Ga bonds. Gallium(II) bromide was utilized with bis(trimethylsilyl)methyllithium in the preparation of the first organometallic compound unambiguously shown to possess a Ga–Ga bond: tetrakis[bis(trimethylsilyl)methyl]digallane, $[(Me_3Si)_2HC]_2Ga–Ga[(CH(SiMe_3)_2)]_2$ (equation 9).[23]



(9)

This novel compound was isolated as yellow crystals from pentane.

The first tetraaryldigallane, $[Pr_3C_6H_2]_2Ga–Ga[C_6H_2Pr_3]_2$, was prepared by reaction of $Ga_2Cl_4(dioxane)_2$ with the corresponding Grignard reagent.[24] Treatment of this digallane with an excess of lithium powder gave a dark solution. The addition of 12-crown-4 and workup produced a radical anion, $[Pr_3C_6H_2]_2Ga–Ga[C_6H_2Pr_3]_2^{\bullet -}$, that was held to possess a measure of multiple bond character in the Ga–Ga bond.

A particularly interesting synthesis concerns reaction of $Ga_2Br_4(dioxane)_2$ with ether-free $LiC(SiMe_3)_3$: this reaction gives the novel $[\{GaC(SiMe_3)_3\}_4]$ tetramer.[25] $[\{GaC(SiMe_3)_3\}_4]$, isolated as a dark red crystalline compound, is noteworthy as it represents the first example of gallium assuming the 1+ oxidation state in an organometallic compound. In addition, this remarkable compound demonstrated unusual thermal stability (only decomposing above 255 °C) and could be stored in air for months without decomposition.

Perhaps the organogallium compound most closely related to the tetrahedral metallic core of $[\{GaC(SiMe_3)_3\}_4]$ is $[\{(Me_3Si)_3C\}_6Ga]_8$.[26] The critical point in this synthesis is the utilization of gallium(I) bromide, GaBr. Reaction of trimethylsilyllithium (dissolved in toluene at −78 °C) with GaBr, after considerable workup, affords $[\{(Me_3Si)_3C\}_6Ga_8]$. This dark red/black crystalline compound contains a Ga_8 core: two Ga_4-tetrahedra linked by a single Ga–Ga bond.

4.1.2 *Gallium Rings*

Organometallic compounds containing gallium rings were first reported in 1995: sodium metal reduction of (2,6-$Mes_2C_6H_3$)$GaCl_2$[27] resulted in a deeply red colored solution from which a red (almost black) crystalline compound was isolated (equation 10). These crystals were determined to be $Na_2[(2,6\text{-}Mes_2C_6H_3)Ga]_3$.[28]

$$3(2,6\text{-}Mes_2C_6H_3)GaCl_2 + 8Na \xrightarrow[-6NaCl]{} Na_2[(2,6\text{-}Mes_2C_6H_3)_2Ga]_3 \quad (10)$$

Quite surprisingly, this compound was shown to contain an unprecedented gallium three-membered ring at its core. The potassium analog, $K_2[(2,6\text{-}Mes_2C_6H_3)Ga]_3$, was subsequently reported by the same laboratory.[29] Similar to the nomenclature used for organic ring compounds (i.e. cyclopropane), this class of organogallium compounds were referred to as *cyclogallanes*. Particularly significant, these compounds were shown to possess a new type of aromaticity – *metalloaromaticity*: traditional aromatic behavior derived from a metallic ring system (instead of carbon).[30–32] A noteworthy Ga_4-based cyclogallane, $K_2[(2,6\text{-}Mes_2C_6H_3)Ga]_4$,[33] and a 'silagallane',[34] an organometallic cluster with a III–IV skeleton of gallium and silicon atoms, have also been reported. In the silagallane, a trigonal arrangement of three gallium atoms is capped by two silicon atoms in the axial positions.

4.2 Structural Characterization

Certainly unambiguous single-crystal X-ray crystal structures are critical in this area of organogallium chemistry. The solid-state structure of tetrakis[bis(trimethylsilyl)methyl]digallane, $[(Me_3Si)_2HC]_2Ga–Ga[(CH(SiMe_3)_2)]_2$ (Figure 6),[23] with its Ga–Ga bond distance of 2.541(1) Å, remains a benchmark in organometallic chemistry. In addition, this gallane possesses a planar $C_2Ga–GaC_2$ core. Valence bond theory would hold that the gallium atoms are sp^2 hybridized with an empty p orbital orthogonal to the planar $C_2Ga–GaC_2$ core. It is also noteworthy that the planar $C_2Al–AlC_2$ core was reported for the corresponding $[(Me_3Si)_2HC]_2Al–Al[(CH(SiMe_3)_2)]_2$ alane.[35] This fact will become important as organometallic compounds containing multiple bond character in the Ga–Ga interaction are approached (vide infra). Perhaps expected, the Ga–Ga bond observed in $[(Me_3Si)_2HC]_2Ga–Ga[(CH(SiMe_3)_2)]_2$ (2.541(1) Å) was lengthened from that reported for the gallium(II) bromide bis(dioxane), $Br_2Ga–GaBr_2·(dioxane)_2$, starting compound (2.395(6) Å).[22] Certainly, the important role of sterically demanding ligands and the manner in which they lend kinetic stabilization to such compounds was critically important in the development of the chemistry of the Ga–Ga bond.

Of all the polyhedra, the tetrahedra hold a unique place. The core of $[\{GaC(SiMe_3)_3\}_4]$[25] (Figure 7) bears a striking resemblance to that of white phosphorus, P_4: a nearly idealized tetrahedral core. The Ga–Ga bond distances in $[\{GaC(SiMe_3)_3\}_4]$, ranging from 2.678(4) to 2.702(4) Å, are slightly longer than those reported for the initial gallane of 2.541(1) Å.

The Ga_4 tetrahedral of $[\{GaC(SiMe_3)_3\}_4]$ readily compared with the striking double gallium tetrahedral, $[\{(Me_3Si)_3C\}_6Ga_8]$, reported by Schnöckel in 2001 (Figure 8).[26] The fact that two Ga_4 tetrahedra are connected by a single Ga–Ga bond is stunning and suggests that the Ga–Ga bond is sufficiently robust to possibly link larger polyhedra. All angles within the two tetrahedral approach 60°. The

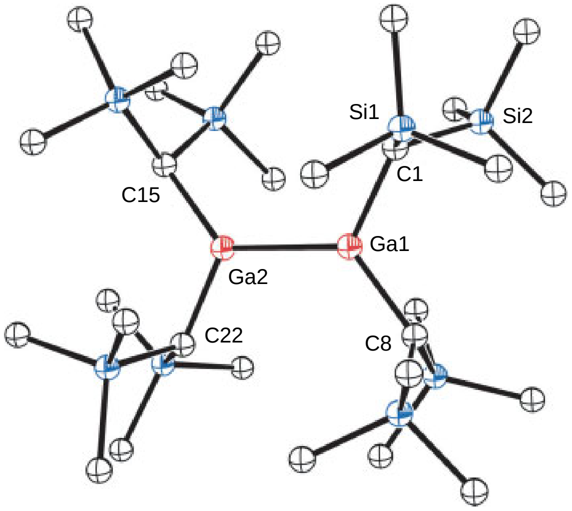


Figure 6 Solid-state structure of $[(Me_3Si)_2HC]_2Ga–Ga[(CH(SiMe_3)_2)]_2$

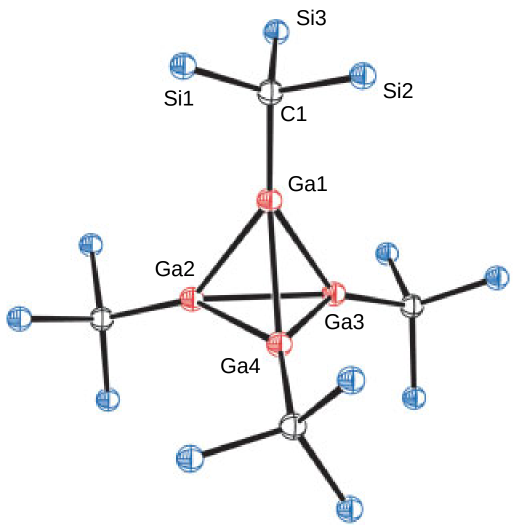

Figure 7 Solid-state structure of $[\{GaC(SiMe_3)_3\}_4]$

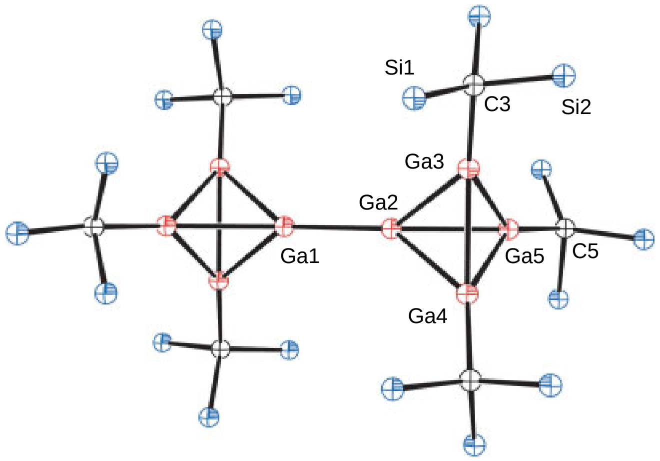

Figure 8 Solid-state structure of $[\{(Me_3Si)_3C\}_6Ga_8]$

Ga–Ga bond distances reside within the somewhat narrow range of 2.605 to 2.648 Å. As the authors stated, this was the first example of 'two tetrahedral R_3M units linked by a single metal–metal bond' in a homonuclear cluster.

The Ga–Ga bond distances in the first reported gallium ring system, $Na_2[(2,6\text{-}Mes_2C_6H_3)Ga]_3$ (Figure 9),[28] were determined to be 2.441(1) Å. The Ga–Ga–Ga bond angles within the metallic triangle were 60.01(1)°. While the sodium atoms do not appear to be engaged in any significant bonding interaction with the gallium atoms (Na···Ga approach: 3.1 Å), the sodium atoms appear to be assisted by subtle, yet significant, interactions with the π-electron cloud of the substituent rings of the m-terphenyl ligands.

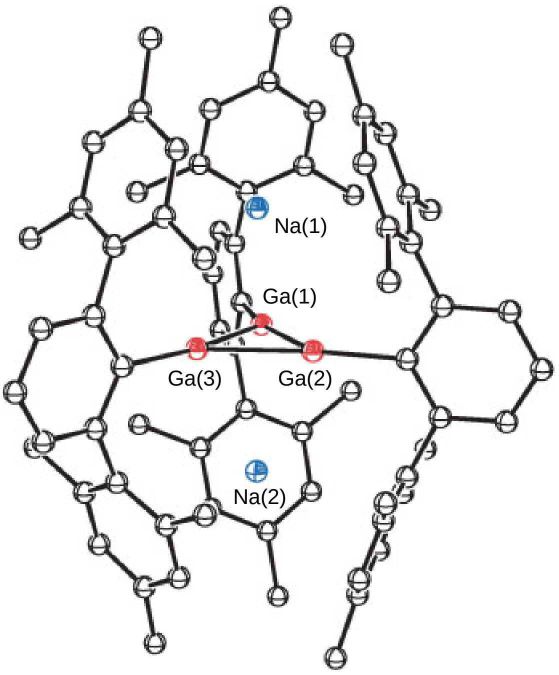

Figure 9 Solid-state structure of $Na_2[(2,6\text{-}Mes_2C_6H_3)Ga]_3$

The structural features of the potassium-based cyclogallane, $K_2[(2,6\text{-}Mes_2C_6H_3)Ga]_3$,[29] are very similar with Ga–Ga–Ga bond angles of 60.0° and Ga–Ga bond distances of 2.4260(5), 2.4317(5), and 2.4187(5) Å. These values are easily compared to $K_2[R_2Ga_4]$($R = 2,6\text{-}(2,4,6\text{-}i\text{-}Pr_3C_6H_2)_2C_6H_3$),[36] which was described as having a 'planar, almost square Ga_4 core'. The Ga–Ga bond distances in this compound were shown to be slightly longer at 2.4624(4) and 2.4685(3) Å while the Ga–Ga–Ga bond angles were shown to be 87.222(11) and 92.778(11)°.

1 INTRODUCTION

Germanium (Ge), the 32nd element in the periodic table, lying between Si and Sn in group 14, was first predicted as the missing element of a triad between silicon and tin by J. A. R. Newlands in 1864. In 1871, D. I. Mendeleev specified the properties that 'eka-silicon' would have (eka = Sanskrit for 'one'). By comparing Si and Sn, remarkably accurate predictions were made of the properties of a range of germanium compounds. When Winkler isolated the element from a new and rare mineral argyrodite, Ag_8GeS_6, in 1886,[1] the name 'Germanium', in honor of his homeland, Germany, came into use. Since then, Germanium has initiated special interest because of its intriguing inorganic and organic chemistry.

Germanium minerals are extremely rare but the element is widely distributed in trace amounts. Its abundance ratio is about 7×10^{-4}% and it is mainly associated with copper, zinc, lead, selenium, arsenic, silver, iron, and so on. There are twenty-one isotopes; ^{70}Ge, ^{72}Ge, ^{73}Ge, ^{74}Ge, ^{76}Ge are naturally occurring. Germanium is common in organisms, but it is not an indispensable trace element. In humans, it is nontoxic, but when it reaches 1000 ppm in animal's food, the growth of animals will be inhibited and 50% of them will die. When drinking water contains 100 ppm GeO_2, a death rate of 50% will result in the fourth week. The hemolytic function of GeH_4 will detrimentally affect animals when its content exceeds 100 ppm.

Germanium's general chemistry is closer to that of Si. It exhibits both +2 and +4 oxidation states when forming inorganic ionic and covalent compounds. It can form a wide range of binary compounds and eutectics with many metals and metalloid elements.[2] Its +2 oxidation state is like that of a singlet-state carbene, in which Ge is sp^2 hybridized with a lone pair of electrons and an empty p orbital. This electronic configuration results in a wide variety of structural types, determined largely by steric factors, and ranges from V-shaped monomeric molecules to polymers. The stability of the +2 state is greater than Si and less than Sn. In its +4 oxidation state, Ge compounds are four-, five-, or six-coordinate.

Structural differences resulting from the larger size of Ge relative to Si seem most apparent in some of the anionic oxides, where both tetrahedrally and octahedrally coordinated Ge atoms occur, as in the ion $[Ge_9O_{20}]^{4-}$.

Mainly used as semiconductor material, germanium also finds its extensive applications relating to optical devices and based on its infrared transmission properties (1 cm of Ge will transmit 25–46% of radiation in the 5000–600 cm^{-1} region).[3] Furthermore, germanium is also used in resistance thermometers and glass semiconductors ($Te_{21}Ge_{15}As_6$, $Te_{50}Ge_{20}As_{30}$). Current uses of germanium have been largely directed to its combination with other metals and metalloids. Table 1 lists selected properties of germanium. Table 2 gives typical bond lengths of germanium compounds. Standard enthalpies of the formation of selected germanium compounds are listed in Table 3.

2 ANALYSIS

Samples can be decomposed with sulfuric acid (sometimes nitric acid is added as an oxidant). When it is high in SiO_2, HF is then needed. Samples with chloride should be melted with alkali to avoid the volatility of $GeCl_4$. After decomposition, common ways such as extraction and distillation based on the volatility of $GeCl_4$ are then applied to separate the noise element. Ion exchange and coprecipitation processes are also used for the extraction of germanium. Classical methods of quantitative analysis involve precipitation of GeS_2 from acid solution, followed by ignition to GeO_2 and photometric measurements based on complexation with phenylfluorone.[3]

3 THE ELEMENT

Few minerals contain significant amounts of Ge, though it is widely distributed in the earth's crust. The first process to

obtain Ge is its enrichment from the ores. Recovery has been achieved from coal ash, but it is now normally recovered from the flue dusts of smelters processing Zn ores. Common ways to fabricate metal Ge from the enriched ores involve three processes: (1) preparation of $GeCl_4$, (2) hydrolysis of $GeCl_4$ into GeO_2, and (3) reduction of GeO_2 into Ge with H_2. For optical or semiconductor use, further purification is achieved by zone refining. Detailed means to obtain Ge can be found elsewhere.[5]

The element crystallizes in a diamond cubic lattice. It is brittle, and has a bright metallic luster. Ge can absorb H_2, O_2, CO_2, H_2O, alcohol, and other common substances containing hydrogen or oxygen.

Germanium is more reactive and electropositive than Si. It is stable in air and water. It dissolves slowly in hot concentrated H_2SO_4 and HNO_3, but does not react with dilute acids or alkalis unless an oxidizing agent such as H_2O_2 or NaOCl is present.

Fused alkalis react with incandescence to give germanates. When heating, it can be eroded by dry HCl. H_2O_2 in 3wt % can slowly dissolve Ge, and when the temperature is raised to 90–100 °C, the dissolution is accelerated. It also can be eroded by many gaseous alkyl- and vinyl-chlorides, and finally yields organic germanium chloride. Powdery Ge can conflagrate in Cl_2 and Br_2.

Germanium nanocrystals embedded in a silicon-oxide matrix display blue luminescence, a desirable property for the development of optoelectronic devices. This has made Ge an interesting subject in recent nano-material study.

In the following sections, the chemistry of neutral, anionic, and cationic germanium compounds are described for both oxidation states.

3.1 Anionic Germanium Clusters

Like Sn and Pb, anionic Germanium clusters are formed from the reaction of germanium and alkali metals.[6] The common way is to dissolve a binary compound of germanium and alkali metal in ethylenediamine or liquid ammonia, and, if the cation (Na^+, K^+) is suitably coordinated, a product containing the cluster can be crystallized by addition of cation-sequestering agents.[7] The anionic Ge_4^{2-}, Ge_9^{2-}, and Ge_9^{4-} clusters have so far been characterized (equations 1 and 2 show the related reactions).[8,9] The tetranuclear Ge_4^{2-} ion is diamagnetic and a crystal-structure determination on a disordered crystal reveals a disordered crystal slightly elongated to C_{3v} symmetry with Ge–Ge distances of 277 and 279 pm. In both the Ge_9^{2-} and Ge_9^{4-} anions, the shortest Ge–Ge distance is about 255 pm, considerably shorter than that in $[Ge_4]^{2-}$. The Ge_9^{4-} ion, like $[Sn_9]^{4-}$, has a monocapped square antiprism (C_{4v}) geometry, whereas $[Ge_9]^{2-}$, with two less electrons, forms a distorted tricapped trigonal prismatic (D_{2h}) structure.

$$\text{NaGe} + \text{2,2,2-crypt in liq. } NH_3 \longrightarrow 2[\text{Na(crypt)}]^+[Ge_4]^{2-} \quad (1)$$

$$\text{KGe} + \text{2,2,2-crypt} + \text{en} \longrightarrow 6[\text{K(crypt)}]^+[Ge_9]^{2-}[Ge_9]^{4-}[2.5\text{en}] \quad (2)$$

The tight-binding (TB) approach to total-energy calculation is one of the simplest methods that explicitly treats the quantum-mechanical nature of electrons that form interatomic bonds. Some theoretical studies have given the TB models for germanium,[10] and the lowest energy geometries of small Ge_n ($n = 2-7$) clusters are summarized in Table 4.

Table 4 The lowest energy geometries of small Ge_n ($n = 2-7$) clusters

Ge_n	Sym.	Ge_n	Sym.
Ge_3	C_{2v}	Ge_4	D_{2h}
Ge_5	D_{3h}	Ge_6	O_h
Ge_7	D_{5h}		

Anion photoelectron spectra of small germanium clusters ($n = 2-15$) have been used to determine electronic properties and the most stable geometric configuration for Ge_n anions.[11]

4 HYDRIDES

Varieties of polymeric hydrides (GeH, GeH_2, and nonstoichiometric materials, $GeH_{0.9}$ to $GeH_{1.2}$) have been obtained by reactions such as the hydrolysis of Na_2Ge or CaGe. Monomeric Ge dihydride has not been described so far, even as a matrix isolated species. $(GeH_2)_n$ (equation 3) is a white solid, insoluble in liquid NH_3. It decomposes above – 33 °C to GeH_4 and a yellow polymer $(GeH)_n$. Although there is no structural information on these hydrides, it seems likely that they involve Ge–Ge as well as bridging and terminal Ge–H bonding.

$$GeH_3Na + PhBr \xrightarrow{NH_3} GeH_2 + NaBr + C_6H_6 \quad (3)$$

Ge^{IV} binary hydrides, with the general formula Ge_nH_{2n+2} (see Table 5), are colorless gases or volatile liquids for $n = 1-5$, and their preparation, physical properties, and chemical reactions are very similar to those of silanes. They were first obtained by the acid hydrolysis of Mg_2Ge, which yielded mono- to pentagermanes, including isomers of Ge_4H_{10} and Ge_5H_{12}.

Monogermane together with Ge_2H_6 and Ge_3H_8 can be made by heating GeO_2 and $LiAlH_4$, or by addition of $NaBH_4$ to GeO_2 in acid solution. Higher germanes are prepared by the action of a silent electric discharge on GeH_4. No cyclic or unsaturated hydrides have yet been prepared.

GeH_4 is a colorless gas, and it does not ignite in contact with air and is unaffected by aqueous acid or 30% aqueous NaOH. It acts as an acid in liquid NH_3 forming NH_4^+ and GeH_3^- ions, and reacts with alkali metals in this solvent

Table 5 Selected properties of Ge_nH_{2n+2} ($n = 1-5$)

Property Ge_nH_{2n+2}	GeH_4	Ge_2H_6	Ge_3H_8	Ge_4H_{10}	Ge_5H_{12}
MP/°C	−164.8	−109	−105.6	–	–
BP/°C	−88.1	29	110.5	176.9	234
Density (T°C)/g cm^{-3}	1.52(−142 °C)	1.98(−199 °C)	2.20(−105 °C)	–	–

to give $MGeH_3$, which are white, crystalline compounds of considerable synthetic utility.

The higher hydrides become increasingly more reactive toward air or water, though less than Si analogs; even Ge_3H_8 is only slowly oxidized in air and is thermally stable to 190 °C. The higher germanes decompose thermally to H_2, GeH_4, and polymeric hydrides.

The reaction of GeH_4 with Na or K in liquid ammonia has been interpreted in terms of rapid formation of the solvated $[GeH_2]^{2-}$ ion, which is subsequently converted into $[GeH_3]^-$ (equations 4–6). The $[GeH_3]^-$ ion, extensively used in the synthesis of derivatives, may also be prepared in hexamethylphosphoric triamine (HMPT) solution or from GeH_4 and NaOH in monoglyme. Some structural information is available on these alkali metal derivatives: X-ray diffraction analysis shows that $KGeH_3$ and $RbGeH_3$ have the NaCl-type structure, implying free rotation of GeH_3^-. $CsGeH_3$ has the rare T1I structure. Similar reactions using Ge_2H_6 provide evidence for $[Ge_2H_4]^{2-}$.

$$GeH_4 + 2Na \longrightarrow Na_2GeH_2 + H_2 \quad (4)$$

$$Na_2GeH_2 + GeH_4 \longrightarrow 2NaGeH_3 \quad (5)$$

$$Na_2GeH_2 + NH_3 \longrightarrow NaGeH_3 + NaNH_2 \quad (6)$$

4.1 Hydrido Halides

The germanium hydrohalides GeH_xX_{4-x} (X = Cl, Br, I; $x = 1, 2, 3$) are colorless, volatile, reactive liquids. Preparative routes include reactions of Ge, GeX_2, or GeH_4 with HX (equations 7–11). The compounds are valuable synthetic intermediates; they readily undergo halide exchange and provide a convenient route to a range of pseudohalide derivatives (CN, CNO, SCN), for example, GeH_3Br with $Pb(OAc)_2$ and $Pb(NCS)_2$ gives $GeH_3(OAc)$ and $GeH_3(SCN)$ respectively.

Oxidation of GeS by HCl gives $GeHCl_3$, which can slowly decompose to $GeCl_4$, $GeCl_2$, and H_2 in alcohol, and can be oxidized into the white $GeOCl_2$ in the air. GeH_3Br and GeH_2Br_2 are most readily prepared from GeH_4 and Br_2, whereas the thermally unstable $GeHBr_3$, mp – 24 °C, has been obtained from Ge and HBr. $GeHI_3$, formed from GeI_2 and HI, evidently exists only in HI solution.

$$GeH_4 + SnCl_4 \longrightarrow GeH_3Cl \quad (7)$$

$$GeH_4 + HCl/AlCl_3 \longrightarrow GeH_2Cl_2 \quad (8)$$

$$GeH_4 + I_2 \longrightarrow GeH_3I + GeH_2I_2 \quad (9)$$

$$Ge + HCl \xrightarrow[500\,°C]{N_2} GeHCl_3 \quad (10)$$

$$GeCl_2 + HCl \longrightarrow GeHCl_3 \quad (11)$$

Digermane likewise may be halogenated to yield unstable H_3GeGeH_2X compounds, and even Ge_3H_8 has been converted into an unstable monoiodide.

5 BORON DERIVATIVES

Germylpotassium and diborane form the Ge–B bonded anion $[H_3GeBH_3]K$. Several Ge^{II}–carborane complexes have been described for the +2 oxidation state of Ge (equations 12 and 13). In this compound (equation 12), Ge^{II} occupies a vertex of the icosahedron, being bonded to three B and two C atoms. It is a stable, colorless sublimable solid that reacts with MeOH to give the $[B_9C_2H_{12}]^-$ ion.[12]

$$[1,2\text{-}B_9C_2H_{11}]^{2-} + GeCl_2 \longrightarrow \textit{closo}\text{-}Ge(BH)_9(CH)_2 \quad (12)$$

Using a Me_3Si-substituted carborane anion with Ge^{II} (equation 13) or Ge^{IV} chlorides gives germacarboranes. In the Ge^{IV} derivative *closo*-$[(Me_3SiC)_2(BH)_4]_2Ge$, germanium is 10-coordinate.

$$Li[(Me_3SiC)_2B_4H_5] + GeCl_2 \longrightarrow \textit{closo}\text{-}[(Me_3SiC)_2(BH)_4Ge] \quad (13)$$

Anhydrous $GeCl_4$ reacting with the *closo*-stannacarboranes 1-Sn-2-$(SiMe_3)$-3-(R)-2,3-$C_2B_4H_4$ (R = $SiMe_3$, Me, and H) in the absence of solvents gives the corresponding germacarboranes 1-Ge-2-$(SiMe_3)$-3-(R)-5-$(GeCl_3)$-2,3-$C_2B_4H_4$ (R = $SiMe_3$, Me, and H) respectively.[13]

6 NITROGEN COMPOUNDS

6.1 Nitrides

Ge_3N_2 is a brown/black solid, bp 650 °C; it decomposes to Ge and N_2 at 850 °C. Ge_3N_2 is prepared by heating the yellow imide $[GeNH]_n$ to 300 °C, which is formed from dissolving GeI_2 in liquid NH_3 (equation 14).

$$GeI_2 + \text{liq. } NH_3 \longrightarrow [GeNH]_n \longrightarrow Ge_3N_2 \quad (14)$$

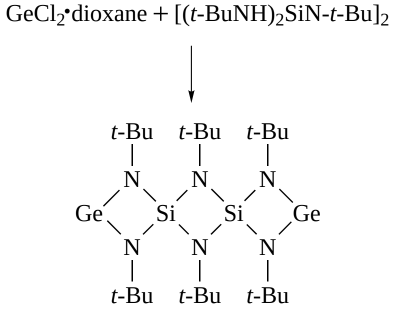
Ge^{IV} nitride, Ge_3N_4, is formed as a black solid from Ge and ammonia at 650 °C, or by heating the imide $[Ge(NH)_2]_n$ at 400 °C. It exists in two forms, both of which have a phenacite-type structure. It decomposes to the elements at 900 °C. Ge_3N_4 is stable to air and insoluble in HCl, HNO_3, H_2SO_4, and NaOH aqueous. At 700 °C, reaction of Ge_3N_4 with H_2 results in Ge and NH_3.

6.2 Amides and Azide of Ge^{II}

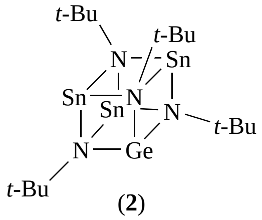
6.2.1 *Two-coordinate Compounds*

Two-coordinate Ge^{II} amides, $Ge(NR_2)_2$, have been obtained in cases where the ligand is very bulky. Many have sharp melting points and can be distilled or sublimed

in vacuum; they remain monomeric both in solution and in the solid state. Typically, the N–Ge–N angle is 111° in the solid state and 101° as a gas. Examples include $Ge[(N(t\text{-}Bu)_2)]_2$, $Ge[N(SiMe_3)_2]_2$, $Ge[N(C_6H_2Me_3\text{-}2,4,6)_2]_2$, and $\overline{GeNC(Me)_2(CH_2)_3C(Me)_2N}$, formed from $GeCl_2$·dioxane and the lithio derivative of the amine.[14] More complex examples, also with two-coordinate Ge, are illustrated in structures (**1**) and (**2**).[16]



(**1**)



(**2**)

Reaction of $Ge[N(SiMe_3)_2]_2$ with bulky primary amines RNH_2 ($R = C_6H_3\text{-}i\text{-}Pr_2\text{-}2,6$) results in the formation of a cyclic trimer $[GeNR]_3$ with a planar Ge_3N_3 ring and a stereochemically active lone pair on each Ge. The Ge–N bond length of 186 pm is close to the value (189 pm) for $Ge[N(SiMe_3)_2]_2$. Using $GeCl_2$(dioxane) and RNH_2 ($R = C_6H_2\text{-}t\text{-}Bu_3\text{-}2,4,6$) has yielded $Ge(NHR)_2$, RNHGeN(R)GeNHR, and $(GeNR)_2$.[17]

Monomeric mixed O- and N-bonded Ge^{II} compounds with sterically hindered ligands have been obtained, for example, *t*-$BuOGeNR_2$ (R = 2,2,6,6-tetramethylpiperidino). Other types of Ge^{II}–N compounds include $Ge(NCO)_2$ and $Ge(NCS)_2$, readily formed from $GeCl_2$·dioxane and the cyanate or thiocyanate anions.

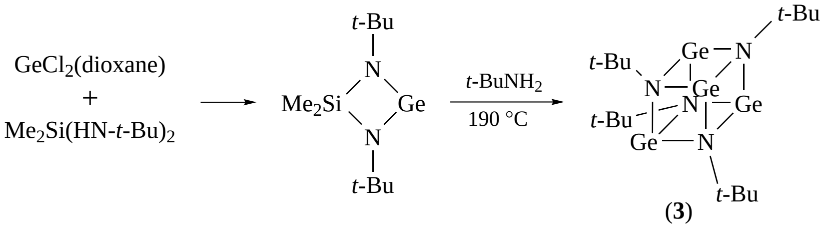
6.2.2 *Three-coordinate Compounds*

Ge^{II} amides containing Ge bonded to three nitrogen donors, such as $[CyNC(Me)NCy]_2Ge$,[18] $[CyNC(^tBu)NCy]_2Ge$, $[CyNC(Me)NCy]Ge[N(SiMe_3)_2]$,[18] $[CyNC(^tBu)NCy]_2Ge[N(SiMe_3)_2]$ (Cy = cyclohexyl),[18] $[Me_3SiNC(^tBu)NSiMe_3]Ge$ $[N(SiMe_3)_2]$,[19] and $[MeSi(N^tBu)_3]Ge_2[N(SiMe_3)_2]$[20] have been prepared by the reaction of $GeCl_2$·dioxane with the lithio derivative of the amine. These compounds possess similar geometries based on distorted tetrahedra in which one of the vertices is occupied by a stereochemically active lone pair of electrons. Ge^{II} azides, $(NRN)GeN_3$, have been isolated from (NRN)GeCl treated with NaN_3.[21,22] Monomeric mixed C- and N-bonded Ge^{II} compounds have been obtained, for example, $[Ge(2\text{-}\{(Me_3Si)_2C\}\text{-}C_5H_4N)\{CH(PPh_2)_2\}]$,[23] $[Ge(2\text{-}\{(Me_3Si)_2C\}\text{-}C_5H_4N)Cl]$,[23] and $py\cdot Ge(Cl)C_6H_3\text{-}2,6\text{-}Trip_2$ (py = pyridine, Trip = $C_6H_2\text{-}2,4,6\text{-}i\text{-}Pr_3$).[24]

The cubane-like Ge^{II} compound $[GeN\text{-}t\text{-}Bu]_4$ (**3**) has been obtained as a crystalline sublimable solid by the reaction shown in Scheme 1.[15,16,25] The related cage structure of $Ge_3(N\text{-}t\text{-}Bu)_2(HN\text{-}t\text{-}Bu)_2$ consists of a Ge–N cube with one corner vacant; this ‘open’ polycycle can be protonated by HCl to form $[Ge_3(N\text{-}t\text{-}Bu)(HN\text{-}t\text{-}Bu)_3]Cl$, in which Cl effectively occupies the vacant corner, interacting with the protons on three N atoms of the cube.

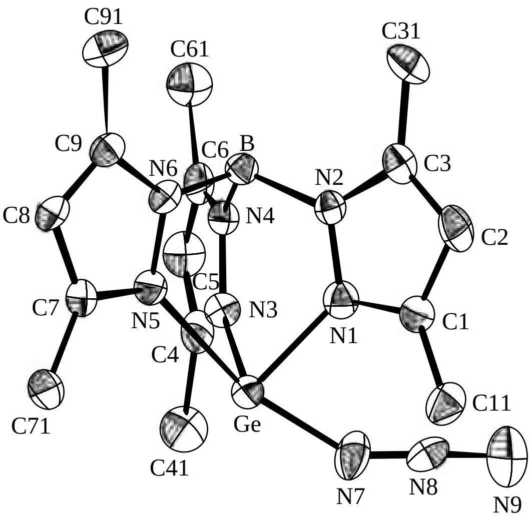
6.2.3 *Four-coordinate Compounds*

Ge^{II} compounds containing Ge in four coordination, such as $(CyNC(R)NCy)_2GeCh$ (R = Me, ^tBu; Ch = S, Se; Cy = cyclohexyl)[18] have been prepared by the reaction of $(CyNC(R)NCy)_2Ge$ with Se or styrene sulfide. Ge^{II} azide, $TpAGeN_3$ [TpA=hydrotris(3,5-dimethylpyrazol-1-yl)borato] (**4**),[26] synthesized from TpAGeCl and NaN_3, is a white, slightly air-sensitive solid, which is soluble in CH_2Cl_2, moderately soluble in THF, and insoluble in pentane. The mixed C- and N-bonded Ge^{II} compound, GeR_2 [$R = CPh(SiMe_3)(C_5H_4N\text{-}2)$],[27] has been synthesized by the reaction of two equivalents of the appropriate



(**3**)

Scheme 1



(**4**)

(Ref. 26. Reproduced by permission of The Royal Society of Chemistry)

lithium reagents LiR(tmen) (tmen = $Me_2NCH_2CH_2NMe_2$) with $GeCl_2$(dioxane) in diethyl ether solution. Crystal-structure analysis has shown that compound GeR_2 is monomeric with the *N*-functionalized alkyl ligands R bonded to the metal center in a C,N-chelate fashion, and the geometry around Ge is pyramidal, consistent with a stereoactive lone pair at the metal.

The reaction of two equivalents of $[MeC(N\textit{i}Pr)_2]Li{\cdot}THF$ with $GeCl_2{\cdot}$dioxane affords $[MeC(N\textit{i}Pr)_2]_2Ge$.[28] In the monomeric molecule, the germanium atom is surrounded by four nitrogen atoms originating from two amidinate ligands, each spanning an axial and an equatorial site of a heavily distorted ψ-trigonal bipyramid, with the 'lone pair' of germanium(II) occupying the third equatorial position.

6.3 Amides and Imines of Ge^{IV}

Trigermylamine, $(H_3Ge)_3N$, prepared from H_3GeCl and NH_3, is extremely unstable. It has a planar (D_{3h}) structure in the vapor phase like the Si analog. The lowest IP in its photoelectron spectrum is due to the lone pair electrons of nitrogen, and the order of IPs in the series Me_3N, $(H_3Si)_3N$, $(H_3Ge)_3N$ is consistent with the idea that the lone pair electrons interact with empty d orbitals of Si or Ge.

Ge^{IV} amides, $Ge(NR_2)_4$, are obtained by standard procedures (equation 15); they are thermally stable and readily hydrolyzed. $GeCl_4$ and primary amines or ammonia yield white, involatile polymeric products. A polymeric imide, $Ge(NH)_2(NH_3)_n$, appears to be the final product of the reaction between $NaGeH_3$ and liquid ammonia.

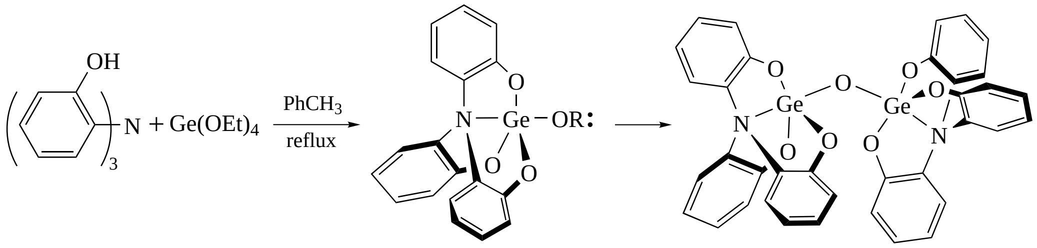
$$GeCl_4 + R_2NH \longrightarrow Ge(NR_2)_4 \qquad (15)$$

The monomeric mixed O- and N-bonded Ge^{IV} compound, [GeCl(bipy)(Hcit)] (bipy = 2,2′-bipyridine, H_4cit = citric acid),[29] has been prepared by the reaction of $[GeCl_4(bipy)]$ with H_4cit in acetonitrile solution. In this compound, the Ge center possesses an octahedral geometry coordinated with two nitrogen donors of a bipy group, three oxygen atoms of Hcit group, and one chlorine atom.

The dimeric mixed O- and N-bonded Ge^{IV} compound, 1,1′-oxybis(1-germa-5-aza- 2,8,9-trioxatribenzobicyclo[3.3.3]undeca-3,6,10-triene) (**5**)[30] has been synthesized by the reaction of tris(2-hydroxyphenyl)amine with $Ge(OEt)_4$. This reaction proceeds via 1-ethoxy-1-germa-5-aza-2,8,9-trioxatribenzobicyclo[3.3.3]undeca-3,6,10-triene (Scheme 2). In the oxo-bridged germatrane dimer, the Ge–O–Ge moiety is bent at an angle of 131.2(4)°, and Ge–O bridge distances are 175.0(7) and 174.3(6) pm. The other Ge–O distances, by comparison, average 178.5(7) pm. The germanium centers in the germatrane dimer are nearly trigonal bipyramidal by virtue of significant interaction with transannular nitrogen. The Ge–N distances are 223.5(8) and 224.7(7) pm.

Reaction of $[MeC(N\textit{i}Pr)_2]Li{\cdot}THF$ with $GeCl_4$ results in the formation of $[MeC(N\textit{i}Pr)_2]_2GeCl_2$.[28] Four nitrogen atoms originating from two amidinate ligands, each spanning an axial and an equatorial site of a distorted octahedron, with two chlorine atoms occupying other equatorial positions, surround the germanium center in the compound.

Monomeric germaimines have recently been prepared (equation 16), in which R is a bulky substituent such as C_6H_3-*i*-Pr_2-2, 6. The measured Ge=N bond length of 170.3 pm is



(**5**)

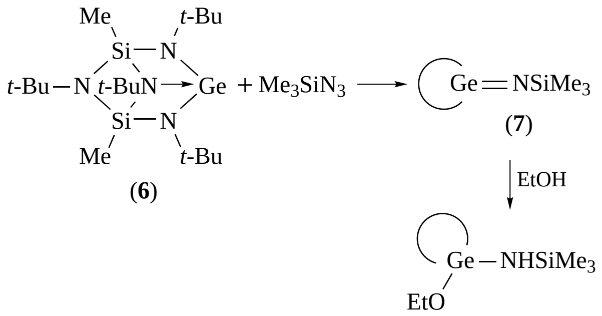
Scheme 2

close to the value predicted for the hypothetical compound $H_2Ge{=}NH$ of 169.5 pm.[31]

$$[R(Me_3Si)N]_2Ge + RN_3 \longrightarrow [R(Me_3Si)N]_2Ge{=}NR + N_2 \quad (16)$$

Similarly, the Ge^{II} complex (**6**) has been converted to the base-stabilized imine (**7**) that readily undergoes addition reactions, for example, with EtOH (Scheme 3).[32]

Porphyrin complexes, (porph)Ge and (porph)$GeCl_2$, are known for the +2 and +4 oxidation states. Reaction of phthalocyanine with $GeCl_4$ in quinoline gives the highly stable complex (phthalo)$GeCl_2$ in which the two Cl atoms are necessarily trans. It sublimes without decomposition at 450 °C. Recently, the crystal structure of bis(acetato)(*meso*-tetraphenylporphyrinato)germanium(IV), Ge(tpp)$(OAc)_2$[33] (**8**), has been reported. The acetate groups are unidentately coordinated to the germanium(IV) atom. Other Ge–N bonded derivatives include the azide, carbodiimide, isocyanate, and



Scheme 3

thiocyanate (equations 17–20). In H_3GeNCS, the Ge–N–C angle is 180° (C_{3v}), implying significant d–p π bonding, whereas H_3GeNCO and H_3GeN_3 are bent in the vapor phase.

$$H_3GeF + Me_3SiN_3 \longrightarrow H_3GeN_3 \quad (17)$$

$$H_3GeF + (Me_3SiN)_2C \longrightarrow H_3GeN{=}C{=}NGeH_3 \quad (18)$$

$$H_3GeBr + AgSCN \longrightarrow H_3GeNCS \quad (19)$$

$$GeCl_4 + AgCNO \longrightarrow Ge(NCO)_4 \quad (20)$$

7 PHOSPHORUS AND ARSENIC COMPOUNDS

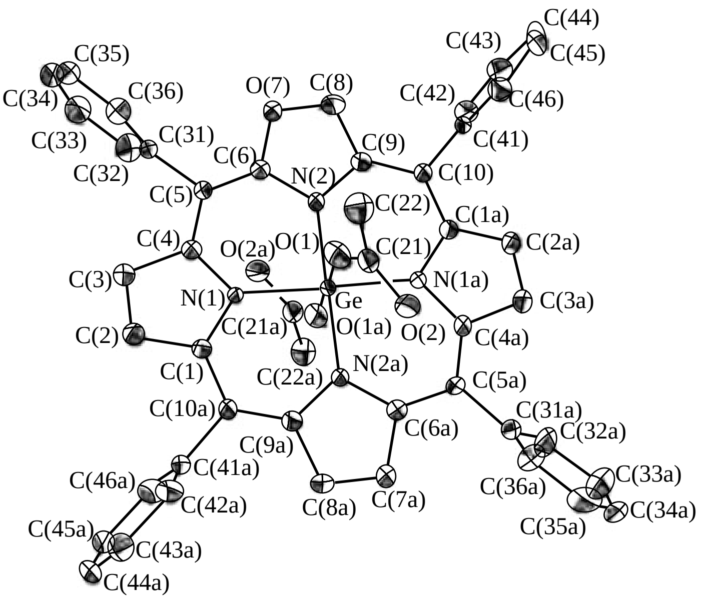
Both GeP and GeAs are semiconductors, formed from the elements at 600–1200 °C and high pressure. They become superconductors at about 4K.

$CdGeP_2$, formed from the elements at 800 °C, has a strictly ordered tetragonal chalcopyrite structure having a symmetry that is almost tetragonal. A glassy disordered structure can be obtained through rapid quenching of the molten material.

Cy(H)$PGeCl_3$, produced by the 1:1 reaction of $CyPH_2$ and $GeCl_4$, is a white solid, which appears stable in solution under an inert atmosphere but immediately turns to an oil on exposure to air.[35]

The 1:1 reaction of $GeCl_4$ with PhPH yields a solid precipitate but this turns to oil on drying in a vacuum. Microanalyses of this oil confirm the formula $C_{12}H_{11}Cl_2PGe$.

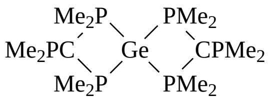
Ge^{II}- and Ge^{IV}- phosphorus compounds exhibit a variety of structures. $GeCl_2{\cdot}$dioxane reacts with $[(Me_2P)_3C]^-$ to produce a stable crystalline four-coordinate Ge^{II} compound (**9**) with a distorted tbp structure in which the Ge lone



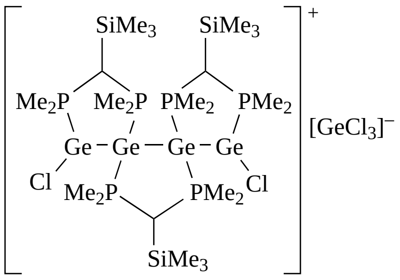
(**8**)

(Reprinted with permission from Ref. 33. © 1997 American Chemical Society)

pair occupies an equatorial position. $GeCl_4$ reacts with $[(Me_2P)_2CSiMe_3]^-$ forming an octahedral derivative, *trans*-$GeCl_2[(PMe_2)_2CSiMe_3]_2$. If the reaction is carried out in the presence of Mg, the more complex Ge–Ge bonded product (**10**) is formed.



(**9**)



(**10**)

H_3GePH_2 redistributes to $H_2Ge(PH_2)_2$, $He(PH_2)_2$, and GeH_4 above – 30 °C. Mono- and trisgermylphosphines have been obtained through the reactions, such as equations (21) and (22).

$$LiAl(PH_2)_4 + H_2GeBr \longrightarrow H_3GePH_2 \qquad (21)$$

$$H_3GeX + (H_3Si)_3P \longrightarrow (H_3Ge)_3P \qquad (22)$$

The unusual layered compounds $K_8In_8Ge_5As_{17}$ and $K_5In_5Ge_5As_{14}$,[34] are formed from the elements at high temperature. Both contain In–Ge–As layers with interleaved potassium ions, Ge–Ge bonds, $InAs_4$ tetrahedra, As–As bonds, and rows of Ge_2As_6 dimers.

8 OXYGEN-BONDED COMPOUNDS

8.1 Oxides

Germanium(II) oxide was formed by reducing GeO_2 with H_3PO_2 in HCl solution. The immediate product, $Ge(OH)_2$, dehydrates on heating and GeO may be sublimed above 700 °C. In addition, reaction of Ge with CO_2 at 700 °C and heating Ge or GeO_2 at 800 °C also could gain GeO. In the gas phase or as a matrix in Ar, $\nu_o(^{74}Ge–O) = 977.4\,cm^{-1}$.

GeO is variously described as a yellow or dark brown solid. It may be sublimed or disproportionated to Ge and GeO_2 above 700 °C, and is stable to air and water at room temperature. It is unaffected by HCl, H_2SO_4, and $NaOH/H_2O$. Oxidation in air to GeO_2 is rapid at 550 °C; HCl at 175 °C gives $HGeCl_3$, and Cl_2 and Br_2 oxidize it to GeO_2 and GeX_4.

The germanium(IV) oxide was obtained by the hydrolysis of $GeCl_4$. It exists in hexagonal, tetragonal, and vitreous forms. Of these, the hexagonal form has a β-quartz structure with four-coordinate Ge, and it is commercially available. It dissolves in HF and is moderately soluble in hot water. It reacts with BrF_3, forming GeF_4. The tetragonal form is obtained through evaporating an aqueous solution of GeO_2 followed by heating at about 380 °C. It is slightly dissolved in water, unaffected by aqueous HCl or HF, but dissolves in 5M NaOH at 100 °C. The tetragonal form has a rutile-type structure (six-coordinate Ge). Vitreous GeO_2, which resembles fused silica, is formed when the fused dioxide solidifies. GeO_2 is less acidic than SiO_2.

8.2 Anionic Oxides

The known chemistry of germanates is much less extensive than that of silicates. Although there are many similarities, some differences exist because Ge more readily accepts higher coordination numbers. A wide range of anionic Ge^{IV} oxides are known. Examples include $[GeO_3]^{2-}$, $[GeO_4]^{4-}$, $[Ge_2O_7]^{6-}$, $[Ge_3O_{10}]^{8-}$, $[Ge_5O_{11}]^{2-}$, $[Ge_5O_{12}]^{4-}$, $[Ge_6O_{18}]^{12-}$, $[Ge_8O_{17}]^{2-}$, and $[Ge_9O_{20}]^{4-}$.[36–38]

Preparative methods include precipitation of the anion from aqueous solutions of GeO_2 at defined pH values and fusion techniques. For example, $Li_4Ge_5O_{12}$ is obtained from a melt of GeO_2 and Li_2O. When heating CsO, Li_2O, and GeO_2 at 600 °C, $Cs_2Li_2Ge_4O_{10}$ can be yielded. In aqueous solution, with pH ranging from 6.9–9.4, the dominant species is evidently $[Ge_5O_{11}]^{2-}$. Oxygermanate $K_2Ge_2O_3$ in addition to $K_6Ge_2O_7$ will form from the reaction of KGe and oxygen at 400 °C.

Varieties of germanium containing zeolite structures are known. Typical structures with framework compositions include feldspar, paracelsian, sodalite, analcime, natrolite, cancrinite, DAF-2(DFT), gismondine, and faujasite. $BaGaGe_2O_8$ and $NaAlGe_3O_8$ are well-established Ge analogs with feldspar structures. $SrGa_2Ge_2O_8$ and $BaGa_2Ge_2O_8$ own the paracelsian framework.[56] $AlGeO_4$, $BeGeO_4$, $GaGe_5O_{12}$, and $GaGe_2O_6$ are germanate sodalites with framework compositions.

GeO_4 tetrahedra, GeO_6 octahedra, and GeO_5 trigonal bipyramids are the common coordination forms that Ge atoms adopt in these oxyanions. In $K_6Ge_2O_7$, the Ge atoms are tetrahedrally coordinated with a common apex, the Ge–O–Ge angle being 157°, whereas in $[Ge_9O_{20}]^{4-}$ and $[Ge_5O_{12}]^{4-}$, four and three of the Ge atoms are octahedrally coordinated respectively. The metagermanate $BaTiGe_3O_9$ has cyclic Ge_3O_9 units and infinite GeO_3 chains, whereas in $Pb_4Ge_4O_9$, both tetrahedrally and octahedrally coordinated Ge atoms exist. In $K_2Ba[Ge_4O_9]$, the anions consist of rings built up from GeO_4 tetrahedra linked to GeO_6 octahedra in

a three-dimensional network. Two forms of $BaGeO_3$ have been characterized: an α-form with a pseudo-wollastonite hexagonal ring structure and a β-form consisting of infinite chains of GeO_4 tetrahedra. In the mixed oxide, $Na[AlGeO_4]$, Al and Ge are randomly distributed on octahedral sites. In $K_2Ge_8O_{17}$, six of the Ge atoms are in GeO_4 tetrahedra but two are five-coordinate, as silicon seldom is under normal conditions.

Reaction of GeO_2 with $[Me_4N][OH]$ in H_2O at 180 °C yields a microporous germanate. The asymmetric unit contains $[Ge_6O_{12},Me_4NOH]$ and the three-dimensional framework is composed of GeO_4 tetrahedra and GeO_5 tbp's that form four-, six-, and eight-membered ring channels along the c-axis with the cation located in the six-membered ring channel.[39]

These kinds of microporous materials have been consecutively synthesized, mainly under hydrothermal conditions. Table 6 gives some materials synthesized in the recent years. The basic framework units involving Ge are also exhibited.

8.3 Hydroxides

$Ge(OH)_2$ is a yellow solid. When GeO_2 is reduced by H_3PO_2 in HCl solution, the immediate product, $Ge(OH)_2$, is formed after raising the pH value by the addition of NH_3. It readily dehydrates and is oxidized in a strong alkaline solution. Its IR spectrum provides evidence for the species.[55]

Evidence for $Ge(OH)_4$ is scant: ^{73}Ge NMR resonance of GeO_2 in neutral D_2O solution has been assigned to the $Ge(OD)_4$ molecule, whereas in the presence of a base (Et_3N), the signal corresponds to $[Ge(OD)_6]^{2-}$. In dilute aqueous solution, the main germanate ions have been identified as $[GeO(OH)_3]^-$, $[GeO_2(OH)]^{2-}$, and $\{[Ge(OH)_4]_8(OH)_3\}^{3-}$. The crystalline mineral stoettite contains the anion $[Ge(OH)_6]^{2-}$.

$GeO(OH)_2$ is planar and electronically analogous to H_2CO_3. It is not possible to determine which species is obtained; coexistence of the both hydroxides must be considered (equations 23 and 24).[55]

$$GeO_2 + H_2O \longrightarrow GeO(OH)_2 \quad (23)$$

$$GeO(OH)_2 + H_2O \longrightarrow Ge(OH)_4 \quad (24)$$

(phthalocyanine)$Ge(OH)_2$, obtained by the hydrolysis of (phthalocyanine)$GeCl_2$, is very stable. When heated under vacuum at 440 °C, it forms a Ge–O bridged polymer.

8.4 Alkoxides and Esters

8.4.1 *Compound of Ge (II)*

Ge^{II} dialkoxides, $Ge(OR)_2$, are polymeric if the R groups are small. $Ge(O\text{-}t\text{-}Bu)_2$ is a cyclic dimmer. When R groups are even bulkier, monomeric compounds, which can usually be sublimed in vacuum, will result readily, examples include R = C-t-Bu_3 and C_6H_2-t-Bu_3-2,4,6. They are usually made from $GeCl_2$·dioxane,[14] or by exchange reactions (equation 25).[57]

$$Ge[N(SiMe_3)_2] + t\text{-}Bu_3COH \longrightarrow Ge[OC\text{-}t\text{-}Bu_3]_2 \quad (25)$$

Table 6 Information about the materials with framework structure

Molecular formula	Structure feature	Reference
$GaGe_3O_8$	I-centered cubic	40
$GaGe_5O_{12}$	The first germanate with five rings	40
$Ga_2Ge_4O_{12}$	GeO_4	40
$NH_4GaGe_2O_6$	Analcime-like structure	40
$CsGaGe_2O_6$	Analcime-like structure	40
$(CH_3NH_3)2Ga_2Ge_3O_{10}$	The first germanate with ternary Ga rings	41
$(NH_4)_2Ge_7O_{15}$	GeO_4 and GeO_6	42
$(NH_4)^+$ $[M(NH_3)_2]^+$ $(Ge_9O_{19})^{2-}$ (M = Cu, Ag)	The first microporous germanates containing a transition metal complex in the channels	43
$(NH_4)(CH_3NH_3)(Ge_9O_{19})$	Eight GeO_4 and one GeO_6	44
$K_2ZrGe_2O_7$	GeO_4 and ZrO_6	45
$[Ge_9O_{18}(OH)_4]\cdot 2H_2ppz\cdot 0.5H_2O$	GeO_4 and GeO_6	46
$[Ge_9O_{18}(OH)_4]\cdot 2(NH_3CH_2CH_2CH_2NH_3)\cdot H_2O$	GeO_4 and GeO_6	47
$[Ge_9O_{17}(OH)_4][N(CH_2CH_2NH_3)_3]_{2/3}$ $[HCON(CH_3)_2]_{1/6}(H_2O)_{11/3}$	GeO_5	48
$Ge_8O_{16}[(OH)^-$ $(MeNH_3)^+$ $(MeNH_2)]$	GeO_4	49
$Ge_{10}O_{21}(OH)\cdot N_4C_6H_{21}$	GeO_4, $GeO_3(OH)$, GeO_5, and GeO_6	50
$Cu_2Fe_2Ge_4O_{13}$	GeO_4	51

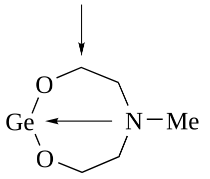
$Zr_3Ge_6O_{18}(OH_2F)_4F_2\cdot[H_2DAH]\cdot[HDAH]_2H_2O$	GeO_4	52
$ZrGe_3O_9\cdot H_2DAP$	GeO_4	52
$ZrGe_3O_9\cdot H_2DAE$	GeO_4	52
$K_2ZrGe_3O_9\cdot H_2O$	GeO_4	52
$(C_2H_{10}N_2)H_2O[ZrGe_3O_9]$	GeO_4	53
$In_2Ge_6O_{15}(en)_2$	GeO_4	54

Stable monomeric complexes can also be obtained without the presence of bulky ligands. Intramolecular donation of electrons into the empty valency orbital of Ge^{II} from nitrogen renders them stability,[58] as seen in (**11**), which is stable to dry oxygen, but readily hydrolyzes. The same phenomenon occurs in the acetylacetonato complex of Ge(II) and Ge(acac)I, in which germanium is three-coordinate with a stereochemically active lone pair.

$$Ge(OEt)_2{\cdot}nEtOH + MeN(CH_2CH_2OH)_2 \longrightarrow$$



(**11**)

In these monomeric compounds, the O–Ge–O angle is close to 90°, compared to 110° in the analogous N–Ge–N compounds.

8.4.2 Compounds of Ge (IV)

Germanium alkoxides are widely used in sol-gel processes for the preparation of Ge-containing glasses[59] and important materials such as GeS_2,[60] and in vapor chemical processes for deposition of GeO_2 and organogermanium films.[61] The search for synthetic pathways of germanates that can be used as frameworks of new porous materials[62] also provides a timely motivation for exploring the reactivity of germanium alkoxides.

Ge^{IV} tetraalkoxides and alkoxyhalides are colorless liquids that are thermally stable but readily hydrolyzed. Partial hydrolysis has yielded alkoxygermoxanes (equation 26). The simplest Ge^{IV} tetraalkoxide, methoxygermane, is unstable even at – 23 °C.

$$Ge(O\text{-}i\text{-}Pr)_4 + H_2O \longrightarrow [(i\text{-}PrO)_3Ge]_2O + [Ge_2O_3(O\text{-}i\text{-}Pr)_2]_n \quad (26)$$

Ge^{IV} tetraalkoxides can be produced through the complete alcoholysis of Ge halides in the presence of a base. Partial substitution yields many Ge^{IV} alkoxy derivatives (alkyl orthogermanates) (equations 27 and 28).

$$H_3GeCl + NaOMe \longrightarrow H_3GeOMe \quad (27)$$

$$GeCl_4 + nROH[NaOR \text{ or pyridine}] \longrightarrow (RO)_nGeCl_{4-n} \quad (28)$$

The exchange between different Ge^{IV} tetraalkoxides can be easily obtained through alkoxide exchange. $AlCl_3$-catalyzed reactions and cleavage of cyclic ethers can also produce alkoxyhalegermanes (equations 29 and 30).

$$GeCl_4 + nROH \xrightarrow{AlCl_3} (RO)_3GeCl + (RO)_2GeCl_2 + ROGeCl_3 \quad (29)$$

$$GeCl_4 + MeCHCH_2O \longrightarrow (MeCHCl_2H_2O)_nGeCl_{4-n} \quad (30)$$

A digermoxane compound, $(GeH_3)_2O$ with the Ge–O–Ge angle of 126.5°, can be prepared by hydrolysis of GeH_3Cl or from the reaction of $(H_3Ge)_2S$ with HgO. Compared to the predicted value of 182.7 pm, the shorter distance of Ge–O, 176.6 pm, is attributed to some degree of p–d π bonding.

Reaction of GeH_3Cl with $Pb(OAc)_2$ yields H_3GeOAc. $Ge(OCOCF_3)_4$ is prepared from $GeCl_4$ and $Hg(OCOCF_3)_2$. $Ge(OAc)_4$, with the unidentate acetato group, is formed from $GeCl_4$ and TlOAc or Ac_2O.

Esters of various oxyacids have been isolated: the anhydrous sulfate (equation 31), formed at 160 °C, is unstable.

$$GeCl_4 + 6SO_3 \longrightarrow Ge(SO_4)_2 + 2S_2O_5Cl_2 \quad (31)$$

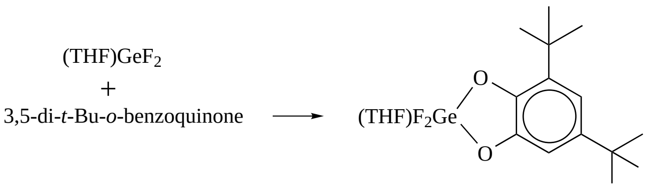
White crystalline phosphite, GeOP(O)OH, is formed from the reduction of GeO_2 with hypophosphorous acid.

Reaction of $GeCl_4$ with Cl_2O_6 produces four-coordinate complexes such as $Cl_3GeOClO_3$ and $Cl_2Ge(OClO_3)_2$. With excess Cl_2O_6, the octahedral complex $2[ClO_2]^+$ $[Ge(OClO_3)_6]^{2-}$ is formed.[63]

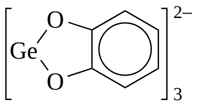
8.5 Chelate Complexes of Ge^{IV}

Chelating ligands frequently yield five- or six-coordinate complexes. For example, the octahedral anion (**12**) is obtained through the reaction of GeO_2 with catechol in NaOMe/MeOH, whereas in the presence of pyridine, the neutral six-coordinate complex $[C_6H_4O_2]_2Ge(py)_2$ is formed. Square pyramidal anionic Ge^{IV} complexes, such as (**13**), have been characterized.

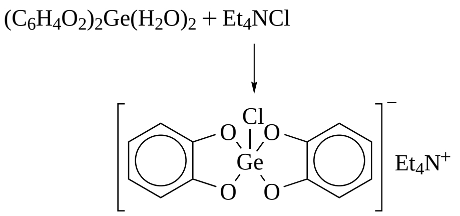
A F,O-bonded Ge^{IV} complex is obtained when GeF_2 is oxidized by reaction with quinines (equation 32).



(32)



(**12**)



(**13**)

The reaction of GeO_2 with oxalic acid evidently gives $H_2[Ge(C_2O_4)_3]$. The enantiomers of the tris-oxalato complex $K_2Ge(C_2O_4)_3 \cdot H_2O$ have been separated. The *cis*-octahedral complex $(acac)_2GeCl_2$, with a dipole moment of 7.4 D, is formed from the combination of acetylacetone and $GeCl_4$. The absolute configuration of the corresponding cationic complex, $[Ge(acac)_3]^+ [ClO_4]^-$, has been determined. In the EDTA complex of Ge^{IV}, the ligand is pentadentate, with H_2O occupying the sixth coordination site.

Subvalent germanium complexes combined with a dianionic calixarene ligand have been found. The reaction of *p-tert*-butylcalix[4] arene with Me_3SiI in the presence of pyridine provides a useful synthetic route for $[Butcalix^{(TMS)2}]H_2$.

The divalent Ge complex $[Butcalix^{(TMS)2}]Ge$ (**14**) can be readily obtained by the reaction of $[Butcalix^{(TMS)2}]H_2$ with $M[Ge(SiMe_3)_2]_2$, as illustrated in Scheme 4.[64]

9 SULFIDES, SELENIDES, AND TELLURIDES

9.1 Preparation and Properties of Simple Compounds

GeS can be made through reduction of GeS_2 using H_2 or H_3PO_2. The GeS single crystal is orthorhombic with a = 429 pm, b = 1042 pm, c = 364 pm, and space group, Pnma-D^{16}_{2h}, in which each Ge atom is surrounded by six S atoms exhibiting octahedral configuration. It has a layer structure similar to the isoelectronic black phosphorus.[65] It is a red–brown solid and sublimes in vacuum at 600 °C. It is readily hydrolyzed, and is oxidized in air at 350 °C to GeO_2. HCl at 175 °C converts it into $HGeCl_3$ and H_2S.

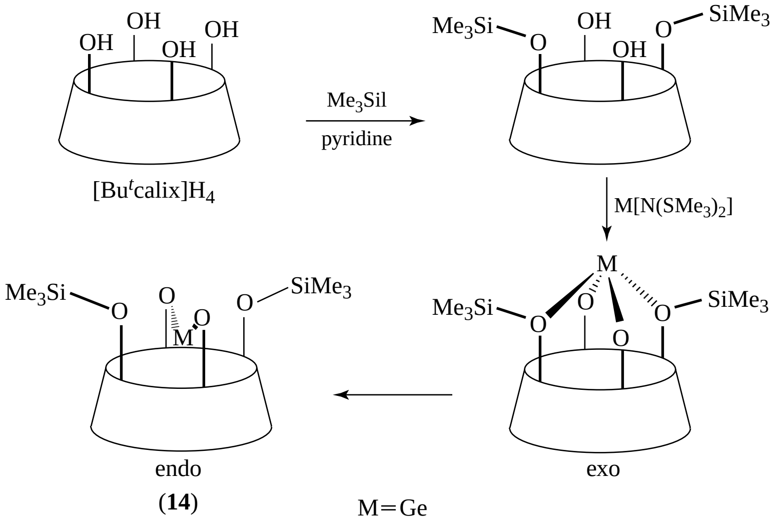
GeS_2 is formed from GeO_2, H_2SO_4, and H_2S. GeO_2, is orthorhombic with a = 1166 pm, b = 2234 pm, c = 686 pm, and Z = 16. It has an unusual structure with Ge_3S_3 rings that transform into a crystobalite structure at high pressure.

GeSe can be prepared by two methods. One is the direct combination of the elements Ge and Se in CO_2 atmosphere at 500 °C, and the other is the reaction of H_2Se with $GeCl_2$. It is a brown solid and is readily oxidized in air, having the same structure with GeS.[65] The GeSe crystal is tetragonal with a = 883 pm, c = 976 pm, Z = 16. Its melting point is about 667 °C. It is unaffected by 5% HCl solution, alcohol, or ether, but dissolves in HCl solution containing bromine. It can be oxidized by nitric acid to GeO_2 and H_2SeO_3.

$GeSe_2$, formed from GeO_2/H_2SO_4 and H_2Se, is orthorhombic with a = 1296 pm, b = 693 pm, c = 2209 pm, Z = 24, $D^{25} = 4.56\,g\,cm^{-3}$, mp. = 707 °C. It is a white crystalline solid. It is unaffected by HCl and H_2SO_4 solution but is oxidized to Se by H_2O_2 in alkaline solution.

GeTe, mp. = 725 °C, can react with dense HCl solution, H_2SO_4 solution, and water when it is heated, while the mixture of royal water, H_2O_2, and HCl solution can erode it without heating.

In recent years, germanium sulfides have been prepared for glass films that are widely applied in many fields.



Scheme 4 (Ref. 64. Reproduced by permission of The Royal Society of Chemistry)

9.2 Structures of the Germanium Anions

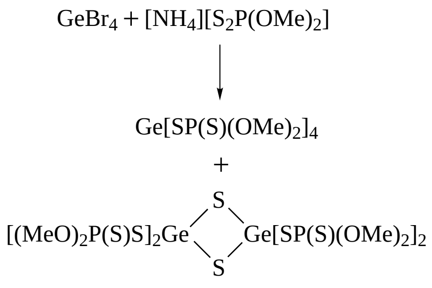
Considerable structural variations have been found in germanium sulfide anions obtained, which is obviously indicated in the reaction of GeS_2 with Na_2S. In Na_2GeS_3, the $[GeS_3]^{2-}$ ions form infinite chains of tetrahedra, whereas in $Eu_3[Ge_3S_9]^{6-}$, the anion forms a $(Ge–S)_3$ six-membered ring having a chair conformation with two exo sulfur atoms bridging each Ge and Eu. By contrast, La_2GeS_5 has a two-dimensional sheet structure. The $[GeS_4]^{4-}$ ion is tetrahedral, whereas $[Ge_2S_6]^{4-}$ consists of edge-sharing tetrahedra and the $[Ge_2S_7]^{6-}$ ion has vertex-sharing tetrahedra. The selenides are structurally similar, but by contrast $[Ge_2Te_6]^{6-}$ has a Ge–Ge bond with a staggered conformation of tellurium atoms. $[Ge_4S_{10}]^{4-}$ together with the Se and Te analogs have adamantane-like structures, that is, four GeS_4 tetrahedra sharing two vertices with adjacent tetrahedra. The telluride $[Ge_4Te_{10}]^{8-}$ has a cyclic structure, $[Te(GeTe_2)_4Te]^{8-}$.

Alkylthiogermanes have been prepared by ligand exchange (equation 33). In $(H_3Ge)_2S$, the Ge–S bond length, 220.9 pm, and Ge–S–Ge angle of 98.9° indicate negligible d–p π interaction. Treating GeH_3Cl with AgSCN gives H_3GeSCN; similar reactions lead to H_3GeSMe.

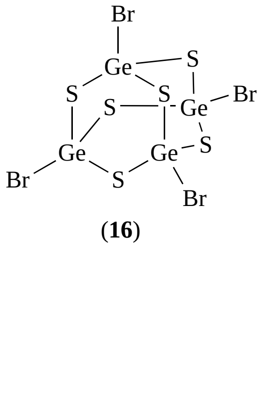
$$GeCl_4 + RSH \longrightarrow (RS)_4Ge \longleftarrow (RO)_4Ge + RSH \qquad (33)$$

Reactions involving sulfides have produced some unexpected structures, such as (**15**), in which the $S_2P(OMe)_2$ ligands are unidentate.

The reaction between $GeBr_4$ and H_2S in CS_2 gives $Ge_4S_6Br_4$ with the adamantane-like structure (**16**),[66] similar to the isoelectronic P_4O_{10}.



(**15**)



(**16**)

9.3 Terminal Multiple Bonds Between Chalcogen Elements and Ge

Recent developments in the preparation of complexes with terminal multiple bonds between chalcogen elements and Ge have yielded significant results,[18] as illustrated by the successful isolation and structural characterization of several terminal chalcogenido complexes $\{\eta^3$-[(μ-Bu^{t}N)$_2$(SiMeNBu^t)$_2$]}GeS and (Tbt)(Tip)GeE (E = S, Se) (Tbt = 2,4,6-[$(Me_3Si)_2CH]_3C_6H_2$, Tip = 2,4,6-$Pr^i_3C_6H_2$).[67]

Isolation and structural characterization of species with Ge=S, Ge=Se, and Ge=Te moieties have been realized by virtue of kinetic stabilization provided by sterically protecting groups on the Ge center (e.g. Tbt(CH$(SiMe_3)_2$)Ge=Te). Complexes [η^4-Me_8taa]Ge=E (E = S, Se, Te) (taa = tetraazaannulenes) are all structurally characterized. A series of compounds bis[(2-pyridyl)-bis(trimethylsilyl)methyl]Ge=E (E = S, Se, Te) have been reported, and meanwhile Se and Te derivatives have also been structurally characterized.[18]

Although compounds featuring a double bond between heavier main group C14–16 elements are considered to be unstable due to the weak pπ–pπ bonding, thioketone analogues comprised of group 14 and group 16 congeners such as germanethione (Ge=S) and germaneselone (Ge=Se), have been isolated in the past few years. These compounds are stabilized either by alkali or by using a sterically hindered protecting group, as in [Tip(Tbt)Ge=E] (E = S and Se).[68]

Ge amidinate complexes are susceptible to oxidation of elemental chalcogens. Many of these complexes are excellent catalysts for the cyclization of aryl isocyanates.[69]

10 HALIDES

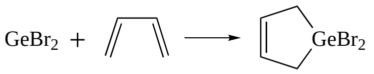
All four Ge^{II} halides are known. GeF_2, $GeCl_2$, and $GeBr_2$, formed reversibly by heating Ge with GeX_4, are polymeric in the solid state but monomeric as a gas. Electron diffraction examination of $GeBr_2$ reveals the presence of the monomer with a Br–Ge–Br angle of 101.2° and a bromine-bridged dimer. GeF_2 and $GeCl_2$ have carbene-type structures in the vapor phase with bond angles of 97.2° and 100.3°, respectively. In the solid state, GeF_2 forms spiral chains involving bridging F atoms; each Ge has a pseudo tbp geometry with an equatorial lone pair. It undergoes a phase change from orthorhombic to monoclinic at 62°C. GeI_2 is an orange solid that is grown in a vapor reaction or is best prepared by reduction of GeI_4 with aqueous H_3PO_2 in the presence of HI to prevent hydrolysis.[70,71] It is structurally similar to CdI_2, with the Ge atoms octahedrally coordinated. It can be sublimed and is stable in air; when heated it disproportionates to Ge and GeI_4.

Apart from GeI_2, the other dihalides are rapidly hydrolyzed by water. All four are readily oxidized by O_2 at an elevated temperature and by halogens. $GeCl_2$ reacts easily with Cl_2 and

Br_2 to gain $GeCl_4$ and $GeBr_4$ respectively. The reaction between $GeCl_2$ and H_2S gives GeS and HCl at room temperature. $GeCl_2$ is a strong deoxidizer in aqueous HCl solution. $GeBr_2$, mp 122°C, dissolved slightly in 5 mol L^{-1} HBr, reacts with dry HBr gas to gain $GeHBr_3$ immediately. $GeBr_2$ is liable to decompose to $GeBr_4$ and Ge at 150°C.

The dihalide solids react with donors or with butadiene to complete their octets, for example, equations (34) and (35).

$$GeI_2 + R_3P \longrightarrow R_3PGeI_2 \quad (34)$$



(35)

$GeCl_2$(dioxane) is a useful source of $GeCl_2$ and can fast and selectively react with various chloro and hydrido complexes of molybdenum and tungsten to afford trichlorogermyl and dichlorogermyl complexes respectively, $(\eta^5\text{-}C_5R_5)M(CO)_{3-n}L_n(GeCl_{3-m}H_m)$ (R = H, Me; M = Mo, W; $n = 0\text{–}2$; L = EtNC, PMe_3; $m = 0, 1$)[72–74] and $[(\eta^5\text{-}C_5R_5)M(CO)_3]_2GeX_2$ (R = H, Me; M = Mo, W; X = H, Cl).[75] During these reactions, the metal complex acts as a Lewis base and $GeCl_2$ as a Lewis acid.[76] These complexes contain two reactive sites (i.e. transition metal and the germanium center) that provide the possibility for further functionalization.

GeI_2 reacts with $Na[\{Cp'(CO)_2Mn\}_2H]$ to form an inidene type compound, $[\{Cp'(CO)_2Mn\text{-}GeI\text{-}Mn(CO)_2Cp'\}]^-$, with Ge in a trigonal planar coordination embedded between two $Cp'(CO)_2Mn$ groups and an iodo ligand.[77]

All of the tetrahalides, and most of the mixed halides (e.g. $GeClF_3$ and $GeCl_2F_2$), are known and are stable in dry air. GeF_4, bp −36.5 °C, is made by decomposing $BaGeF_6$ at 600 °C. It is thermally stable to about 1000 °C and hydrolyzes readily to GeO_2. $GeCl_4$, bp 83.1 °C, is best prepared from GeO_2 and conc. HCl, or by passing Cl_2 over Ge. It is very stable thermally but readily hydrolyzed; it is the starting material for many synthetic reactions. $GeBr_4$ has been made from Ge and Br_2, whereas the tetraiodide is most readily made from GeO_2 and aqueous HI; both are crystalline solids at room temperature. GeI_4 sublimes at 100°C.

All Ge tetrahalides are tetrahedral and monomeric. They are freely soluble in most organic solvents, and in aqueous acid solution hydrolysis is only partial, in contrast to silicon. Reaction of GeF_4 with various anhydrous chlorides at 200−600°C gives only $GeCl_4$, with no evidence for intermediate chlorofluoro compounds, but the Raman spectra of mixtures of GeX_4 compounds provide evidence for the presence of all combinations of mixed halides. GeX_4 compounds are sufficiently strong Lewis acids that can form a range of five- and six-coordinate complexes with, for example, amines. In py_2GeCl_4, the pyridines are *trans*-$GeCl_4$ and bidentate donors such as ethylenediamine and bipyridyl form 1:1 complexes. H_3P and Me_3P form 1:1 complexes with GeF_4, which evidently sublime with some dissociation at 25 °C. Oxygen donors, as in ketones, ethers, and amine oxides, form both 1:1 and 1:2 complexes with GeF_4, as do sulfides like H_2S and Me_2S. Whereas the 1:2 complexes are undoubtedly six-coordinate with the possibility of cis/trans isomers, the five-coordinate 1:1 complexes are associated so that the Ge becomes six-coordinate. ^{19}F NMR spectra of GeF_4 complexes give definitive evidence of stereochemistry and of temperature-dependent reversible dissociation of coordinated ligands. There are, however, examples of five-coordination complexes, for example, Me_3N, $GeCl_4$, and $AgClO_4$ that yield a salt $[(Me_3N)_2GeCl_3]ClO_4$ in which the cation has D_{3h} symmetry. Photochemical reaction of $W(CO)_6$ with bicyclo[2.2.1]hepta-2,5-diene and $GeCl_4$ forms a heterobimetallic complex $[W(\mu\text{-}Cl)(GeCl_3)(CO)_3(\eta^4\text{-}C_7H_8)]$. The germanium atom in the compound is five-coordinate, with one chlorine atom occupying a bridging position between the two metal atoms. This complex has been found to be an active catalyst for the ring-opening metathesis polymerization of norbornene and norbornadiene.[78] Reaction of equivalent $[MeC(N\textit{i}Pr)_2]Li\cdot THF$ and $GeCl_4$ affords $[MeC(N\textit{i}Pr)_2]_2GeCl_2$.[28]

Dropwise addition of an ice-cooled (0 °C) solution of $GeCl_4$ in toluene to a solution of 2,2′-bipyridyl in toluene gives a colorless diamond-shaped crystal $[GeCl_4(bipy)]$. $[GeCl_4(bipy)]$ further reacts with citric acid (H_4cit) in acetonitrile solution to give a colorless crystal [GeCl(bipy)(Hcit)].[29]

$[GeCl_3(L^1)]_2^+ [H_3O]^+ Cl_3^-\cdot MeCN$ (L^1 = 1,4,7-trimethyl-1,4,7-triazacyclononane), which are light yellow needles, is made by $GeCl_4$ with L^1 in acetonitrile.[79] The structure of the $[GeCl_3(L^1)]^+$ cation of $[GeCl_3(L^1)]_2^+ [H_3O]^+ Cl_3^-\cdot MeCN$ is shown in Figure 1.

Catenated germanium halides are rare, in contrast to Si. The well-characterized polygermanium Ge_2Cl_6, a colorless solid, has been prepared.[80–83] An improved method involves passing $GeCl_4$ at low pressure through a microwave discharge.[81,82]

$Ge_5Cl_{12}\cdot GeCl_4$, a colorless cuboidal crystal, is moisture-sensitive. The structure consists of discrete Ge_5Cl_{12} and $GeCl_4$

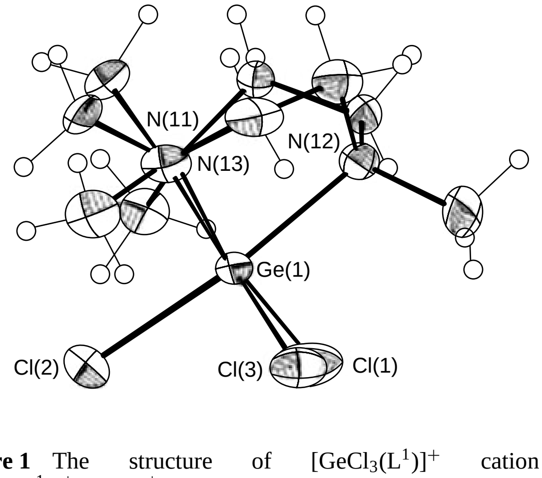


Figure 1 The structure of $[GeCl_3(L^1)]^+$ cation of $[GeCl_3(L^1)]^+{}_2[H_3O]^+ Cl_3^-\cdot MeCN$. (Ref. 79. Reproduced by permission of The Royal Society of Chemistry)

molecules. The present Ge–Ge distance is 2.4131 Å; the Ge–Ge angle is 109.5°; the Cl–Ge–Ge–Ge torsion angle is 38.68°.[84]

A highly unusual mixed oxidation state compound, $(F_8Ge_4)GeF_4$, is formed from GeF_4 and Ge at 350 °C as a colorless crystalline solid. The overall structure is polymeric with fluorine bridges; the Ge^{IV} atom is octahedrally coordinated by fluorines and four Ge^{II} atoms fall into two groups, both with distorted square pyramidal coordination by F and active lone pairs.

10.1 Anionic Halides

$[GeX_3]^-$ ions are readily obtained by reactions such as equations (36) and (37), and can hydrolyze with $Ge(OH)_2$ precipitates. The pyramidal $GeCl_3{}^-$ ion occurs in $RbGeCl_3$. By contrast, $CsGeCl_3$ has a perovskite-type structure; it is a hexagonal crystal and is changed into a cubic crystal at 155 °C. The $[GeCl_3]^-$ ion forms a series of complexes with strong Lewis acids (equation 38). The semiconductor $RbGeI_3$ and conductor $CsGeI_3$ both belong to the orthorhombic crystal system. The weak base pyridine has been found to deprotonate trichlorogermane $HGeCl_3$ with a quantitative formation of pyridinium trichlorogermanate(II), $[Py\text{-}H]^+$ $[GeCl_3]^-$, which is monoclinic and a $P2_1/c$ space group (equation 39).[85]

$$CsF + GeF_2 \longrightarrow CsGeF_3 \quad (36)$$

$$GeCl_4 + CsCl + H_3PO_2 \longrightarrow CsGeCl_3 \quad (37)$$

$$[Ph_4As]^+[GeCl_3]^- + BX_3 \longrightarrow [Ph_4As] + [X_3BGeCl_3]^- \quad (38)$$

$$HGeCl_3 + Py \longrightarrow [Py\text{-}H]^+[GeCl_3]^- \quad (39)$$

CsBr added to $GeBr_2$ solution can produce brick-red $CsGe_2Br_3$, but $RbGe_2Br_3$ cannot be obtained by using the same method.

In $[GeF_5]^-$ complexes, prepared from GeF_4 and a fluoride donor, Ge is six-coordinate (equations 40–42). The xenon complex consists of GeF_6 octahedra sharing trans vertices, whereas in the $[ClO_2]^+$ complex, GeF_5 units form an infinite chain of octahedra sharing cis vertices, the chain being an extended helix with all Ge atoms of a chain essentially coplanar. In the $[SF_3]^+$ complex, GeF_6 octahedra share cis vertices.[86]

$$GeF_4 + XeF_6 \longrightarrow [XeF_5]^+[GeF_5]^- \quad (40)$$

$$GeF_4 + ClO_2F \longrightarrow [ClO_2]^+[GeF_5]^- \quad (41)$$

$$GeF_4 + SF_3BF_4 \longrightarrow [SF_3]^+[GeF_5]^- + BF_3 \quad (42)$$

Octahedral $[GeF_6]^{2-}$ complexes have been obtained (equations 43–47). Thermolysis of K_2GeF_6 gives a complex mixture of products, including GeF_4 and K_3GeF_7. In $[SF_3]^+$ $[GeF_6]^{2-}$, each SF_3 makes close contact with one F from each of the three octahedral $GeF_6{}^{2-}$ ions, resulting in a distorted octahedron of fluorines about sulfur. $MnGeF_6$ can be prepared in HF (equations 48 and 49), however, the pure product can only be obtained by the reaction in equation (48). $Mn(GeF_5)_2$, formed from XeF_5GeF_5 and $Mn(AsF_6)_2$ (equation 50), decomposes to $MnGeF_6$ and GeF_4 due to its instability. So $MnGeF_6$ is dominant and only slight amounts of $Mn(GeF_5)_2$ are present in the final products.[87–89] The $[GeF_6]^{2-}$ ion is completely hydrolyzed in alkaline solution.

$$GeF_4 + 2KF/HF/H_2O \longrightarrow K_2GeF_6 \quad (43)$$

$$Ge + CuF_2 + 2RbF \longrightarrow Rb_2GeF_6 \quad (44)$$

$$GeF_4 + 2BrF_3 \longrightarrow 2[BrF_2]^+[GeF_6]^{2-} \quad (45)$$

$$GeF_4 + 2SF_3BF_4 \longrightarrow 2[SF_3]^+[GeF_6]^{2-} + 2BF_3 \quad (46)$$

$$CsGeF_3 + CsF + 2HF \longrightarrow Cs_2GeF_6 + H_2 \quad (47)$$

$$MnF_4 + nGeF_4 \xrightarrow[298\,K]{HF} MnGeF_6 + (n-1)GeF_4 \quad (48)$$

$$K_2GeF_6 + Mn(AsF_6)_2 \xrightarrow{298\,K} MnGeF_6 + 2KAsF_6 \quad (49)$$

$$2XeF_5GeF_5 + Mn(AsF_6)_2 \xrightarrow{298\,K} Mn(GeF_5)_2 + 2XeF_5AsF_5 \quad (50)$$

11 METALLOID AND METAL-BONDED COMPOUNDS

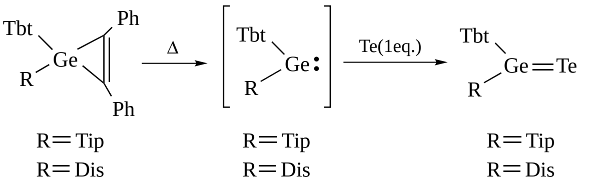
Germanium forms a wide range of compounds with hydrogen, silicon, the heavier group 14 elements, some main group metals, and transition metals. Catenated hydrides, Ge_nH_{2n+2}, have already been discussed. The majority have carbon bonded to Ge and are included in the next article (*see* ***Germanium: Organometallic Chemistry***).

11.1 Ge–M Compounds (M = Al, Ba, Te)

The cubane-type compound $[GeN\text{-}t\text{-}Bu]_4$, referred to earlier, forms a Lewis acid–base complex with $AlCl_3$ having the composition $[GeN\text{-}t\text{-}Bu]_4{\cdot}2AlCl_3$ with Ge–Al bonding.[25]

In polycrystalline Ba_6Ge_{25}, the Ba atoms interact strongly with the Ge host.[90]

Ge–Te double bond compounds and germanetellones are successfully synthesized through the reaction illustrated in equation (51).[91–93]



(51)

11.2 Ge–M Compounds (M = Si, Ge, Sn)

Germylsilane,[94] a gas stable at room temperature, can be obtained by equation (52).

$$Si_2H_6 + KH \longrightarrow H_3SiK + SiH_4$$
$$H_3SiK + H_3GeCl \longrightarrow H_3SiGeH_3 \quad (52)$$

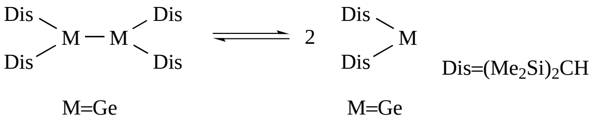
H_3GeSiH_3, n-$SiGe_4H_{12}$, and *iso*-$Si_2Ge_4H_{14}$ can be obtained by passing a mixture of GeH_4 and SiH_4 (or Si_2H_6) through a silent electric discharge. Ge–Si bonds are formed by equation (53). In this reaction, a Ge–Ge single bond is also formed.

$$GeCl_4 + Me_3SiCl + Li/THF \longrightarrow (Me_3Si)_4Ge \text{ or} (Me_3Si)_3Ge\text{-}Ge(SiMe_3)_3 \quad (53)$$

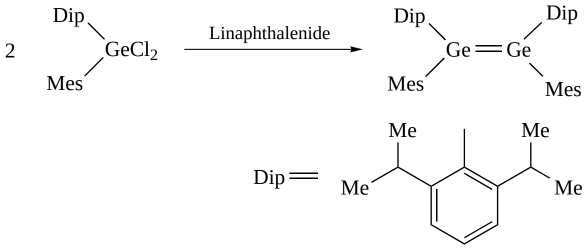
The following is a further example of bulky substituents influencing the course of a reaction, in which a likely intermediate $(Me_3Si)_3SiGeCl_2Li$ is formed by halogen–metal exchange (equation 54).[95]

$$GeCl_4 + (Me_3Si)_3SiLi(THF)_3 \longrightarrow (Me_3Si)_3SiGe(Cl)_2Ge(Cl)_2Si(SiMe_3)_3 \quad (54)$$

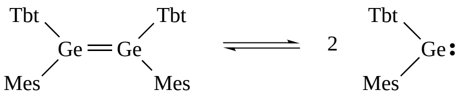
Some compounds with a Ge=Ge double bond have been synthesized.[96–99] (examples are in equations 55–57)



(55)



(56)

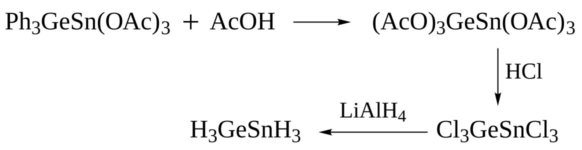


(57)

Scheme 5 gives some reactants involving the formation of the Ge–Sn bond.

11.3 Inorganic Ge–Transition Metal Compounds

The chemistry of Ge-transition metal compounds is a field experiencing relatively fewer studies. However, varieties of such compounds have been prepared and characterized. In reactions with transition metal complexes, Ge^{II} behaves as a



Scheme 5

donor–acceptor ligand like CO or an alkene; crystallographic studies indicate that the Ge–M bonds have a significant double bond character.

The following are the common ways used to establish Ge-transition metal bonds.

11.3.1 *Ge^{II}-Transition Metal Compounds*

Such compounds are usually obtained through addition of neutral or anionic Ge^{II} compounds to transition metal complexes (equations 58–68).

$$X_2GeH\cdot dioxane + M(CO)_6 + THF \longrightarrow X_2GeM(CO)_5THF + CO$$
$$X = F, Cl; M = Cr, W \quad (58)$$

$$GeI_2 + 2[R_2N]^-[Cr_2(CO)_{10}]^{2+} \longrightarrow [(CO)_5CrGe(I)_2Cr(CO)_5]^{2+} \quad (59)$$

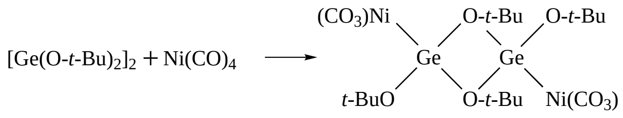
$$[Ph_4As]^+[GeCl_3]^- + M(CO)_6 \longrightarrow [Cl_3GeM(CO)_5]^- + [(Cl_3Ge)_2M(CO)_4]^{2-} \quad (60)$$
$$M = Mo, W$$

$$[Et_4N]GeCl_3 + Cr(C_6H_6)_2 \longrightarrow [Cr(GeCl_3)_6]^{6-} \quad (61)$$

$$[Et_4N]GeCl_3 + Mo(mesitylene)(CO)_3 \longrightarrow [(Cl_3Ge)_3Mo(CO)_3]^{3-} \quad (62)$$

$$(OEP)GeCl_2 + Na_2Fe(CO)_4 \longrightarrow (OEP)GeFe(CO)_4 \quad (63)$$
$$(OEP = octaethylporphyrin)$$

$$GeI_2 + Co_2(CO)_8 \longrightarrow I_2Ge[Co(CO)_4]_2 \quad (64)$$



(65)

$$[Et_4N]GeCl_3 + Ni(CO)_4 \longrightarrow [Cl_3GeNi(CO)_3]^- + [(Cl_3Ge)_2Ni(CO)_2]^{2-} \quad (66)$$

$$Ge[N(SiMe_3)_2]_2 + Pd(cod)_2 \longrightarrow Pd\{Ge[N(SiMe_3)_2]_2\}_3 \quad (67)$$

$$CsGeCl_3 + Rh(PPh_3)_2(CO)Cl \longrightarrow Cl_3GeRh(PPh_3)_2(CO) \quad (68)$$

A trichlorogermyl–Mn complex has been made by the chlorinative cleavage of phenyl groups from $Ph_3GeMn(CO)_5$, reflecting the stability of the Ge–Mn bond.

11.3.2 Ge^{IV}-Transition Metal Compounds

1. Reactions between GeH_4, GeX_4, or GeH_nX_{3-n}, and transition metal complexes (equations 69–74).

$$GeH_4 + HMn(CO)_5 \longrightarrow (CO)_5MnGe(H)_2Mn(CO)_5 \quad (69)$$

$$HGeX_3 + ClMn(CO)_5 \longrightarrow X_3GeMn(CO)_5 \quad (70)$$

$$X = Cl, Br$$

$$H_3GeBr + NaMn(CO)_5 \longrightarrow H_3GeMn(CO)_5 \quad (71)$$

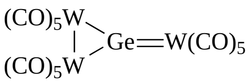
$$GeCl_4 + (bipy)(CO)_4Mo \longrightarrow Cl_3GeMo(CO)_3(bipy) \quad (72)$$

$$H_3GeBr + Na_2Fe(CO)_4 \longrightarrow trans\text{-}(H_3Ge)_2Fe(CO)_4 \quad (73)$$

$$GeF_4 + Me_3SiCo(CO)_4 \longrightarrow F_3GeCo(CO)_4 \quad (74)$$

Some of the isolated products can be explained in terms of a series of oxidative addition/reductive elimination intermediates. The orange linear complex $Me_5C_5(CO)_2Mn{=}Ge{=}Mn(CO)_2C_5Me_5$ is formed from the reaction of GeH_4 with $Me_5C_5(CO)_2THF$. The Ge–Mn bond length is 218 pm, indicating a considerable double bond character. When GeH_4 reacts with the less sterically hindered complex $CpMn(CO)_3$, the product is μ_3-Ge[CpMn$(CO)_2]_3$.

Trigonal planar complex (**17**), presumably formed via $(CO)_5WGeCl_2$, is prepared through the reaction of $GeCl_4$ with $Na_2W_2(CO)_{10}$.



(**17**)

Schemes 6 and 7 show the types of Ge–Fe compounds and their chemistry.[100]

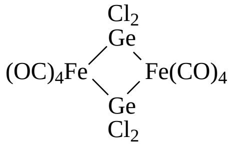
2. Oxidative addition of Ge–H or Ge–X to a transition metal complex (equations 75 and 76).

$$2GeCl_4 + 2Fe(CO)_5 \longrightarrow cis\text{- and } trans\text{-}(GeCl_3)_2Fe(CO)_4 + FeCl_2 + 6CO \quad (75)$$

$$GeCl_4 + Cp(CO)_2Co \longrightarrow Cl_3GeCo(CO)(Cl)Cp + (Cl_3Ge)_2Co(CO)Cp \quad (76)$$

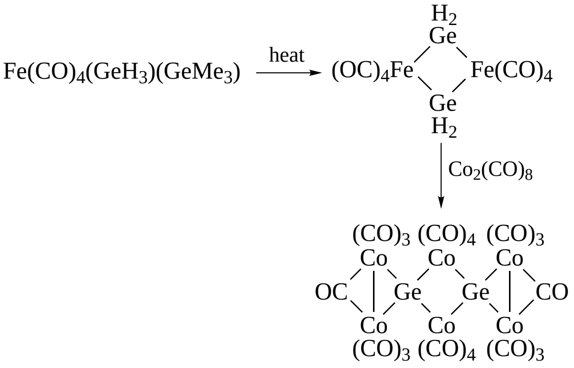
Under vigorous conditions, the four-membered ring is produced (**18**).

Adding $HGeCl_3$ to rhodium (I) complexes produces Rh^{III} products that may react further under proper experimental conditions (Scheme 8).



(**18**)

A series of oxidative addition/reductive elimination stages follow the oxidative addition of $HGeCl_3$ to $[PtCl_4]^{2-}$, yielding five- and six-coordinate products: $[Pt(GeCl_3)_5]^{3-}$, with a tbp structure, and the octahedral complexes $[PtH(GeCl_3)_5]^{2-}$ and $[PtCl_4(GeCl_3)_2]^{2-}$. In other cases, the primary oxidative addition product (**19**) can be isolated.



Scheme 7

$$HGeCl_3 + Rh(PPh_3)_3Cl \longrightarrow Rh(PPh_3)_2(GeCl_3)(H)Cl$$

$$\downarrow \text{excess } HGeCl_3$$

$$3[Ph_3PH]^+ [Rh(GeCl_3)_6]^{3-}$$

Scheme 8

$$Na_2Fe(CO)_4 + GeBrH_3 \longrightarrow cis\text{-}Fe(CO)_4(GeH_3)_2 + cis\text{-}HFe(CO)_4GeH_3$$

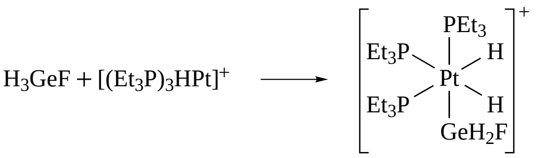
$$\downarrow HCl$$

$$Fe(CO)_4(GeH_2Cl)(GeH_3)$$

$$\downarrow HCl$$

$$HFe(CO)_4(GeH_2Cl)$$

Scheme 6



(**19**)

12 POLYOXOMETALATES OF GERMANIUM

The early transition metals (V, Nb, Ta, Mo, W) in their highest oxidation states are able to form metal–oxygen cluster anions, commonly referred to as polyoxoanions[101] or polyoxometalates.[102] In the gigantic family, the Keggin polyoxoanion is an important and classic subclass. Its general formula is $[XM_{12}O_{40}]^{n-}$ ($X_{heteroatom} = P^{V}$, Si^{IV}, Ge^{IV}, As^{V}, $M_{coordinated\ atom} = Mo^{VI}$, W^{VI}). Ge, as one of heteroatoms, forms two classic Keggin heteropolyoxometalates, $[GeW_{12}O_{40}]^{4-}$ and $[GeMo_{12}O_{40}]^{4-}$, in which heteroatom Ge exhibits $\{GeO_4\}$ tetrahedral geometry and coordinated atoms W or Mo exhibit $\{MO_6\}$ octahedral configuration. Each three edge-sharing $\{MO_6\}$ octahedra constitute a $\{M_3O_{13}\}$ cluster; four such corner-sharing trimetal clusters are arrayed around the center $\{GeO_4\}$ tetrahedron forming a beautiful 'basket' structure (see Figure 2). The forty oxygen atoms in the Keggin anion can be divided into four groups, that is, four O_a, twelve O_b, twelve O_c, and twelve O_t. O_a represents oxygen atoms of a $\{GeO_4\}$ tetrahedron; both O_b and O_c are bridging oxygen atoms, O_b are the common oxygen atoms of different trimetal clusters, while O_c are the common oxygen atoms of a trimetal cluster; O_d are terminal oxygen atoms, that is, noncommon oxygen atoms of each $\{MO_6\}$ octahedron. In the four kinds of oxygen atoms, terminal oxygen atoms (O_d) are the most active, and many new compounds are formed through the further linkages of them. Since the $[GeW_{12}O_{40}]^{4-}$ anion was first found in 1930, extensive research for the potential applications of heteropolyoxogermanates has been carried out. To date, plenty of research work mainly focuses on medicine. In vitro antiviral activities of many polyoxogermanates derivatives have been studied.[103] Furthermore, the specific resistance of the compression molded $H_4GeW_{12}O_{40}\cdot 30H_2O$ plate has been studied, which indicates that it may function effectively as partition walls between the anode and cathode chambers of H_2 (catalyst Pt or Pd)/O_2 fuel cells.[104] These excellent properties increasingly prompt the development of polyoxogermanate chemistry.

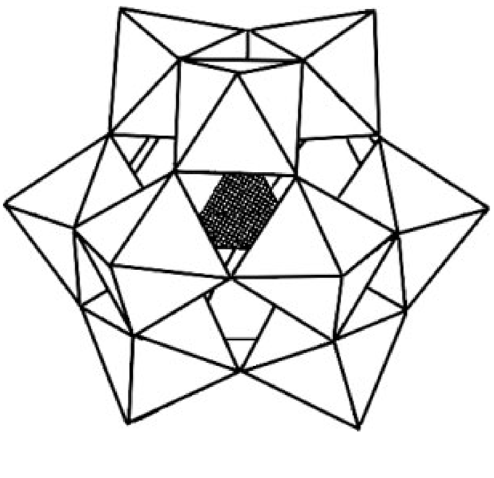


Figure 2 The structure of the Keggin polyoxoanion $[GeM_{12}O_{40}]^{4-}$ (M = Mo or W)

12.1 Preparation and Properties of Classic Keggin Polyoxogermanates

An alkaline germanate solution is added to a solution of molybdate or tungstate, and the mixture is acidified with nitric acid. After a classical Et_2O extraction process, water is added to the separated Et_2O layer. Then the mixture of Et_2O and H_2O is put in a vacuum desiccator with concentrated H_2SO_4, and it is left without disturbance. Finally, yellow or colorless aim crystals with $[GeMo_{12}O_{40}]^{4-}$ or $[GeW_{12}O_{40}]^{4-}$ anions are obtained. Detailed synthetic steps can be seen in Reference 105.

$[GeW_{12}O_{40}]^{4-}$ and $[GeMo_{12}O_{40}]^{4-}$ anions are stable in acid solution, however, when the pH value reaches 5.3 or 7.3, they decompose to GeO_2 and polyoxomolybdate or polyoxotungsten.

12.2 Derivatives of Polyoxogermanates

Polyoxometalates have been found to be extremely versatile inorganic building blocks due to their ability to accept electrons. Being members of them, polyoxogermanates make no exceptions. The oxygen atoms on the surface of polyoxogermanates are rather reactive and are easily combined with the highly oxophilic rare earth ions to form precipitation. However, if suitable organic-ligands-coordinated rare earth ions are introduced, a crystallized product can be obtained. Three lanthanide-containing compounds, $[Ce(NMP)_4(H_2O)_4][GeMo_{12}O_{40}]\cdot 2NMP\cdot 3H_2O$, $[Pr(NMP)_4(H_2O)_4][GeMo_{12}O_{40}]\cdot 2NMP\cdot 3H_2O$, and $[Nd(NMP)_4(H_2O)_4][HGeMo_{12}O_{40}]\cdot 2NMP\cdot 3H_2O$[106] have been prepared. In these compounds, the building blocks of $[GeMo_{12}O_{40}]^{4-}$ anions and $[Ln(NMP)_4(H_2O)_4]^{3+/4+}$ cations are connected via hydrogen-bonding interactions, and the whole crystal structure of these compounds displays a two-dimensional supramolecular network with porous structures. By contrast, the two-dimensional network $[\{Ba(DMSO)_3(H_2O)_3\}\{Ba(DMSO)_5(H_2O)\}(GeMo_{12}O_{40})]$[107] is formed by covalent linkages of terminal oxygen atoms of $[GeMo_{12}O_{40}]^{4-}$ with Ba^{2+} ions.

With the wide use of hydrothermal and solvothermal synthesis, many polyoxogermanates with unique structures have been prepared. Polyoxoalkoxovanadium germanate, $(NH_4)_2[H_2V_9Ge_8O_{26}(L)_6]\cdot 0.65H_2O$ ($H_2L = HOCH_2CH_2$-

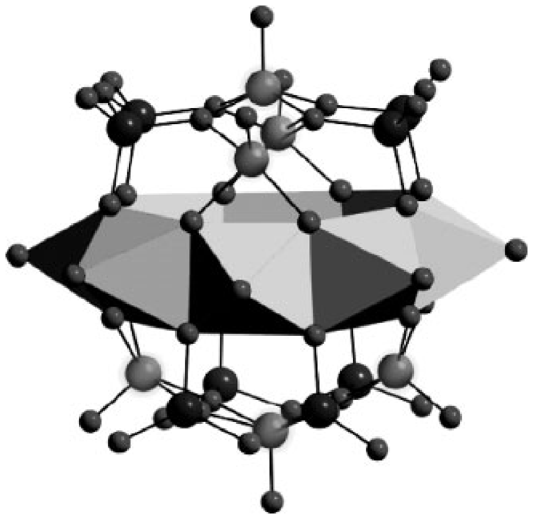

Figure 4 The structure of $[V_{14}O_{44}(GeOH)_8]^{8-}$. Gray polyhedra and large balls represent V, the large black balls represent Ge atoms, and the smallest black balls are oxygen atoms. (Reprinted in part with permission from Ref. 109, © 2003 American Chemical Society)

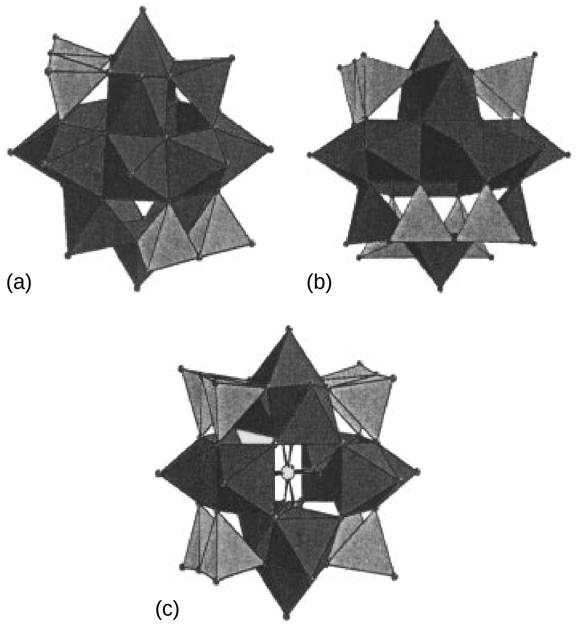

Figure 5 Polyhedral representations of the cluster ions. VO_5 polyhedra are black and GeO_4 polyhedra are gray. (Reprinted in part with permission from Ref. 110, © 2003 American Chemical Society)

OH),[108] is synthesized solvothermally by a mixture of NH_4VO_3, GeO_2, H_2O, and ethylene glycol at 170 °C for 3 d. Its polyanion is made up of six VO_6 octahedra, three VO_5 square pyramids, and six GeO_4 tetrahedra with six bridging ethylene glycol ligands projecting outwards from the central core (Figure 3). $(H_2DAB)_4[V_{14}O_{44}(GeOH)_8]\cdot 6H_2O$ (DAB = 1,4-diaminobutane)[109] is synthesized by a hydrothermal method with the mixture of GeO_2, V_2O_5, DAB, and water at 170°C for 5 d. The structure of the nearly spherical cage includes fourteen tetravalent VO_5 square pyramids sharing edges via basal oxygen atoms and four Ge_2O_7 dimers, as shown in Figure 4. $Cs_8[Ge_4V_{16}O_{42}(OH)_4]\cdot 4.7H_2O$

(a), $(pipH_2)_4(pipH)_4[Ge_8V_{14}O_{50}\cdot(H_2O)]$ (pip = $C_4N_2H_{10}$) (b), and $K_5H_8Ge_8V_{12}SO_{52}\cdot H_2O$ (c),[110] deriving from the cluster anion shell $\{V_{18}O_{42}\}$, although isolated, are the first examples that contain Ge_2O_7 anions incorporated into vanadate polyhedra based on the Keggin cluster anion (Figure 5).

1 INTRODUCTION

1.1 Scope

The field of organogermanium chemistry describes those compounds containing at least one germanium–carbon bond. This review describes the major advances made in the field since 1993. For work prior to that time, the reader is referred to the article 'Germanium: Organometallic Chemistry' in the first edition of the Encyclopedia of Inorganic Chemistry written by Mikhail P. Egorov and Peter P. Gaspar. The brief history of germanium chemistry included in the first edition, and the sections on the 'Comparison of Organogermanium Compounds with Other Elements', and on the 'Coordination State of Germanium in Organogermanium Compounds' discuss material that is largely unchanged. It is not repeated here. A new section entitled 'Advances in Physical Chemical Understanding of Organogermanium Compounds' has been included, reflecting the advances in both computational chemistry and experimental measurements of the electronic structure of organogermanium compounds.

1.2 Evolution of Interest

In the conclusions of the chapter on organogermanium chemistry for the first edition, Egorov and Gaspar presciently stated that emphasis in the field was '... shifting from the accumulation of knowledge about the synthesis and properties of organogermanium compounds to the study of reaction mechanisms and reactive intermediates'. The past decade has seen a major focus on the development of new reactions and the development of novel germanium-based chemistries. This experimental work has been accompanied by major advances in theoretical understanding. There has been a large number of review articles published in the last decade. These can be roughly classified by area: general reviews and discussions of molecular compounds;[1–62] surfaces and materials;[63–69] polymers;[70–75] photochemistry;[76–78] structure;[79,80] biological applications;[47,81–88] spectroscopy and calculations;[89–100] reactivity and reagents.[101–111]

Organogermanium species are still not employed in large-scale synthetic processes, possibly because of the high price as compared to silicon and tin chemistries, and certainly because no chemistry yet discovered was unique enough to warrant the use of the more expensive germanium reagent.

2 ADVANCES IN PHYSICAL CHEMICAL UNDERSTANDING OF ORGANOGERMANIUM COMPOUNDS

The rapid developments in theoretical methods and substantial enhancement of computing power over the past decade have had a dramatic impact on all areas of chemistry including organogermanium chemistry. Advances in computational methods applied to germanium chemistry as well as complementary experiments exploring the electronic structure will be discussed.

2.1 Electronic Structure Calculations Applied to Organogermanium Compounds

The past decade has seen considerable application of density functional calculations to germanium systems. All-electron B3LYP calculations have been applied to germylenes, germynes, germenes, digermenes, and germanones.[112–119] In general, these calculations appear to describe the geometric and electronic structure of germanium systems quite well. For example, B3LYP/6-311G(d, p) structures of CH_3GeH and $(CH_3)_2Ge{=}CH_2$ are nearly identical to those obtained using MP2/DZ + d.[120] Insertion reactions of germylenes have been extensively studied[114,121–124] as well as addition reactions[125] and oxygen atom transfer reactions.[126] Estimation of the standard reduction potential for a stable germylene (a

diazagermol-2-ylidene) has been performed using B3LYP/6-31 + G* (−2.88 V vs. SCE) and compared to experimental values for germylenes of this type which showed a reduction wave at ∼ −2.8 V.[127]

2.2 Recent Experimental Advances in the Physical Chemistry of Organogermanium Compounds

Photoelectron spectra have been experimentally measured and calculated for (1,3-di-*tert*-butyl-1,3,2-diazagermol-2-ylidene).[128] For this germylene, the HOMO is a π-symmetry orbital containing substantial Ge, N, and C=C π-character. The Ge-based lone pair is actually found to be ∼2 eV lower in energy. The He II gas-phase photoemission spectrum is shown in Figure 1.

Gas-phase photoelectron spectra have also been obtained for germaimines, germaisonitriles, and additional germylenes.[129–131]

The electron affinity (31.9 ± 0.7 kcal mol^{-1}) and gas-phase acidity (361.5 ± 2.8 kcal mol^{-1}) for Me_3GeH have been determined using photodetachment spectroscopy.[132] The bond dissociation energy (Ge–H) derived from these values was determined to be 79.8 ± 3.5 kcal mol^{-1}, in excellent agreement with other determinations.[133,134]

Ion/molecule reactions of F^- or MeO^- with $Ge(OMe)_4$ can be used to generate germyl anions such as $Ge(OMe)_3{}^-$ and $GeF(OMe_2)^-$.[135,136] The electron affinities of the corresponding neutral three-coordinate compounds have been calculated and follow the expected trend of increasing electron affinity with an increasing number of electronegative ligands bound to germanium.[133]

Significant progress has also been made in the area of ^{73}Ge NMR spectroscopy.[137,138] The ^{73}Ge nucleus has low natural abundance (7.61%), poor sensitivity (0.00140 at constant field as compared to ^{1}H), and a high spin (s = 9/2). These factors combined with a high quadrupole moment have typically resulted in extensive line broadening and efficient quenching of spin–spin coupling with neighboring nuclei. The key exceptions to these problems have been spectra of compounds with high symmetry (T_d or C_{3v}) securing a zero field gradient at the germanium nucleus.[139] Recently, ^{73}Ge NMR spectra have been obtained for a family of aryl germanes $HGePh_3$, H_2GePh_2, and H_3GePh_3 where the Ge–H coupling contants were well-resolved and had values of 98, 94, and 98 Hz respectively.[139] A number of other compounds with substituted aryl groups were reported as well. However, similar germanes with thiophene substitutents showed substantial peak broadening and no ^{1}H-^{73}Ge coupling could be resolved.[140] It has also been noted that hypervalent organogermanes compounds show a much larger ^{73}Ge peak half-width (100–600 Hz) as compared to similar nonhypervalent germanes (25–100 Hz).[141,142] ^{73}Ge NMR have been obtained for organogermanes in the solid state and spin-lattice relaxation times (T1) obtained.[143,144] The ^{73}Ge NMR spectra of a variety of other organogermanes have also been reported.[145–148]

3 METHODS FOR FORMATION AND CLEAVAGE OF GERMANIUM–CARBON BONDS

3.1 Formation of Germanium–Carbon Bonds

An excellent discussion of the primary methods used for germanium–carbon bond formation (direct synthesis, salt elimination, redistribution, and hydrogermylation) was provided in the first edition. The techniques all typically employ Ge(IV) starting materials. Key updates are provided below for these areas as needed. In the past decade, the application of Ge(II) starting materials has allowed observation of the following new germanium–carbon bond forming reactions: C–X insertions, CH-insertions, CH-activations, and formal 4 + 2 cycloadditions.

3.1.1 *Direct Synthesis*

Major advances in the application of the direct synthesis method, reaction of metallic germanium with an alkyl halide, have been realized. Solvochemical activation of germanium via the $Li[Et_3BH]$ reduction of $GeCl_2$•dioxane yields amorphous, orange-colored 'activated' germanium.[149] Upon reaction of this material with methyl ester, cyano, and chloro functionalized alkyl bromides at 130–150 °C, germanes of general stoichiometry R_2GeBr_2 can be formed in 80–95% yield. In contrast to industrial direct synthesis, the whole family of organobromogermanes $R_{4-n}GeBr_n$ are not formed. Recent studies on the use of metal chloride catalysts for the direct reaction to make phenylchlorogermanes from metallic germanium and chlorobenzene have also been reported.[150] Additionally, a noncatalyzed method to selectively make phenyltrichlorogermane from a mixture of germanium metal, germanium tetrachloride, and chlorobenzene takes advantage

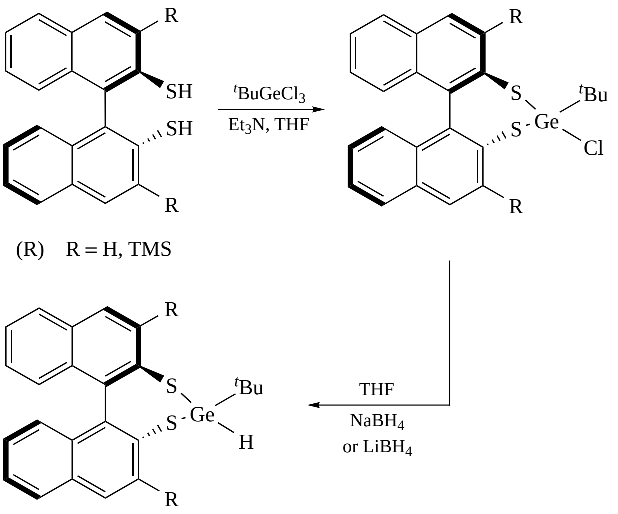
of the in situ generation of divalent germanium, $GeCl_2$, as an intermediate.[151]

In 2002, the formation of a germanium–carbon bond directly from GeO_2 was reported.[152] The synthesis of $MeGe(OMe)_3$ was accomplished by heating a mixture of GeO_2 and 5% KOH to 350 °C in a fixed bed reactor while flowing dimethyl carbonate over the mixture (equation 1).

(1)

3.1.2 Hydrogermylation

Chiral organogermanes have been directly synthesized by utilizing C_2-symmetric dithiol complexes[153,154] (equation 2).



(2)

Dendrimeric macromolecules containing germanium have also been made via hydrogermylation.[155] The cyclization/hydrogermylation of functionalized 1,6-dienes catalyzed by cationic palladium complexes has also been carried out.[156] Hydrogermylation is also an effective synthetic method for the synthesis of germatranes.[157]

Hydrogermylation chemistry has been employed to make germanium–carbon bonds at surfaces via the reaction of alkynes and alkenes with the Ge–H bonds of HF-treated surfaces.[158] Recently, this method has also been employed to functionalize the surface of germanium quantum dots[159] (Figure 2).

3.1.3 Salt Elimination

Salt elimination reactions can also be used to form germanium–carbon bonds at surfaces. This has recently

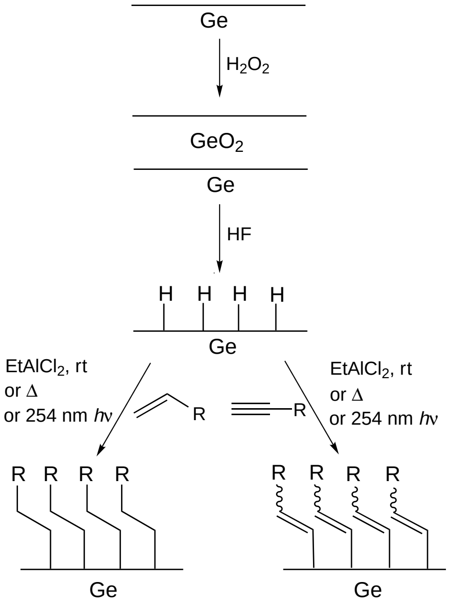


Figure 2 Preparation of hydrogen-terminated Ge followed by hydrogermylation

been studied for the case of Ge(111)-Cl reacting with Grignard reagents to form self-assembled alkyl monolayers on germanium.[160] The formation of (diarylgermyl) lithium reagents (R_2HGeLi) has allowed the salt elimination reaction to be employed with a greatly enhanced degree of specificity[161] (equation 3).

$$RR'GeH_2 \xrightarrow{^{t-}BuLi/THF} RR'GeHLi \xrightarrow[LiI]{MeI} RR'GeHMe \qquad (3)$$

3.1.4 C–X Insertion Reactions

Chiral adamantyl cages containing C–Br bonds at the bridgehead carbons will undergo oxidative-addition reactions with $GeCl_2$•dioxane to yield chiral germanes.[162]

3.1.5 C–H Insertion Reactions

The first report of germylene insertion into a CH-bond occurred in 1987.[163] Subsequently, it was demonstrated that this reactivity was Lewis acid dependant.[164] Intramolecular CH-insertion has also been observed as part of the reaction of silylene insertion into $Ge[N(SiMe_3)_2]_2$ and occurs spontaneously for a remarkable germylene containing a Fe–Ge bond.[165,166] In addition to these solution-phase reactions, Me-Ge-$SiMe_3$ can be thermally generated by the reductive elimination of $HSiMe_3$ from $MeHGe(SiMe_3)_2$. This germylene subsequently undergoes an intramolecular C–H insertion reaction to generate 1,1,2-trimethyl-silagermirane[167] (Figure 3). In this case, Lewis acids do not appear to play a role.

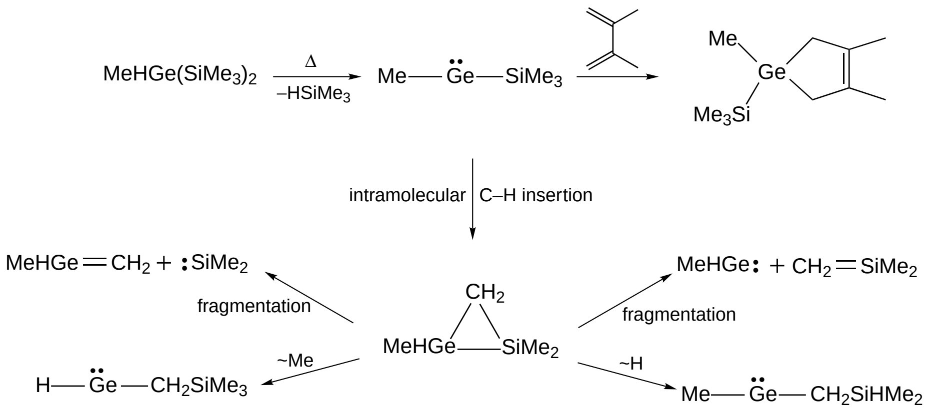

Figure 3 Thermal generation of a germylene followed by intramolecular C–H bond insertion

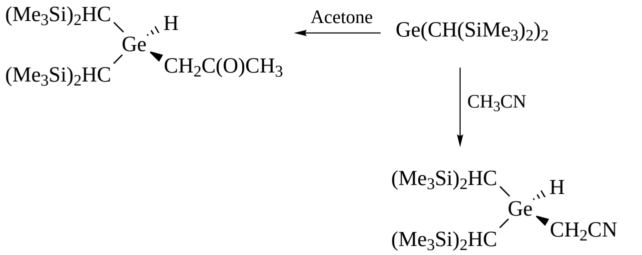
Intermolecular CH-insertion chemistry has been achieved for the cases of nitriles[168] and acetyl groups[169] by employing $Ge[CH(SiMe_3)_2]_2$ accompanied by a salt promoter (equation 4).



(4)

For the case of nitriles, LiX (X = Cl, Br, I) or $MgCl_2$ were shown to be effective. For the case of acetyl groups, only $MgCl_2$ effectively promoted the reaction.

This reaction has attracted recent theoretical attention in the form of Density Functional calculations.[114,121] These studies indicate that CH-insertion chemistry should be favored for germylenes containing bulky, electropositive substituents and disfavored for germylenes containing electronegative or π-donating substituents. Provocatively, it is suggested that unactivated C–H bonds such as methane should be amenable to germylene-based CH-insertion chemistry.

3.1.6 CH-activation Reactions

An initial report of CH-activation for the formation of germanium–carbon bonds appeared in 2003[170] (Figure 4).

A mixed reagent formed from $Ge[CH(SiMe_3)_2]_2$ or $Ge[N(SiMe_3)_2]_2$ and PhX (X = Cl, Br, I) was shown to reaction directly with alkanes (cyclohexane, cyclopentane, butane, methylcyclopentane), aromatics (toluene, ethyl

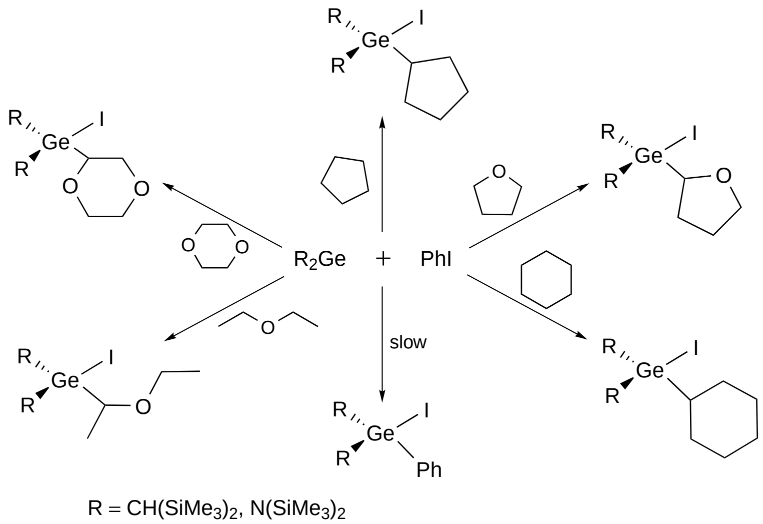


Figure 4 Intermolecular CH-activation reactions reported for GeR_2/PhI reagent

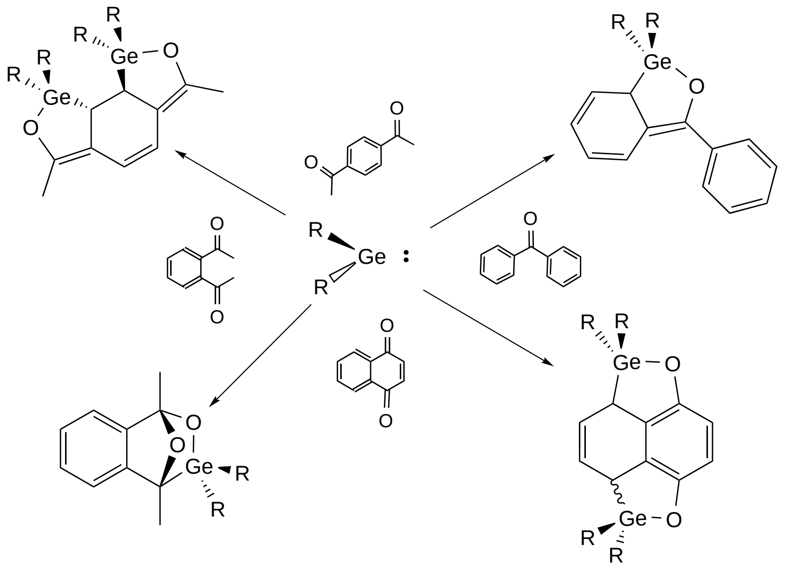

Figure 5 Reactions of GeR_2 with phenone and quinones

benzene, cumene), and ethers (tetrahydrofuran, diethyl ether, 1,4-dioxane) to yield products of the general form L_2GeRX. The regioselectivity of the reaction was observed to be radical-like: tertiary > secondary > primary.

3.1.7 Formal 4 + 2 Cycloadditions

Germanium–carbon bond formation can also be achieved with Ge(II) by taking advantage of formal 4 + 2 cycloaddition reactions. For example, it was shown in the 1970s that $GeCl_2$ will reaction directly with butadiene to form 1,1-dichlorogermacyclopent-3-ene, albeit in a low 15% yield.[171] This general reaction was extended to include phenones and quinines[172,173] (Figure 5).

The germylene forms new bonds with the ketone oxygen and the ortho carbon of the adjacent phenyl group to form a five-membered ring.

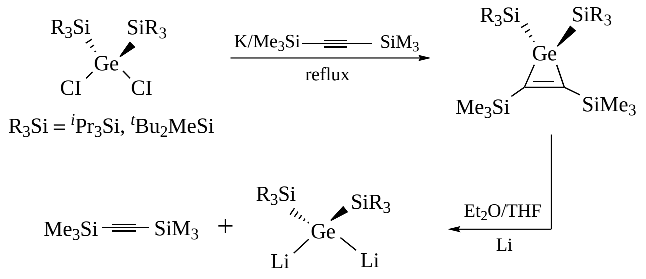
Cycloadditions have also been used to form germanium–carbon bonds at germanium surfaces. For example, 1,3-butadiene and 2,3-dimethyl-1,3-butadiene react with the dimers present on Ge(100)-2x1 to form a six-membered ring and two new Ge–C bonds.[174,175] Reactions with other unsaturated species such as ethylene, ketones, and nitriles have also been explored.[176–179]

3.2 Reactions of Germanium–Carbon Bonds

Although several methods for the formation of germanium–carbon bonds now exist, the chemistry of germanium–carbon bond reactions remains woefully underdeveloped by comparison to silicon and tin. The importance and utility of many of the formation reactions will likely remain low until a set of reactivity can be developed that mirrors the important chemistry of the Sn–C (Stille-Migata-Kosugi reaction) and Si–C bonds (Hiyama reaction). The general reactivity towards oxygen and sulfur, halogens, acids, and nucleophiles was previously reviewed in the first edition. This section will focus on new developments of the past decade.

3.2.1 Reductive Cleavage

Reduction of R_2GeX_2 compounds to transiently yield R_2Ge species followed by trapping with alkynes is a well-established method for making Ge–C bonds in the form of germacyclopropenes.[180–182] Recently, it has been discovered that lithium reduction of the germacyclopropene generates the corresponding dilithiogermane and an equivalent of the original alkyne[183] (equation 5).

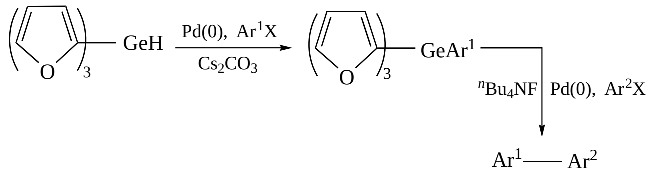


(5)

3.2.2 Cross-coupling Reactions

Palladium-catalyzed cross-coupling of a variety of alkyl groups with germatranes and carbogermatranes with aryl

halides has recently been demonstrated.[184,185]



(6)

The internal coordination of the nitrogen to germanium is thought to be the source of the increased reactivity of these species as compared to tris(alkoxy) germanes. Significant improvements in cross-coupling have also been realized by employing tris(2-furyl)germane[186] (equation 6).

4 ORGANOGERMANIUM HETEROCYCLES

4.1 Heterocycles Containing Germanium in an Aromatic Ring

An important milestone in the field of organogermanium heterocycles was achieved over the past decade with the syntheses and full characterization of germabenzene and 2-germanaphthalene.[187–190] In both cases, kinetically stabilized compounds were obtained by employing 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl (Tbt) ligated to germanium. On the basis on NMR, UV-Vis, and Raman spectra it was concluded that a significant amount of aromatic character existed for both the germabenzene and the 2-germanaphthalene. The amount of electronic stabilization is not sufficient to prevent the Ge–C bond from reacting like a typical germanium–carbon double bond. For example, the Ge–C bond of germabenzene reacts in a $4+2$ sense with styrene and phenylacetylene and in a $2+4$ sense with dimethylbutadience and mesitonitrile (Figure 6).

In addition, both water and methanol are observed to add across the Ge–C bond. Similar results were obtained for the 2-germanaphthalene. Sulfur and selenium have also been observed to add across the Ge–C bond.[191,192] Although these compounds show spectroscopic and structural data consistent with aromatic behavior, their reaction chemistry is generally more like a germanium–carbon double bond and does not exhibit significant signs of deactivation as noted for the all organic parent compounds benzene and naphthalene. Germabenzene has been successfully employed to make η^6-π-complexes of both Cr and Mo.[193]

4.2 Nonaromatic Organogermanium Heterocycles

A wide variety of other organogermanium heterocycles have been synthesized, characterized, and applied to a variety of synthetic transformations. Selected examples are discussed below.

4.2.1 Three-membered Rings

A particularly interesting three-membered ring, an alkylidenetelluragermirane, provides a convenient route to a 1-germaallene via abstraction of tellurium with hexamethylphosphorus triamide.[194,195] Analogous rings can also be synthesized containing Se or S. Another novel three-membered ring recently synthesized is a germacyclopropylbenzene.[196] Heterocyclic three-membered rings can also be made via atom transfer to M–Ge bonds.[197]

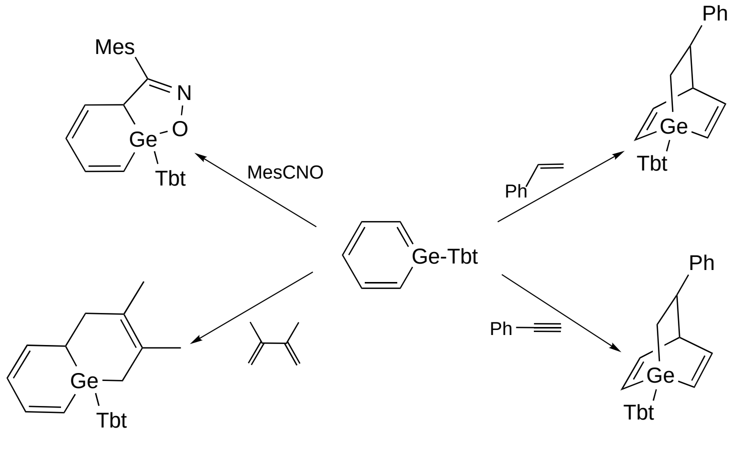


Figure 6 Cycloaddition reactions of germabenzene

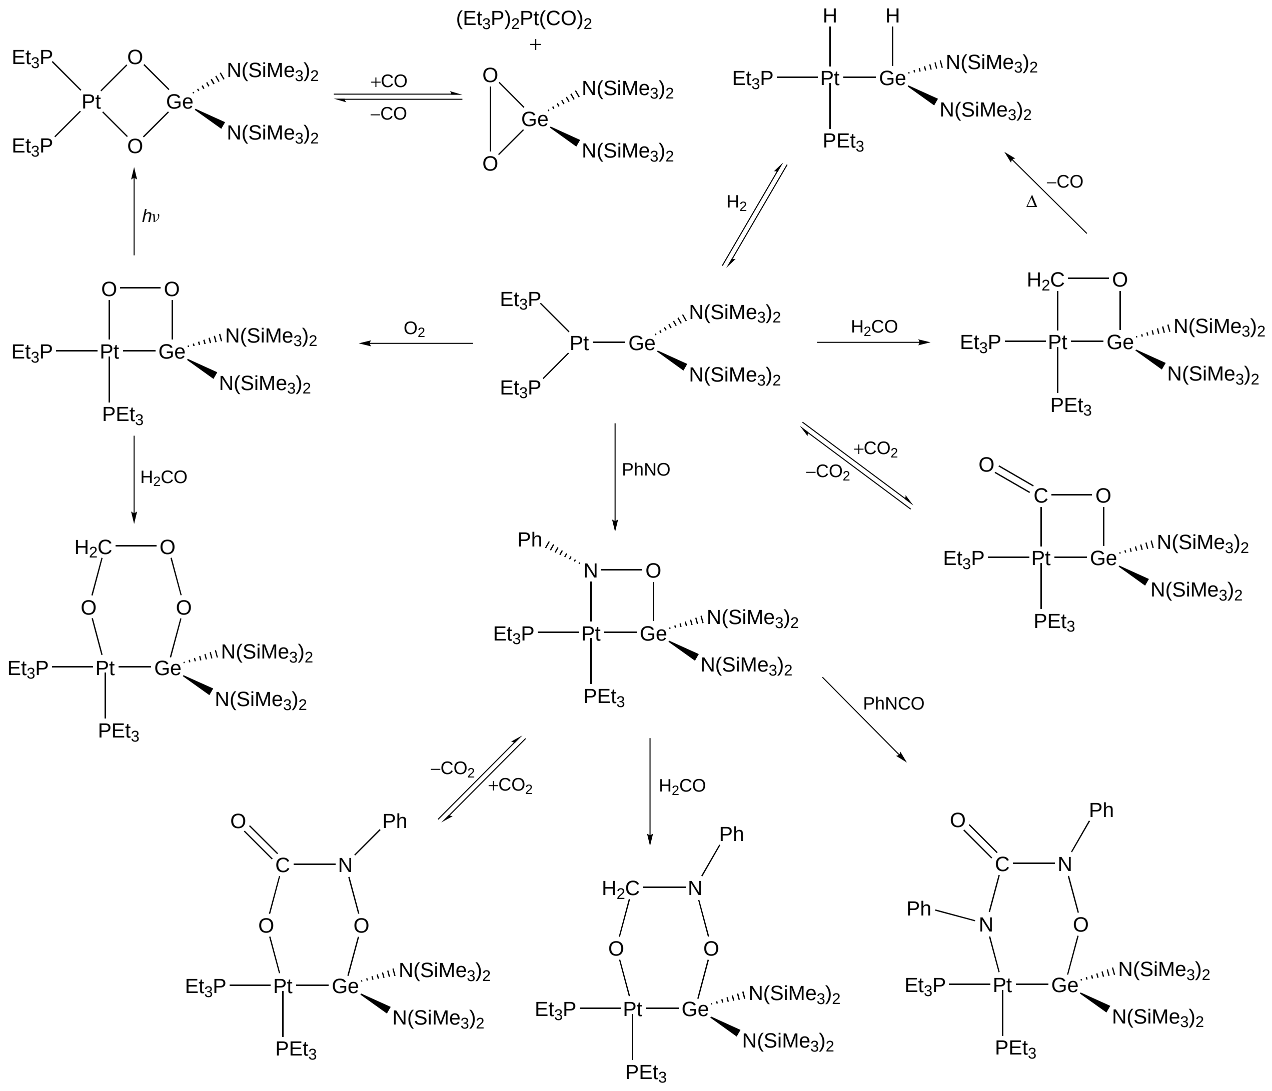

Figure 7 Examples of heterocycle formation and reactions using $(Et_3P)_2PtGe[N(SiMe_3)_2]_2$

4.2.2 Four- to Six-membered Rings

Cycloaddition reactions are common routes to the formation of four- to six-membered ring heterocycles. Germylenes,[198,199] germenes,[200–203] and metal germylene complexes[204–209] have been utilized extensively for these reactions (Figure 7).

Absolute rate constants for the head-to-tail [2 + 2]-dimerization of 1,1-diphenylgermane have been measured.[200] Heterocyclic rings can also be made by metathesis reactions using germanium halides.[210,211] Five-membered ring heterocycles can make effective cyclopentadienyl (Cp) analogs as exemplified by the η^5-germolyl complexes that have been made for Zr and Hf.[212,213] The germanium in the ring can be used to bond to another metal and heterobimetallic Hf–Ir and Hf–Rh complexes have been synthesized.[214]

The detailed structure of germacyclobutane has been studied using gas-phase electron diffraction.[215]

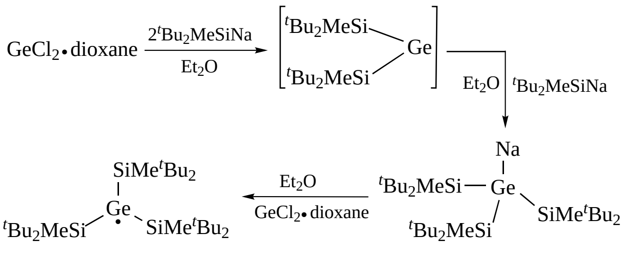
5 ORGANIC DERIVATIVES OF THREE-COORDINATE GERMANIUM

Three-coordinate organogermanium complexes will be discussed in terms of seven primary classes: (1) germanium-centered radicals, (2) germenes, (3) germanium with a double bond to an element other than carbon, (4) aromatic germanium rings, (5) cationic compounds, (6) three-coordinate germylenes, and (7) germylenes acting as donors in transition metal complexes.

5.1 Germanium-centered Radicals

Persistent and stable organogermanium radicals were recently reviewed as part of a comprehensive article on 3rd row and heavier main group radical species.[216] In 2002, the first example of a stable, three-coordinate R_3Ge germanium

radical was reported (equation 7).[217]



(7)

This remarkable compound, Ge[SiMe^{t}Bu$_2$]$_3$, was characterized by mass spectrometry, UV/vis spectroscopy, electron paramagnetic resonance (EPR), and X-ray crystallography. Two stable germanium radicals containing germanium triangles have been isolated. Both [2,6-Mes$_2$C$_6$H$_3$Ge]$_3$ and 1,6,7-trigermabicyclo[4.1.0]hept-3-en-7-yl have also been characterized by EPR and X-ray crystallography (Figure 8).[218,219]

Calculations on organometallic radicals such as GeCH$_3$ and GeC$_2$H$_5$ have been performed because of relevance of these species to chemical vapor deposition.[220]

5.2 Germenes

Many reviews have been written recently on the subject of germenes[4,45,96,221,222] and they have been the subject of numerous computational studies.[112,223–227] In the absence of sterically bulky ligands, germenes rapidly dimerize or react with available substrates. For this reason, germenes are frequently studied as transient, reactive intermediates[77,200,228,229] isolated in a matrix,[230,231] or inferred from trapping reactions.[232,233]

Sterically bulky ligands allow the isolation of stable germenes. A recent example was made via the reaction of 2 equivalents of a sterically bulky germylene with CS$_2$ to yield a germaketenethioacetal.[234] Germenes have been applied to a variety of reactions with organic molecules.[201,235]

The synthesis of stable germaallenes and 1,3-germaphosphaallenes has occurred in the past decade.[195,236–238] These species are reactive towards atom transfer reactions (S, Se, Te), additions of O–H bonds, and cycloaddition chemistry at the Ge=C bond.[203,239,240]

5.3 Compounds with Ge Double Bonds to Elements Other Than Carbon

5.3.1 *Heavy Ketone Analogs of Germanium (O, S, Se, Te)*

Substantial progress has been made synthesizing stable ‘heavy ketone’ analogs of germanium R$_2$Ge=E (E = O, S, Se, Te).[20,26,30,241–247] A number of computational studies have been reported.[248–251] The germanone can only be generated solution, it has not yet been isolated as a stable species. The reaction products of germanone decomposition have been studied.[252,253] Germanones are frequently invoked as transient species present in reactions.[199,254,255]

5.3.2 *Organogermanium Imines*

A number of reports of stable R$_2$Ge=NR species have appeared.[256–259] The stable germaphosphene Mes$_2$Ge=PAr has been shown to react in a 4 + 2 sense with *o*-quinones and α-diketones.[260]

5.3.3 *Organogermanium Compounds Containing Ge=Si, Ge=Ge, and Ge=Sn Bonds*

The synthesis and reactivity of germanium compounds containing double bonds to Si, Ge, and Sn has been a very active area of research over the past decade and has been extensively and recently reviewed.[1,40,261,262] Particularly striking

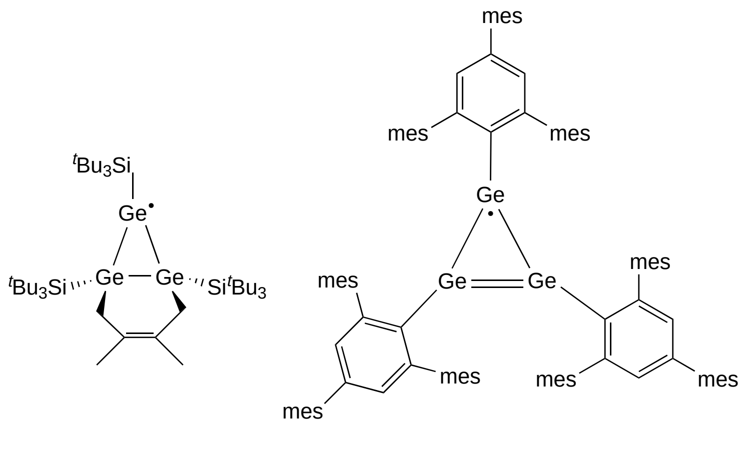


Figure 8 Stable germanium radicals based upon a germanium triangle

new examples of molecules include a hexaaryltetragermabuta-1,3-diene containing conjugated Ge–Ge double bonds,[263] a four-membered ring composed of 2 Si atoms, 2 Ge atoms, and a Ge=Ge,[264] and the synthesis of the first Ge=Sn.[265] In addition, general methods for making digermenes with mixed aryl and alkyl substituents was demonstrated.[266] Digermenes that are analogs of cyclopropenes have also been synthesized.[1,267,268]

A series of detailed mechanistic studies have been published delineating the addition reaction of carbonyl compounds, alkenes, Grignard reagents, and halocarbons to digermenes, germasilenes, and disilenes.[269–282] The preference of biradical intermediates (for disilenes) and zwitterionic intermediates (for germasilenes and digermenes) provides insight into the different reactions observed for germanium and silicon organometallics. Detailed laser pulse photolysis and ^1H Chemically Induced Dynamic Nuclear Polarization (CIDNP) studies of the photolysis of 7,8-digermabicyclo[2.2.2]octadiene have provided insight into the reverse reaction to form alkene and digermene.[283,284]

5.4 Aromatic Germanium Rings

The germanium-ring cyclopropene analogs can be oxidized to yield 2π-electron aromatic rings.[1,285–287] These compounds, $[{}^tBu_3EGe]_3{}^+[BF_4]^-$ (E = Si, Ge), are not technically organometallic compounds, as no Ge–C bonds are present; however, this remarkable discovery is included here because of the significance of this chemistry and its close relationship to the chemistry discussed in Section 5.3. These compounds can be further converted to a cationic trishomoaromatic cluster with a Ge_{10} core.[288,289]

5.5 R_3Ge Cations

Simple three-coordinate organogermanium cations, R_3Ge^+, have not yet been isolated and characterized crystallographically. There are two reports of the cations being generated in solution, $[Mes_3Ge]^+$ and $\{[(Me_3Si)_2CH]Me_2Si\}\{[4\text{-}tert\text{-}Bu\text{-}C_6H_4]_3C\}\{Me_2Si\}HCMe_2Ge^+$, and characterized by ^1H and ^{13}C NMR.[290,291] Both compounds were obtained using the $[B(C_6F_5)_4]^-$ anion. In addition to these compounds, the protonated digermyl ether, bis(trimethylgermyl)oxonium, has been studied by X-ray crystallography. The existence of a long Ge–O bond and a flattening of the pyramidal geometry around Ge are both consistent with the development of a substantial positive charge on Ge.[292] Norbornyl cations have also been generated, although these species are more realistically considered five-coordinate species.[293] Lastly, an isolable free germylium cation, $[{}^tBu_2MeSi]_3Ge^+$, has been fully characterized including by X-ray crystallography.[294] Note that like the cation three-membered rings described in Section 5.4, this compound does not contain a Ge–C bond.

5.6 Three-coordinate Germylenes

The use of the bidentate, anionic amidinate ligands has allowed the synthesis of three-coordinate germylene compounds.[247] Carbenes have been used as the ligand in the third site although this results in a very long Ge–C bond and may be best considered as an acid-based adduct.[295] In general, base-adducts of germylenes are a very well explored area of chemistry and are not being considered in this class of three-coordinate germylene complexes. The first example of a germanium(II) hydroxide was recently reported as a three-coordinate germylene.[296]

5.7 Germylenes Acting as Donors to Transition Metals

Over the past decade, several more transition metal germylene complexes with μ_1 coordination have been synthesized and characterized by X-ray crystallography for Mo,[297] W,[298,299] Rh,[300] Ir,[301] Ni,[302,303] Pd,[304] and Pt.[305] Germylenes bound in an μ_2 sense have been synthesized and characterized by X-ray crystallography for Cr,[306] Mo,[307] W,[307] Mn,[308] Fe,[309–311] Ru,[312–314] Os,[315,316] Co,[317] Rh,[318] and Pt.[314]

6 ORGANIC DERIVATIVES OF TWO-COORDINATE GERMANIUM

6.1 Organogermylenes

Substantial progress in both the synthesis and reactivity of germylenes has been made in the past decade. The development of a high-yield, convenient synthesis of $GeCl_2$•dioxane has greatly helped the field.[319] Numerous reviews have been published.[3,21,22,30,37,56,109,320]

6.1.1 Preparation of Organogermylenes

Germylenes can be made via a number of synthetic pathways including thermal or photochemical elimination reactions and redistribution reactions (see 1st edition). These methods are particularly convenient for generating germylenes that are not stable as monomers. The most flexible method for making sterically bulky, monomeric germylene is salt elimination. The reagent of choice has typically been $GeCl_2$•dioxane which is best prepared by

organosilane-based reduction of $GeCl_4$.[319] Other important synthetic methods have included alcoholysis and metathesis reactions employing $Ge[N(SiMe_3)_2]_2$ and direct reduction of R_2GeCl_2. New examples of germylenes synthesized are found for the classes of alkyl,[321] aryl,[322–324] carbodiimide,[325,326] and 1,8-di(isopropylamino)naphthalene ligands.[302]

Considerable progress has been in the area of heteroleptic germylenes. Cyclopentadienyl derivatives include $(Me_2NCH_2CH_2)Me_4C_5GeCl$,[327] Cp*GeCl, $[Cp^*GeBr]_2$ and $[Cp^*Ge][BF_4]$.[328] The use of the supermesityl ligand, $(^tBu_3C_6H_2)$, has allowed the isolation of $^tBu_3C_6H_2GeCl$, $^tBu_3C_6H_2Ge[Fe(CO)_2Cp]$, and $^tBu_3C_6H_2Ge\mu_2$-Cp*.[166] A transiently stable heteroleptic germylene was obtained by the reduction of $(Me_3Si)_3CGeBr_3$ with magnesium to yield $(Me_3Si)_3CGeBr$.[329] The germylene fragment has also been incorporated into a variety of heterocyclic frameworks containing both Ge–O and Ge–S bonds.[330] Application of the bis(2-pyridyl)bis(trimethylsilyl)methyl ligand (2-$\{(Me_3Si)_2\}$-C_5H_4N) has allowed the isolation of [Ge(2-$\{(Me_3Si)_2\}$-C_5H_4N)X] compounds (X = Cl, $CH(PPh_3)_2$).[331]

This last example fits in the general class of base-stabilized germylenes and the ligand has also been employed to make homoleptic examples.[246] Nitrogen base stabilization has been used for several other examples even allowing the rather shocking isolation of a heteroleptic germylene containing a hydroxyl as one of the ligands.[332–335] Aryl ligands containing ether functionality in the ortho position have also been developed.[334,336]

Photochemical methods have been particularly popular for generating transiently stable germylenes. Example precursors include cyclotrigermanes,[337] disiladigermacyclobutane,[338] siladigermiranes,[339] and 1,2-digermacyclobutane.[340] The electronic structure of nitrogen stabilized germylenes has been pursued experimentally using photoelectron spectroscopy as well as theoretically.[118,128]

Evidence for the formation of a surface stabilized organogermylene has also been presented.[341] Lastly, both experimental and theoretical papers have appeared describing the formation of germylene radical anions.[127,342,343]

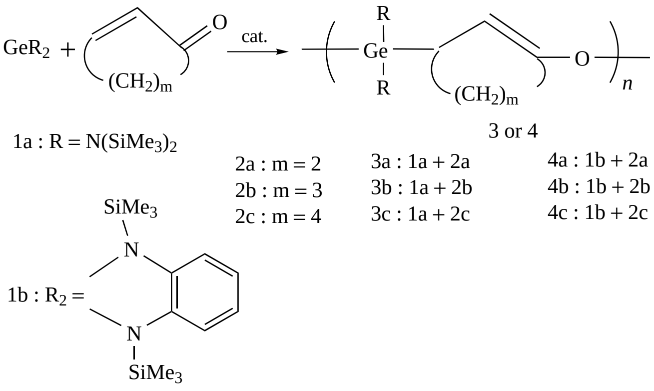
6.1.2 *Reaction of Germylenes*

Germylenes have long been known to react with multiple bonds such as C=C, C≡C, and C=O. In addition, insertion reactions into carbon halogen, O–H, and N–H bonds, are well precedented. In the last 10 years, substantial progress has been made in the reaction with C–H bonds.

Insertion of Germylenes into σ-bonds. The discussion of germylene insertion into C–X and C–H σ-bonds was presented in Sections 3.1.4 and 3.1.5. Germylene insertion into a variety of other σ-bonds is a common reaction that is been observed for E–H (Si, Ge), and M–X bonds. Selected recent examples include insertion into W–Cl[328] and Si-bonds.[337]

CH-bond Activation Using Germylenes. The discussion of CH-activation using germylenes was presented in Section 3.1.6.

Addition of Germylenes to Multiple Bonds. Addition reactions of germylenes to the C=O of para quinones typically yield alternating 2:1 polymers. An exception was noted for $Ge[N(SiMe_3)_2]_2$ which gave a 1:1 polymer upon reaction with 1,4-quinones.[344–347] Cyclic α, β-unsaturated ketones and ethylene and propylene sulfide have also been found to be excellent monomers for the formation of alternating copolymers.[348–350] Recall that related reactions with quinones and phenones noted in the Ge–C bond formation Section (3.1.7) lead to the dearomatization of the ring and the isolation of molecular products.[173] For 1,4-napthoquinone, both molecular and polymeric products have been observed (equation 8).



(8)

Reduction of Germylenes. Reduction of $Ge[CH(SiMe_3)_2]_2$ in tetrahydrofuran using a sodium mirror results in the formation the radical anion.[342] The solution changes from the yellow–orange color associated with the germylene (λ_{max} = 410 nm) to green (λ_{max} = 666 nm) and a strong 1:2:1 triplet with a hyperfine splitting a = 2.6 G appears in the EPR spectrum. Four weak satellites (a = 12.5 G) are also apparent arising from the I = 9/2 ^{73}Ge nucleus (7.61% abundance).

Reaction of Germylenes with Chalcogens. Germylenes react with elemental chalcogens or chalcogen transfer reagents to give compounds of general formula R_2GeY (Y = S, Se, Te).[351]

Reactions of Germylenes with Stabilized Radicals. The stable germylene $Ge[C_4H_4(SiMe_3)_4]$ reacts with 2 equivalents 2,2,6,6-tetramethylpiperidine N-oxide (TEMPO, -ONR'_2) to

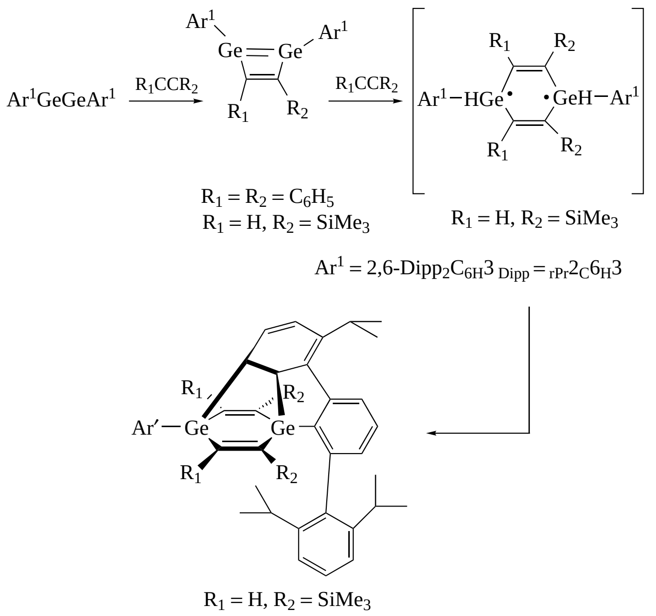
yield the addition product $(R'_2NO)_2Ge[C_4H_4(SiMe_3)_4]$.[352,353] Heating this product extrudes TEMPO, 2,2,6,6-tetramethylpiperidine, and a 1,3-digermadioxetane.

6.2 Multiple-bonded Species

6.2.1 Compounds Containing a Ge Triple Bond

The digermenium analog of an alkyne, Ar*GeGeAr* was synthesized and characterized (Ar* = C_6H_3-2,6Trip$_2$; Trip = C_6H_2-2,4,6-Pr$^i_3$) (Figure 9). The compound exhibits a trans-bent structure (Ge–Ge–C = 128.67(8)°; Ge–Ge bond 2.2850(6) Å) similar to that reported for both the Si and Sn analogs and as anticipated by calculations.[354] Cyclic voltammetry in THF displayed a reduction wave at −1.38 V and an oxidation wave at +0.7 eV. Reduction of Ar*GeCl or Ar′GeCl (Ar′ = C_6H_3-2,6-Dipp$_2$, Dipp = C_6H_3-2,6-Pr$^i_2$) yielded the neutral alkyne analogs as well as the singly reduced species (NaAr*GeGeAr* and KAr′GeGeAr′) and the doubly reduced species (Li_2Ar′GeGeAr′, Na_2Ar*GeGeAr*, and K_2Ar*GeGeAr*).[355–358] Similar compounds have also been synthesized for Sn.

Reaction with one equivalent of a diphenyl acetylene yields a stable digermacyclobutadiene. Two equivalents of the less sterically hindered alkyne $HCCSiMe_3$ react to give a unique bicyclic compound[359] (equation 9).



(9)

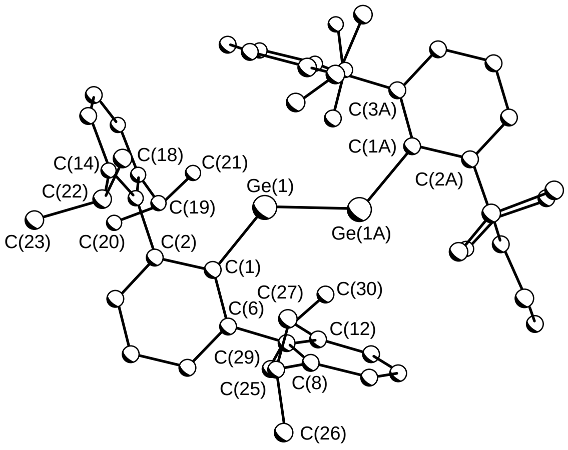


Figure 9 X-ray crystal structure of Ar*GeGeAr*

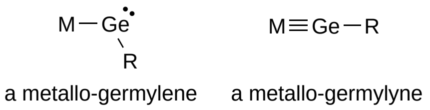

Figure 10 Lewis structures of metallo-germylene and metallo-germylyne

The Metal–germanium Triple Bond. Metal–germanium complexes with the connectivity RGe–M can be considered as germylenes containing one transition metal ligand, for example, (supermesityl)ferriogermylene, or as germylynes containing a germanium–metal triple bond (Figure 10).

A series of complexes have been reported that allow a direct comparison between these two cases.[360] The metallo-germylene complexes of Cr and W were prepared by the metathesis reaction of the requisite organometallic anion with Ge(Cl){C_6H_3-2,6-Trip$_2$} (equation 10).

$$Na[M(n^5\text{-}C_5H_5)(CO)_3]\cdot 2DME + Ge(Cl)\{C_6H_3\text{-}2,6\text{-}Trip_2\} \xrightarrow[M = Cr,\ M = W]{PhMe,\ -78\ to\ 25\,^\circ C} (n^5\text{-}C_5H_5)(CO)_3M\text{-}\ddot{G}e\text{-}C_6H_3\text{-}2,6\text{-}Trip_2 + NaCl \quad (10)$$

Subsequent thermal or photolytic loss of CO results in conversion of the metallo-germylyne complex (equation 11).

$$(n^5\text{-}C_5H_5)(CO)_3M\text{-}\ddot{G}e\text{-}C_6H_3\text{-}2,6\text{-}Trip_2 \xrightarrow[-CO;\ M = Cr,\ M = W]{reflux\ PhMe\ or\ h\nu} (n^5\text{-}C_5H_5)(CO)_2M{\equiv}Ge\text{-}C_6H_3\text{-}2,6\text{-}Trip_2 \quad (11)$$

The metallo-germylenes exhibit C–Ge–M bond angles of 117.9(3)° and 114.7(6)° for Cr and W, respectively, consistent with the presence of a stereoactive lone pair on germanium. By way of contrast, the metallo-germylynes exhibit C–Ge–M bond angles of 175.99(6)° and 170.9(3)° for Cr and W,

respectively, consistent with the linearity anticipated for a metal–germanium triple bond. The germanium–metal bond distances, 2.590(2) and 2.2767(14) Å for Cr and W respectively, are not notably different from the distance anticipated, or obtained experimentally, for comparative M–Ge single bonds. Several additional Mo and W germylyne complexes have also been synthesized and structurally characterized.[360–363] The results from density functional calculations (BP86 and B3LYP) are in good structural agreement with both the metallo-germylenes and metallo-germylynes.[364,365]

7 ORGANIC DERIVATIVES OF HYPERCOORDINATE GERMANIUM

The past decade has witnessed a substantial development of hypercoordinate germanium chemistry. The largest single class of these molecules are the pentacoordinate germatranes, $RGe(OCH_2CH_2)_3N$. Work has also progressed in making compounds in which the ligands have no geometrical constraints that help to drive the structure to a hypercoordinate state. Germanium compounds containing the Cp ligand are formally five-coordinate to each ligand when symmetrically bonded and so are included in this section. Substantial progress has been made in this area in terms of both synthesis and theory. Lastly, new germanium-containing clusters have been synthesized stabilized by bulky organic ligands.

7.1 Germatranes

Germatrane synthesis and control of the desired R′-group has most commonly been accomplished by the addition of triethanolamine to $R'GeX_3$ (X = halogen, OR, NR_2).[366–384] The use of boratrane, $B(OCH_2CH_2)_3N$, as an aprotic source of the triethanol amine ligand, has been found to be a valuable synthetic strategy.[380] Another successful strategy for variation of the R′-group has been the use of metal-catalyzed hydrogermylation reactions employing the parent germatrane, $HGe(OCH_2CH_2)_3N$.[157,385] The Ge–N transannular bond distances are typically 0.05 to 0.1 Å longer the distances obtained for the same compounds containing silicon. This is consistent with the difference in the covalent radii of the elements for these compounds.[386]

7.2 Organogermanium Complexes Containing Cyclopentadienyl and Other Five- and Six-membered Ring Aromatic Heterocyclic Ligands

Trends in the bonding preferences for Cp ligands with main group metals, including germanium, were recently reviewed.[387–389] Germanium adopts a number of different bonding modes with Cp ligands including η^2, η^3, and η^5. Compounds adopting an η^5 bonding configuration include linked di-germanocenes,[390,391] Cp^s (Cp^s = $C_5Me_4(SiMe_2Bu^t)$),[392] Cp* (Cp*=C_5Me_5),[328] and the ligands 1-methylboratabenzene, 1-dimethylaminoboratabenzene, and 2,5-di(tert-butyl)phosphoyl.[393–395] These Ge(II) compounds range from five-coordinate, for example, $[Cp^*Ge][BF_4]$,[328] to 10-coordinate, for example, $Cp^s{}_2Ge$.[392] Other recent Ge(II) compounds have exhibited substantial asymmetry in the Ge-ring bonding and are described as η^2 or η^3 structures.[328,396] For example, Cp*GeCl contains two shorter Ge–C interactions of ∼2.22 Å and three longer interactions of 2.487(3), 2.599(3) and 2.437(3) Å.

7.3 Germane σ Complexes to Transition Metals

Four-coordinate germanes can be considered hypercoordinate at germanium upon the formation of an η^2-Ge-H σ-bond to a transition metal. Such complexes have been characterized by NMR, IR for the interaction of GeH_4 and $PhGeH_3$ with $Mo(CO)(dppe)_2$ and by NMR, IR, and X-ray crystallography for the interaction of Ph_2GeH_2 with $Mo(CO)(depe)_2$ (dppe = $Ph_2PC_2H_4PPh_2$; depe = $Et_2PC_2H_4PEt_2$).[397]

7.4 Other Hypercoordinate Organogermanium Complexes

The reaction of mercaptoacetic acid with $^tBuGeCl_3$ forms pentacoordinate 2-(2-*tert*-butyl-5-oxo-1,3,2-oxathiagermolan-2-ylthio)acetic acid.[398] In this molecule, the covalent Ge–O (2.045(1) Å) and the dative Ge–O bond (2.043(1) Å) are identical within error and both only 0.16 Å longer than the sum of the covalent radii (Figure 11). The phenyl derivative can also be synthesized and both compounds can be deprotonated to yield cationic products that maintain the pentacoordinate geometry.[399] Direct metathesis reactions using Li[naccac] and $GeCl_4$ also yield pentacoordinate germanium.[400]

It has been noted that the chemical shift of ^{73}Ge NMR signals is rather insensitive to hypercoordination; however, the width of the NMR peak changes dramatically. On the basis of the width of the NMR signal, a number of germanes containing Ge–Y (Y = N, O, S) contacts that are a*ll* < 15% shorter than sum of the van der Waals radii are also assigned as hypercoordinate compounds.[141,142]

Fluorine–germanium contacts have also been noted to yield hypervalent germylene and germane species. Four such contacts are observed in $Ge[2,4,6-(CF_3)_3C_6H_2]_2$ at distances of 2.5–2.8 Å, considerably shorter than the sum of the van

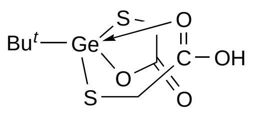

Figure 11 2-(2-*tert*-butyl-5-oxo-1,3,2-oxathiagermolan-2-ylthio) acetic acid

der Waals radii (3.66 Å) and rather longer than the sum of the covalent radii (1.86 Å).[322] Short Ge–F contacts have also been noted for organogermanes.[401]

Hypervalent germanium has also been observed in the clusters $Ge_6Ar'_2$ and $Sn_4(GeAr')_2$ ($Ar' = 2, 6\text{-}Dipp_2$; Dipp = $C_6H_3\text{-}2,6\text{-}{}^iPr_2$).[402] The Ge_6 cluster consists of an octahedron of germanium atoms with opposite vertices capped by Ar′. The capped germanium atom is bound to the phenyl carbon and to the four equatorial Ge atoms of the octahedron. The Sn_4Ge_2 cluster is also an octahedron with opposing vertices consisting of GeAr′. In this instance, the germanium is bound to the phenyl carbon and four Sn atoms.

8 POLYGERMANES

The past decade has seen considerable effort focused on developing new methods for controlling germanium catenation, probing the mechanisms of polygermane degradation, and gaining a deeper understanding of electronic properties. Ten years ago the synthetic methods known for polygermanes were Wurtz coupling (typically sodium reduction of R_2GeCl_2) and electrochemical reduction at a Mg electrode. A much wider array of synthetic approaches is now available.

8.1 Synthesis of Polygermanes

8.1.1 Kipping Method

Wurtz-coupling conditions (Kipping method) for polygermane formation was explored for R_2GeCl_2 with an emphasis on R group (R = Et, Pr, Bu, ^{i}Bu, Hex, PhMe, PhHex), salt-binding additives (hexamethylphosphoric triamide (HMPA) and 18-crown-6), order of addition, and temperature dependence.[403] Weight and number average molecular weight data, yields, and λ_{max} values are reported.

8.1.2 In Situ Generation of Germylenes

In situ generation of germylenes utilizing the reaction of GeI_2 or $GeCl_2$·dioxane with RMgX or RLi has also been employed to synthesize polygermanes.[74,403] This approach often gives improved yields, however, molecular weights (MW) are also typically lower, leading to λ_{max} values of ∼300 nm. Typical molecular weights were greater for Wurtz-coupling leading to λ_{max} values of ∼320 nm.

8.1.3 Copolymerization of Germanes

Copolymerization of germanes with differing R groups, or with silanes and stannanes, has been achieved using electrochemical methods.[404–406] The 1:1 copolymers of Ge and Si give comparable MW values ($M_n \sim 3000$, $M_w/M_n = 2.0$) and intermediate λ_{max} values of 350 nm (as compared to ∼480 nm for a comparable polysilane).[405] The λ_{max} values for mixed Ge and Sn polymers were reported to be ∼320 nm, comparable to pure polygermanes.[406]

8.1.4 Metal-catalyzed Catenation Methods

Metal-catalyzed catenation methods have also been reported. The use of the ruthenium-based catalyst $Ru(PMe_3)_2(GeMe_3)_2$, or the precatalyst $Ru(PMe_3)_4Me_2$, catalytically demethanatively polymerizes $HGeMe_3$ or Me_2GeArH at 25 °C.[407,408] M_w values range from 3000–7000 (gel permeation chromatography (GPC), polystyrene calibration) or 6000–10 100 (light scattering). Demethanative polymerization of meta or para (S)-2-methylbutylphenyldimethygermane yield optically active polygermanes exhibiting a preferential screw sense helicity.[409] Dehydrogenative methods have also been pursued. Treatment of Cp_2ZrCl_2 or $CpCp^*ZrCl_2$ with two equivalents of BuLi followed by the addition of $PhGeH_3$ provides polyphenylgermanes.[410] SmI_2 has been employed to polymerize Et_2GeCl_2 giving low-molecular weight, M_w = 1500–2400, and a corresponding higher energy λ_{max} value of ∼290 nm.[411] Initial species in a Pt-based dehydrogenative coupling were reported for the reaction of $(Et_3P)_2PtGe[N(SiMe_3)_2]_2$ with H_2GePh_2.[412]

8.1.5 Characterization of Polygermanes and Related Species

Variable-temperature Raman spectroscopy has been used to explore the structure of polygermanes.[413] Ultraviolet photoelectron spectroscopy has been employed to characterize the Ge–Ge backbone bonding.[414] Additional, ^{73}Ge NMR spectra have been taken of key precursors for dehydrogenative polymerization, $ArGeH_3$, Ar_2GeH_2, and Ar_3GeH.[415]

8.2 Degradation of Polygermanes

Polygermanes are photosensitive, particularly in the presence of oxygen.[407,416] Ge–Ge bond cleavage to yield digermoxanes, polygermyl radicals, and germylenes has been reported.[416–418] Theoretical calculations suggest that homoleptic (1,2)-translocations of germyl groups is an unlikely mechanistic step in these degradation processes.[419]

8.3 Electronic and Optical Properties and Applications of Polygermanes

Electronic charge transport has been measured for $(PhMeGe)_n$ with M_w values of 2000 and 5700, M_w/M_n

values of 1.3 and 1.4 respectively, and λ_{max} values of 324 and 325 respectively. These materials have a mobility of about 10^{-5} cm^2/Vs.[420] Calculations of electron density for small oligomers of radical anions ($n = 3-7$) of polygermanes suggest the electrons are primarily located in orbitals associated with germanium atoms.[421]

Optical tuning of polygermanes and mixed polysilane/polygermane systems have been discussed.[422] Nonlinear optical effects are of particular interest. Third-order nonlinear susceptibilities (χ^3) for thin films of oligo- and polygermanes have been measured.[423] A χ^3 value of 86×10^{-12} esu was obtained for copoly(methylphenylsilylene/methylphenylgermylene)[424]

Optically-induced degradation has been employed to write GeO_2 and GeC lines starting from polygermane thin films.[425] Photoinduced electron transfer from $(MePhGe)_n$ to C60 has also been explored.[426]

9 BIOLOGICAL ACTIVITY OF ORGANOGERMANIUM COMPOUNDS

A number of reviews have appeared in the past decade regarding the biological activity of organogermanium compounds.[47,84,85,88,427,428] Although organogermanium compounds exhibit many types of biological activity, including analgesic, antimalarial, antitumor, antiviral, bactericidal, fungistatic, hypotensive, immunomodulating, interferon-inducing, radioprotective modalities, no natural role for germanium is known in human biology.

Over the past decade there has been increasing interest in nutritional supplements including those containing germanium. In fact, the leading supplement sold contains 2-carboxyethylgermasesquioxane and is typically solid as Ge-132, propagermanium, or SK-818. In light of this interest in germanium supplements, the United States Food and Drug Administration issued a report in 1997, which summarizes both human and animal studies.[429] Quoting from the report: ‘evidence of Ge-132 toxicity is incomplete; nephrotoxicity was shown in some studies and not in others. However, Ge-132 has also been shown to accumulate, although to a lesser degree than the dioxide, in kidneys, liver, spleen, and other tissues’. By way of comparison, animal studies clearly show that GeO_2 is nephrotoxic and numerous cases of renal failure have been reported related to taking germanium supplements containing GeO_2. The synthesis of Ge-132 starts from GeO_2 and the oxide is a typical impurity. For these reasons, the report concludes that ‘germanium products present a potential human health hazard’.

9.1 Germanium-containing α-amino Acids and Peptides

The (R)- and (S)-enantiomers of β-(trimethyl)germyl)alanine were treated with (fluoren-9-yl)methyl chloroformate to give N-Fmoc-protected amino acids to be used as building blocks in solid-phase peptide synthesis.[430–432] The decapeptides Ac-D-Nal^1-4-Cl-D-Phe^2-D-Pal^3-Ser^4-Me$_3$El-Ala^5-D-Cit^6-Leu^7-Arg^8-Pro^9-D-Ala^{10}-NH$_2$ (El = C, Si, Ge) were prepared and studied for in vivo and in vitro efficacy as GnRH antagonists. Both the Si and Ge derivatives exhibited enhanced testosterone and luteinizing hormone (LH) suppression as compared to the carbon analog.

9.2 Applications to Cancer and Other Human Diseases

A number of organogermanium derivatives have been prepared and tested for anticancer activity.[433–436] Studies to test efficacy against a number of other diseases have also been explored.[372,430–432,437–439] In particular, the dramatic claim has been made that 2-carboxyethylgermasesquioxane (Ge-132) inhibits the Maillard reaction which is responsible for the glycation of proteins in vivo.[440] Protein glycation by this reaction may be related to diseases such as diabetes and Alzheimer’s disease.

9.3 Applications as Insecticides and Antibacterial Agents

Organogermanium species have also been explored for biological activity as insecticide and antibacterials agents.[441] Typically, the hope is that they will maintain activity and be less toxic than existing tin-based reagents.

10 CONCLUSIONS AND FUTURE PROSPECTS OF ORGANOGERMANIUM CHEMISTRY

The first edition concluded with the statement that ‘smaller scale applications in organic synthesis may be envisioned…’. Progress in this direction over the last decade has been substantial in terms of the development of CH-insertion and activation reactions involving germanium and the substantial progress made in terms of Pd/Ge-mediated C–C coupling chemistry. Methods developed for the facile incorporation of germanium into polymers may also prove of substantial importance. Continued progress in these areas can be anticipated.

Substantial progress has also been made in the area of transition metal complexes containing germanium ligands. The metal–germanium bond nexus has been shown to be active to a variety of small molecule activations and to undergo facile reaction in the formal $2 + 2$ sense.

The community has increasingly recognized the importance of radicals in organogermanium chemistry over the past decade. Both the synthesis and characterization of stable radicals and the recognition of the importance of radical mechanisms have dramatically altered the way the chemistry of

organogermanium compounds is viewed. Continued efforts in understanding the role of radicals will be critical to uncovering the mechanistic aspects of organogermanium reactions.

1 INTRODUCTION

Gold is one of the most noble of the metals (the electrochemical potential is the lowest for any metal) and has a unique position among elements in the periodic table. Further, gold is the most electronegative of all the metals (on Pauling scale) and can easily be reduced to Au^-. Similarly, the inorganic and coordination compounds of gold are unique and have displayed exceptional properties like the ability to form Au–Au and metal−gold bonds in clusters, and to form complexes in oxidation states from (−I) to (+V), often with unusual stereochemistry. The linear two-coordinate gold(I) compounds and the square-planar four-coordinate gold(III) complexes are ubiquitous in gold chemistry.[1–5]

2 BONDING IN GOLD(I) AND GOLD(III) COMPLEXES

Molecular orbital (MO) calculations suggest that the bonding in linear gold(I) complexes involves mostly the $5d_z^2$ and 6s orbitals. However, sp hybridization, without the involvement of 5d orbitals, is commonly used to interpret ^{197}Au Mössbauer and magnetic circular dichroism (MCD) spectra of gold(I) complexes. In square-planar gold(III) compounds, the $5d_{x^2-y^2}$,6s,6p_x,6p_y orbitals are used. The gold(I) and gold(III) complexes in their most common stereochemistry, therefore, have 14 and 16 valence electrons, respectively. Most gold complexes are coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*).

3 RELATIVISTIC EFFECTS

The position of gold in the periodic table is such that the *Relativistic Effects* are at a maximum.[6] Many of the anomalous properties of Au, as compared to Ag and Cu, are ascribed to such effects.[7,8] The relativistic effect strongly stabilizes the 6s orbitals, stabilizes the 6p levels to a lesser extent, and destabilizes the 5d levels. The initial resistance of gold to oxidation, its greater extent of oxidation once oxidized, higher melting point, yellow color of gold, and smaller metallic and ionic radii as compared to silver may be attributed largely to the relativistic effect.[9,10] The common occurrence of Au–Au bonds in complexes, the shorter and stronger bonds formed by Au compared to Ag, and the higher ionization energy and electron affinity (EA) of gold can as well be explained in terms of the relativistic contraction of the 6s orbital of Au.

The tendency of gold(I) to form linear two-coordinate complexes can be explained by the large 6s → 6p energy separation caused by relativistic effects of gold. The low 5d → 6s separation of gold, which is also caused by relativistic effects, is responsible for the stabilization of the higher oxidation states +III and +V for gold with respect to Ag and Cu. Gold(0) has the electronic configuration $[Xe]4f^{14}5d^{10}6s^1$; for Au^+, it is $[Xe]4f^{14}5d^{10}6s^0$, and for Au^-, $[Xe]4f^{14}5d^{10}6s^2$. From these electronic configurations, the predominance of the metallic form of gold, Au^0, is not obvious, but it can be explained through consideration of the relativistic effects.

Although relativistic effects contribute to the instability of AuF with respect to AuF_3 and Au, its stability has been predicted and AuF has been shown to exist.[11] The gold(III) halides follow the stability order AuF_4^- >

$AuCl_4^- > AuBr_4^- > AuI_4^-$. The relativistic enhancement of the dissociation energy decreases from AuF_4^- to AuI_4^-.[8]

4 AUROPHILICITY

Many molecular gold complexes pack in their crystal lattice in such a way that there are short intermolecular Au···Au contacts.[12] The intermolecular attractive forces between gold atoms are weak but important in determining structures in the solid state. The phenomenon is most marked for gold and is especially significant for two-coordinate gold(I) centers, and the interactions invariably occur perpendicularly to the molecular axis.[13–15] The effect is called *aurophilicity*. The aggregation occurs with $Au^I \cdots Au^I$ distances between 2.7 and 3.3 Å (the estimated van der Waals distance being 3.60 Å). The estimated bond energy for the $Au^I \cdots Au^I$ interaction is 7–12 kcal mol^{-1}, which is of the same order of magnitude as the hydrogen-bond energy.[16–18] Examples will be found throughout this article.

5 ISOLOBAL ANALOGY

The structures of some heteronuclear transition metal–gold compounds containing $[Au–PR_3]^+$ fragments are very similar to those of the related hydrido complexes. Further, the $[Au–PR_3]$ positions in the compounds have been proposed as evidence for the location of hydrido-ligand positions in hydride analogs. The $[Au–PR_3]^+$ cation is isolobal with H^+.[19] The hydrogen atom uses its 1s orbital, and the $[Au–PR_3]^+$ group mostly uses the 6s orbital of gold in bonding. This isolobal analogy between H^+ and $[AuPR_3]^+$ has been found to be very useful in rationalizing the synthesis and structures of many of these compounds.[20] Some well-known isolobal pairs of complexes are $[Co(CO)_4(AuPPh_3)]$ and $[Co(CO)_4H]$, $[Mn(CO)_5(AuPPh_3)]$ and $[Mn(CO)_5H]$, and $[Fe(CO)_4(AuPPh_3)_2]$ and $[Fe(CO)_4H_2]$. However, a strict relationship fails in some cases where two or more $[AuPPh_3]^+$ groups are present, there being a marked tendency to form Au–Au bonds in such compounds. The $Au_2(PPh_3)_2$ species present in clusters are sometimes considered as isolobal models of dihydrogen complexes. This analogy is further extended[21] between H_3^+ and $[Au_3(PR_3)_3]^+$.

6 GOLD IN OXIDATION STATE −I

The relatively high electron affinity of Au (EA = 2.3 eV) suggests that Au could behave as a pseudohalogen in forming negatively charged ions. In addition, Au^- (electronic configuration [Xe] $4f^{14}5d^{10}6s^2$) is isoelectronic with Hg^0. A few alkali metal aurides M^+Au^- are known (M = Na, K, Rb & Cs). Gold in Cs^+Au^- is present as the Au^- ion.[4] The ionic salt Cs^+ Au^- has the CsCl lattice structure. Metallic gold dissolves in anhydrous liquid NH_3 containing Cs, Rb, or K ro form Au^- in solution. $BaAu_2$ is a semiconductor and has AlB_2-type crystal structure with Au–Au distance of 2.77 Å.[22] The tetramethylammonium auride is found to be isostructural with $(Me_4N)Br$.[23] The auride ion is also found in M_3AuO (M = K, Rb, Cs), aurideaurates $Cs_7Au_5O_2$, which is, in fact, $(CsAu)_4(Cs_3AuO_2)$, and $Rb_5Au_3O_2$, which is $(RbAu)_2(Rb_3AuO_2)$ containing Au^{-1} and Au^I ions.

7 GOLD IN ZERO OXIDATION STATE

In the gas phase, gold exists largely as Au_2 molecules with d(Au–Au) = 2.50 Å and D_0(Au–Au) = 221 kJ mol^{-1}. The simplest gold(0) complex is $[Ph_3PAuAuPPh_3]$.

8 GOLD(I) COMPLEXES

The most common oxidation states for gold are I and III. In general, Au^{III} is favored with hard ligands and Au^I with soft ligands. Au^I complexes are diamagnetic. The majority of Au^I compounds have a coordination number of two with linear geometry. However, compounds with trigonal planar and tetrahedral structures are also known. The compounds of the type $[X(Au\{PR_3\})_n]$, where X = O, S, Se, Cl, Br, I, N, P, As, C, and so on, with $n > 1$ will be discussed in Section 15.

Simple neutral Au^I halides, AuX (X = Cl, Br, I), are all polymers with bridging halide ligands. The complex ions $[AuX_2]^-$, disproportionate in aqueous solution according to equation (1), where X = Cl, Br, or SCN, are stable when X = CN. The ions $[AuX_2]^-$ can be stabilized in the presence of excess of halide or pseudohalide ions.

$$[Au^IX_2]^- \longleftrightarrow [Au^{III}X_4]^- + 2Au + 2X^- \qquad (1)$$

Chloro(carbonyl)gold(I), [AuCl(CO)], is prepared in quantitative yield by the reaction of anhydrous Au_2Cl_6 with CO at atmosphere pressure (equation 2).[24] With insufficient carbon monoxide, Au_4Cl_8 is the product (equation 3). Anhydrous Au_2Cl_6 is itself prepared *in situ* by dehydration of $H[AuCl_4]\cdot 3H_2O$ with thionyl chloride as solvent (equation 4).

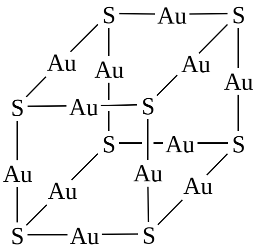
$$[Au_2Cl_6] + 2CO \longrightarrow 2COCl_2 + 2[AuCl(CO)] \qquad (2)$$

$$2[Au_2Cl_6] + 2CO \longrightarrow 2COCl_2 + [Au_4Cl_8] \qquad (3)$$

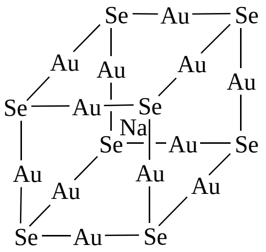
$$H_3O^+ + [AuCl_4]^- + SOCl_2 \longrightarrow 3HCl + SO_2 + \tfrac{1}{2}[Au_2Cl_6] \qquad (4)$$

An interesting gold polysulfide anion $[Au_{12}S_8]^{4-}$ has been prepared[25] by dissolving Au_2S, Au_2S_3, or $[AuCl_4]^-$ in aqueous Na_2S and has been isolated as the Ph_4As^+ salt. The cubane-like anion (**1**) has sulfur atoms at the corners of a cube and Au^I atoms at the center of each edge. In a similar selenium analog (**2**), a sodium ion is encapsulated

at the center of the cube and Na^+ is bonded to all gold atoms (Na $\cdots$ Au = 3.327(3)–3.467(3) Å). The volume of the sulfur cluster is 12% smaller than the selenium analog (98 vs 111 Å^3), and, hence, the sodium anion cannot be included inside the cage.[26] This inorganic cryptand complex anion $[NaAu_{12}Se_8]^{3-}$, (**2**), is prepared from a mixture of AuCN, Na_2Se, and Et_4NCl.



(**1**)



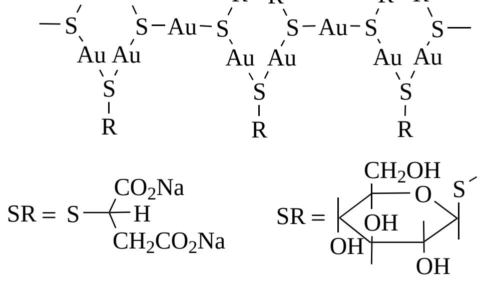
(**2**)

The thioether complexes of the type $[AuCl(SR_2)]$ are useful synthetic intermediates and prepared by the reaction of $[AuCl_4]^-$ with the corresponding dialkylsulfide according to equation (5).

$$[AuCl_4]^- + 2R_2S + H_2O \longrightarrow [AuCl(SR_2)] + R_2SO + 2H^+ + 3Cl^- \qquad (5)$$

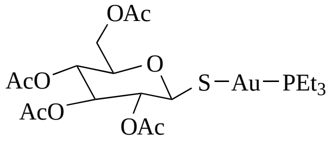
The water-soluble gold–thiourea complex cation $[Au\{S{=}C(NH_2)_2\}]^+$ is useful in the extraction of gold from its ore.

Thiolate compounds of gold(I) have been studied extensively due to their applications in crysotherapy (the treatment of rheumatoid arthritis by gold drugs)[27–30] and in gold coating processes. Gold(I) sodium thiomalate (Myochrysin) (**3**) and gold(I) thioglucose (Solganol) (**4**) have been used for many years, but 2,3,4,6-tetra-O-acetyl-1-β-1-thio-β-D-pyranosato-S-(triethylphosphine)gold(I) (Auranofin or Ridaura) (**5**) has been found to be more effective since it can be given orally. The X-ray structure of the Auranofin (**5**) shows[2] that Au^I has linear two-coordinate geometry with S–Au–P = 173.6°. The structures[27–31] of Myochrisin and Solganol are polymeric with thiolate bridging as shown in (**3**), with R = malate, or (**4**) with R = glucose.



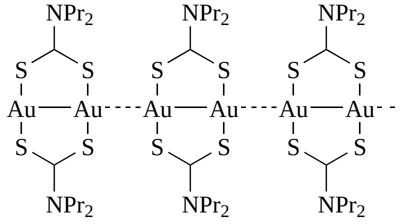
(**3**) (**4**)

Gold(I) forms dinuclear complexes with N,N-dialkyl dithiocarbamates, O,O'-diisopropyl dithiophosphate, and

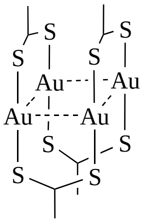


(**5**)

dithio-phosphinates. In the solid state, the dinuclear units are further associated by intermolecular Au–Au interactions to form chains. The intramolecular and intermolecular Au–Au distances in these complexes range from 2.76–3.10 Å and 3.05–3.40 Å respectively, compared to the Au–Au distances of 2.768 Å in metallic gold. A typical structure of a dithiocarbamate is shown as (**6**).



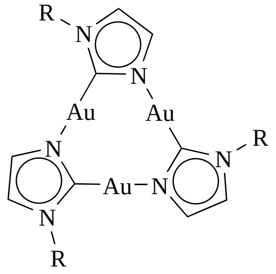
(**6**)



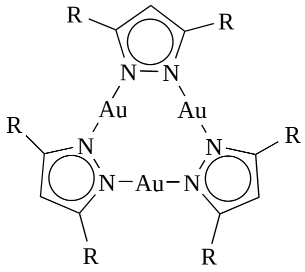
(**7**)

The reaction between $AuCl_4^-$ and dithioacetic acid gives the tetramer $[Au(S_2CMe)]_4$. The molecular structure consists of a square of gold atoms with the dithioacetato ligands bridging above and below the Au_4 plane as shown in (**7**).

The compound $[Me_3P{-}Au{-}OSiMe_3]$ is volatile and sublimes in vacuo. At 190 °C, it decomposes to form a gold mirror and $(Me_3Si)_2O$, Me_3PO, and Me_3P. Another volatile gold compound, $[Me_3P{-}Au{-}N(SiMe_3)_2]$, melts at 35–37 °C, and the liquid can be distilled under vacuum without decomposition.[32] Some gold complexes with ligands containing additional N-donor sites, such as benzylimidazolates (**8**), pyrazolates (**9**), and carbeniates (**10**), are trimers in the solid state and stacked with short Au^I–Au^I contacts. Irradiation with ultraviolet (UV) light causes the crystals of (**8**) to emit red light. A yellow burst of light was observed when a drop of dichloromethane solvent was placed upon the irradiated crystals of (**8**) ('solvoluminescence').[33]

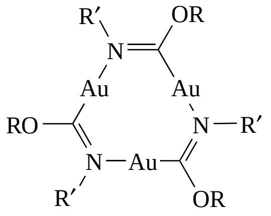


(**8**)



(**9**)

A great number of Au^I complexes with monodentate phosphine, arsine, and stibine ligands of the type $[R_3Y{-}Au{-}Cl]$



(**10**)

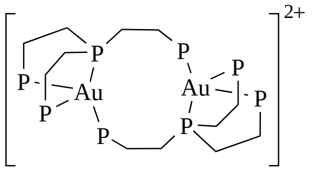
are known. They are easily prepared from the reaction of $[AuCl_4]^-$ with the appropriate tertiary phosphine, arsine, or stibine, R_3Y (equation (6)).

$$[AuCl_4]^- + 2R_3Y \longrightarrow [R_3Y\text{–}Au\text{–}Cl] + R_3YCl_2 + Cl^- \qquad (6)$$

With excess phosphine, Au^I forms complexes of the type $[Au(PR_3)_n]^+$ ($n = 2$, 3, or 4). The maximum coordination number is dependent on the bulk of the phosphine. For example, when $L = P(C_6H_{11})_3$, only $[AuL_2]^+$ is observed in solution. For $L = PBu_3$ or $P(tol)_3$, $[AuL_2]^+$ and $[AuL_3]^+$ are found, and, when $L = PEt_3$ or $P(OEt)_3$, $[AuL_2]^+$, $[AuL_3]^+$, and $[AuL_4]^+$ are detected in solution.

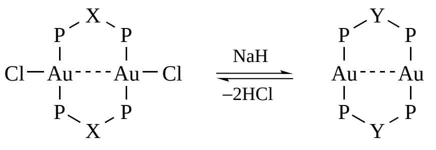
$[AuCl(PPh_3)]$ reacts with excess of phosphine to form $[AuCl(PPh_3)_2]$ and $[AuCl(PPh_3)_3]$. The structures are distorted trigonal planar and tetrahedral, respectively, with coordinated chloride ion. For the same stoichiometry, Au^I in $[Au(PCy_3)_2](SCN)$ has two-coordinate linear geometry, and in $[Au(PPh_3)_2(SCN)]$ has trigonal planar structure, the difference clearly being due to different steric effects of the phosphine ligands. Distorted tetrahedral structures have been reported for $[Au(PPh_3)_3X]$ (X = Cl or SCN), with the Au–X bonds much longer than Au–P, whereas a regular tetrahedral geometry is found for Au^I in $[Au(PPh_2Me)_4]^+$.

In the dinuclear complex $[Au\{P(CH_2CH_2PPh_2)_3\}]_2Cl_2$, (**11**), each gold atom is tetrahedral, and the Au–Au distance of 6.199 Å is clearly nonbonding.[34]



(**11**)

Bidentate phosphines such as $Ph_2PCH_2PPh_2$ or $Ph_2PNHPPh_2$ form cyclic dinuclear complexes with gold(I). These complexes can be deprotonated[35] with strong bases to give the corresponding methanide or amide complex as shown in equation (7).



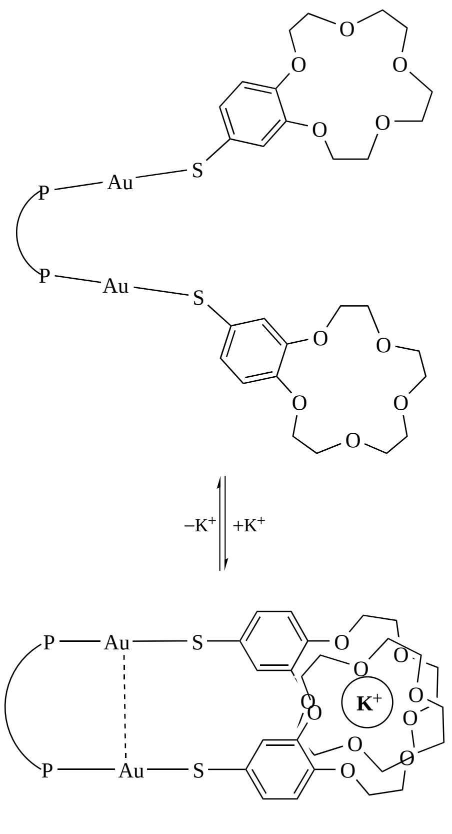
(7)

X = CH_2 or NH; Y = CH or N

Several dinuclear or oligomeric gold(I) complexes as well as gold–metal (M = Ir, etc.) heterobimetallic gold(I) complexes are luminescent with λ_{max} ranging from 465 to 593 nm and excited state lifetimes ranging from 1 to 24 μs in the solid state as well as in solution.[36–38] This photoemission property has been attributed to the Au–Au or Au–M interactions. Molecular orbital calculations carried out on the compound $[Au_2(\mu\text{-}H_2PCH_2PCH_2)_2]^{2+}$ showed the Au–Au σ^* highest occupied molecular orbital (HOMO) has 78% Au character; of this 41% is from the 6s orbital and 41% is from the $5d_{z^2}$ orbital.[39] Gold–heterometal clusters have attracted as candidates for optoelectronic materials as they show interesting optical properties, including phosphorescence.[40]

A few mononuclear Au^I compounds have been found to photoluminesce in the solid state but not in solution. The lowest energy band in the absorption spectrum of $[Au_2(\mu\text{-}dmpm)_2]^{2+}$, which is reported to be luminescent in the solid state, has been assigned by using circular dichroism (CD) spectra to the transition $\sigma(p_z) \leftarrow \sigma^*(d_{z^2})$.[41] However, the compound $[Au_2(\mu\text{-}dcpe)_3](PF_6)_2$, which has no Au–Au contact, emits in the solid state as well as in acetonitrile solution ($\lambda_{max} = 508$ nm, $\tau = 21.5(5)$ μs), indicating that Au–L bonding is also a factor to be considered in Au^I photophysics.[42]

A series of dinuclear gold(I) thiolate complexes with crown ether pendants has been successfully employed to switch on and off the Au–Au interactions (shown in equation (8)), and, hence, the photoemission induced by ion-binding, which provides a new strategy for the design of chemosensors and luminescence signaling.[43,44]



(8)

Perhaps the most stable complex formed by gold(I) is the linear $[Au(CN)_2]^-$.[1] In aqueous solution, the stability constant, K, has been estimated to be $\sim 10^{39}$ for the reaction of equation (9).

$$Au^+ + 2CN^- \longrightarrow [Au(CN)_2]^- \qquad (9)$$

This cyanide complex is used in the extraction of gold from its ore. Gold present in the ore dissolves in alkali cyanide in the presence of compressed air according to equation (10).

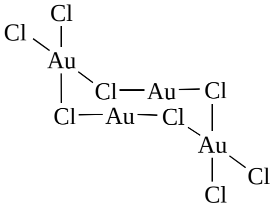
$$4Au + 8CN^- + O_2 + 2H_2O \longrightarrow 4[Au(CN)_2]^- + 4OH^- \qquad (10)$$

The cyanide solution is further filtered and purified, and gold can then be precipitated with zinc (equation (11)).

$$[Au(CN)_2]^- + Zn \longrightarrow [Zn(CN)_4]^{2-} + 2Au \qquad (11)$$

9 GOLD(II) COMPLEXES

Many complexes that appeared to be Au^{II} based on their empirical formulae are really mixed oxidation state Au^I–Au^{III} complexes. A number of well-characterized examples are given in Table 1. Electron spectroscopy for chemical analysis (ESCA), ^{197}Au Mossbauer spectroscopy, and single-crystal X-ray structure analyses have been used to distinguish these mixed oxidation state complexes from true Au^{II} complexes. The compound '$AuCl_2$' was shown to be a mixed Au^I–Au^{III} tetrameric cyclic complex $[Au_4Cl_8]$ (**12**) by X-ray structure analysis.

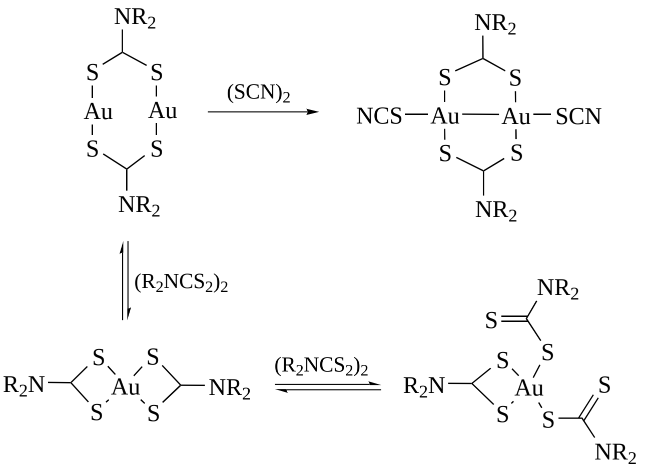


(**12**)

The electronic configuration of Au^{II} is $[Xe]4f^{14}5d^9$, and, hence, the mononuclear gold(II) complexes are paramagnetic

Table 1 Some apparent gold(II) complexes

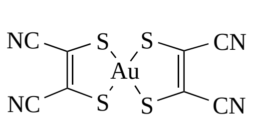
Formula	Correct formulation
AuO	$Au^IAu^{III}O_2$
AuS	$Au^IAu^{III}S_2$
AuSe	$Au^IAu^{III}Se_2$
$AuSO_4$	$Au^IAu^{III}(SO_4)_2$
$CsAuBr_3$	$Cs_2[Au^IBr_2][Au^{III}Br_4]$
Au(maleonitriledithiolate)PPh_3	$[Au^I(PPh_3)_2]^+$ $[Au^{III}$(maleonitriledithiolate)$_2]^-$
(n-Bu_2NCS_2)AuCl	$[(n\text{-}Bu_2NCS_2)_2Au^{III}]^+$ $[Au^ICl_2]^-$

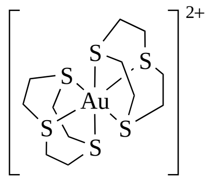


Scheme 1

and have deep color similar to Cu(II) compounds. They have a strong tendency to disproportionate to give Au^I and Au^{III} or to form a dinuclear complex containing a Au–Au bond. Hence, mononuclear Au^{II} compounds are rare. The first evidence for mononuclear Au^{II} complexes was obtained from electron spin resonance (ESR) studies[4] of the reaction mixture in Scheme (1), in which oxidation of $[Au_2(\mu\text{-}S_2CNR_2)_2]$ by $(R_2NCS_2)_2$ to give $[Au(S_2CNR_2)_3]$ was shown to proceed by way of the paramagnetic gold(II) complex $[Au(S_2CNR_2)_2]$. Gold(II) intermediates have been proposed for many redox reactions involving Au^I–Au^{III} interconversions, but they cannot usually be detected by ESR.

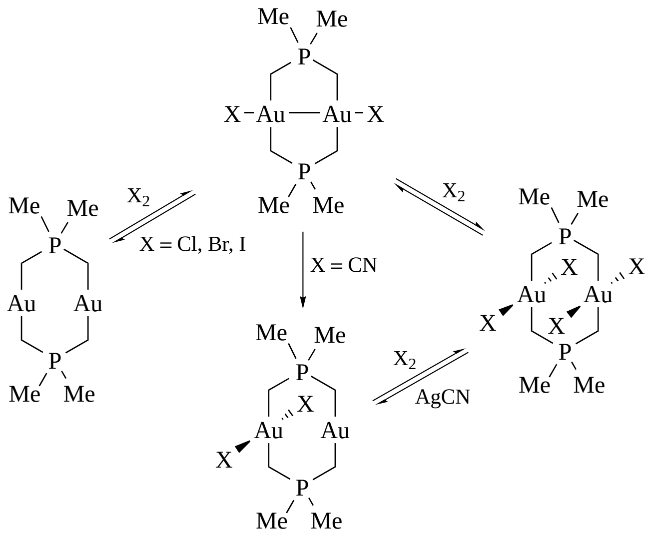
The crystallographically characterized, neutral, and air-sensitive complex of gold(II), $[Au\{S_2C_2(CN)_2\}_2]$ (**13**), which contains the maleonitriledithiolate ligand, has square-planar geometry. An air-stable octahedral Au^{II} complex $[AuL_2](BF_4)_2$ (L = 1, 4, 7-trithiacyclononane) (**14**) is obtained from the reaction of $K[AuCl_4]$ with L.[34]





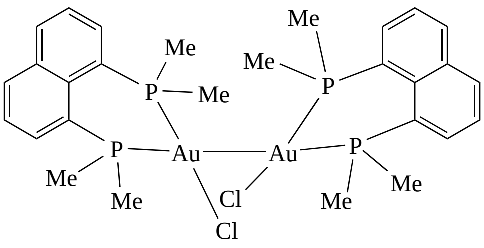
(**13**) (**14**)

The gold(II) compounds without Au–Au bonds are in general prepared by reduction of Au^{III}.[45] There are several dinuclear gold(II) complexes with Au–Au bonds. They are obtained from the corresponding gold(I) complexes by oxidative addition reactions as shown in Scheme (2). In a special case, both the Au^{II}–Au^{II} and $Au^I \cdots Au^{III}$ isomeric products were isolated.[46]



Scheme 2

Several dinuclear units have been assembled to form linear Au_5^{9+} and Au_6^{10+} complexes. However, they were shown to be Au^I–Au^{III} mixed-valent compounds.[45] The normal Au^{II}–Au^{II} distances are in the range 2.5–2.7 Å. The only binuclear gold(II) complex (**15**) with unsupported Au^{II}–Au^{II} bond has been shown to possess interesting photophysical and thermal redox properties.[47]

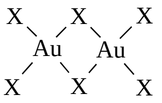


(**15**)

10 GOLD(III) COMPLEXES

All known Au^{III} compounds are diamagnetic ([Xe]$4f^{14}5d^8$ low-spin configuration), and the large majority have square-planar geometry. However, Au^{III} complexes with coordination number five or six are also known.

Gold reacts directly with all the halogens. With chlorine, gold forms AuCl or Au_2Cl_6 depending on the reaction conditions. Liquid bromine reacts with gold powder to form dark red-brown Au_2Br_6. Bright golden yellow AuF_3 can be conveniently produced by reacting either gold(III) chloride or gold powder with fluorine at high temperature. Gold(III) bromide and chloride are both dimeric in the solid state



(16)

as shown in (**16**), whereas the fluoride is polymeric with a helical structure.

Gold metal dissolves in aqua regia or in a mixture of HBr and HNO_3 to give tetrachloroauric(III) acid, H[$AuCl_4$], or tetrabromoauric(III) acid, H[$AuBr_4$], respectively. These strong acids give salts with bases. The $[AuCl_4]^-$ and $[AuBr_4]^-$ ions have regular square-planar geometry both in the solid state and in solution. The halide ligands in these complex anions are easily substituted by other ligands such as NO_2^-, N_3^-, I^-, or SCN^-. The reactions proceed by way of five-coordinate intermediates.

The tetraethylammonium salt of the $[AuI_4]^-$ anion has been prepared by reaction of (Et_4N)[$AuCl_4$] with anhydrous liquid HI. However, $[AuI_4]^-$ is unstable and easily reduced to $[AuI_2]^-$. Au(CO)X (X = Cl, Br) may be obtained by the reaction of AuX_3 with CO as shown in equation (12).

$$AuX_3 + 2CO \longrightarrow Au(CO)X + COX_2 \qquad (12)$$

On oxidation with halogens, the $[Au(CN)_2]^-$ ion forms *trans*-$[Au(CN)_2X_2]^-$ (X = Cl, Br, I). The cyanide complex anion, $[Au(CN)_4]^-$, is prepared by the exchange reaction between $[AuCl_4]^-$ and CN^- ions. The square-planar $[Au(CN)_4]^-$ anion further reacts with cyanide ions in aqueous solution to form $[Au(CN)_5]^{2-}$ and $[Au(CN)_6]^{3-}$ ions.

The nitrogen-donor complexes of gold(III) are usually formed by the displacement of chloride in H[$AuCl_4$] by nitrogen-donor ligands. The complex $[Au(NH_3)_4](NO_3)_3$, for example, is obtained by bubbling gaseous ammonia into an aqueous solution of H[$AuCl_4$] and ammonium nitrate.

The amine complexes of Au^{III} are acidic (pKa 2.2 to 7.5) in nature. The acidity increases with the degree of substitution at nitrogen. The weakening of N–H bonds in amine complexes of gold(III) has been attributed to the high polarizing power of Au^{III}. The ethylenediamine complex $[Au(en)_2]^{3+}$ reacts with chloride ions to form the complex cation $[AuCl_2(en)_2]^+$, which has a distorted octahedral geometry in the solid state.

Au^{III} forms distorted square-pyramidal complexes with 2,2′-biquinolyl and 2,9-dimethyl-1,10-phenanthroline ligands.

The complexes of the type [$AuX_3(PR_3)$] are synthesized by oxidation of [R_3PAuX] with halogen. The complexes [$AuX_nX'_{3-n}(PR_3)$], in which X and X' are different halogens, formed in this way exist as mixtures containing all possible values of n and all possible isomers.

Four-, five-, and six-coordinate Au^{III} compounds $[AuL_2]^{3+}$, $[AuClL_2]^{2+}$, and $[AuCl_2L_2]^+$ have been isolated for the ligand L = diphos. The distorted octahedral complex $[AuI_2(diars)_2]^+$ is isolated from redox reactions between I_2 and $[Au(diars)_2]^+$.

A dinuclear selenide complex anion $[Au_2(\mu\text{-}Se)_2(Se_4)_2]^{2-}$ is the product of the reaction[48] between $[AuCN]_n$ and Na_2Se_5. Square-planar gold(III) complexes are readily formed by a variety of bidentate sulfur-donor ligands such as toluene-1,2-dithiolate, maleonitriledithiolate, and dithiocarbamate. On oxidation with Cl_2 or Br_2, $[\{Au(S_2CNR)_2\}_2]$ forms $Au^I{-}Au^{III}$ complexes, which may be oxidized further to an Au^{III} complex.

Gold(III) has been found to catalyze various organic reactions including Diels-Alder due to its Lewis acidic properties.[49,50]

11 GOLD(IV) COMPLEXES

Gold(IV) complexes are very rare. The only monomer $[Au(bdt)_2]$ characterized by X-ray analysis was found to be square planar. This Au^{IV} compound was prepared from the corresponding Au^{III} anion by one-electron oxidation in an electrochemical cell as shown in equation (13).

$$[(C_5H_9)_4N][Au(bdt)_2] \xrightarrow{-e^-} [Au(bdt)_2] \quad (13)$$

Another Au^{IV} compound, AuL_2 (where L is a dithiolate ligand, 5,6-dihydro-1,4-dithio-2,3-dithiolate), is a dimer in the solid state and has no ESR spectrum due to its dimeric nature, which is maintained in solution.

12 GOLD(V) COMPLEXES

Only fluoride compounds of Au^V are known, and they all have octahedral stereochemistry as expected for a d^6 metal ion. Reaction between AuF_3, fluorine, and XeF_2 yielded the first gold(V) complex $[XeF_{11}][AuF_6]$ (equation (14)).

$$2XeF_2 + AuF_3 + 5F_2 \longrightarrow [Xe_2F_{11}][AuF_6] \quad (14)$$

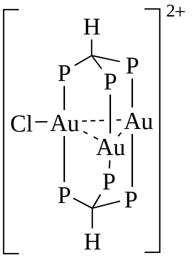
The anion $[AuF_6]^-$ has distorted octahedral structure with $d(\text{Au–F}) = 1.85$ to $1.90\,\text{Å}$. Oxidation of $M[AuF_4]$ (where M = K, Cs, or NO) by fluorine also produced $[AuF_6]^-$. Gold(V) fluoride is formed by the thermal decomposition of $[KrF][AuF_6]$ or $[O_2]^+[AuF_6]^-$. AuF_5 is a fluorine-bridged polymer in the solid state.

13 HOMONUCLEAR GOLD CLUSTERS

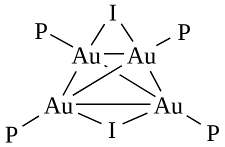
Gold clusters containing 2 to 13 gold atoms have been characterized by single-crystal X-ray crystallography, which is the only definitive technique for structural characterization of gold clusters.[2,11,51] Other techniques such as UV-Visible, Mossbauer and nuclear magnetic resonance (NMR) spectroscopies, conductivity, and fast atom bombardment mass spectrometry (FABMS) are also useful. In these clusters, the average oxidation state of gold is less than one. These compounds are usually synthesized by reduction of $[Au(PR_3)X]$ (X = halide, NO_3^-, etc.) by such reducing agents as $NaBH_4$, CO, H_2, B_2H_6, and $Ti(C_6H_5{-}CH_3)_2$. The nuclearity of the clusters appears to be dictated by the nature of the PR_3 used. Cluster degradation, aggregation, and substitution reactions are often employed to convert one cluster into another using phosphines, halides, and pseudohalides.

The simple dinuclear complex $[Au_2(PPh_3)_2]$ has the trans bent structure with $d(\text{Au–Au}) = 2.76$ Å and Au–Au–P angle of 129°. It was prepared from the reaction of $[AuI(PPh_3)]$ with sodium naphthalide. The trinuclear gold-cluster (**17**), P = PPh_2, is photoluminescent in solution.[52]

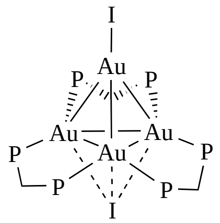
Two tetrahedral gold clusters have been reported. The cluster $[Au_4(PPh_3)_4I_2]$ (**18**) was prepared by the reaction of $[Au_9(PPh_3)_8]^{3+}$ with iodide ion, and has a tetrahedral Au_4 unit bridged on opposite edges by iodide. However, the compound $[Au_4(dppm)_3I_2]$ (**19**) contains a tetrahedron of gold atoms, in which a terminal iodide binds to one gold atom and the second iodide is bonded rather weakly to the other three Au atoms.



(**17**)



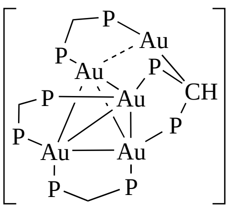
(**18**)



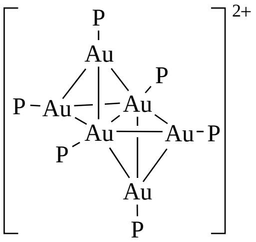
(**19**)

The structure of the pentanuclear gold-cluster $[Au_5(dppm)_3(dppm{-}H)]^{2+}$ is related to that of the Au_4 clusters, with the fifth gold atom appended (**20**). This Au_5 cluster can be synthesized by reduction of $[Au_2(dppm)](NO_3)_2$ with $NaBH_4$ by the evaporation of metallic gold into ethanolic solution of dppm and NH_4NO_3 or by reaction of $[Au_9(PPh_3)_8]^{3+}$ with dppm ligand.

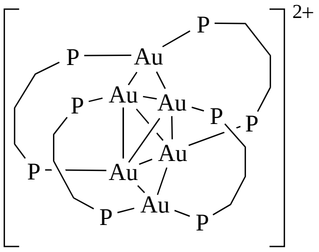
Addition of $[Ag(CN)_2]^-$ to $[Au_8(PPh_3)_8](NO_3)_2$ has produced the cluster $[Au_6(PPh_3)_6](NO_3)_2$, which has an edge-shared bitetrahedral structure (**21**). Another Au_6 cluster, $[Au_6(dppp)_4](NO_3)_2$, has a structure described as bis(edge-capped) tetrahedral as shown in (**22**).



(**20**)



(**21**)



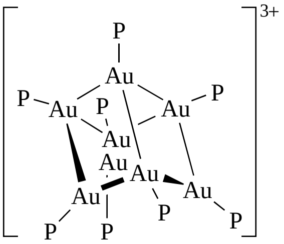
(**22**)

Low-temperature ^{31}P NMR studies showed that the energy difference between the edge-shared bitetrahedral and bis(edge-capped) tetrahedral structures is very small. The Au_7 cluster having pentagonal bipyramidal geometry was synthesized from the gold vapor as shown in equation (15).

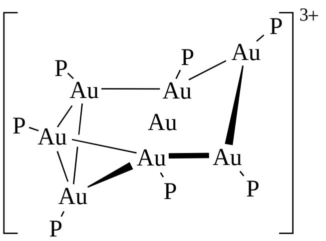
$$Au(vapor) + PPh_3 \xrightarrow{\text{toluene}} [Au_7(PPh_3)_7](OH) \qquad (15)$$

The cluster ion $[Au_8(PPh_3)_8]^{2+}$ has been synthesized from $[Au_9(PPh_3)_8]^{3+}$ and PPh_3, and has the structure (**23**). The structure may be described in terms of a centered chair of gold atoms with an additional gold atom capping the chair by bonding to three alternate gold atoms in the chair. A phosphine ligand can be removed from this cluster by the addition of $[RhCl(C_8H_{14})]$. The resultant cationic cluster $[Au_8(PPh_3)_7]^{2+}$ has the structure (**24**), described as a centered chair of gold atoms with an additional gold atom attached to three adjacent Au atoms in the chair.

The structures of the large Au clusters with 8–13 gold atoms may be described to be derived from a centered icosahedral Au_{13} cluster by removal of peripheral gold atoms. The structure of $[Au_9(Ptol_3)_8]^{3+}$ can be derived from a centered icosahedron, but it is more simply pictured as a bicapped centered chair as shown in (**25**). The cluster $[Au_9(Ptol_3)_9](NO_3)_3$ has been prepared by $NaBH_4$ reduction of $[Au(Ptol)_3(NO_3)]$. The structure of the related ion,

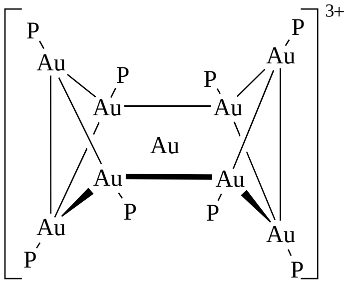


(**23**)

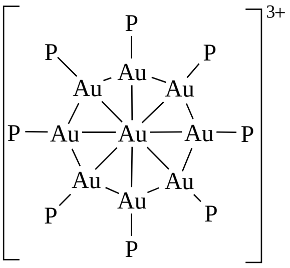


(**24**)

$[Au_9(P(4\text{-}MeOC_6H_4)_3)_8]^{3+}$, has a centered crown structure (**26**). The two compounds have similar electronic spectra and ^{31}P NMR spectra even at low temperature, indicating that these compounds undergo facile intramolecular skeletal rearrangement in solution.

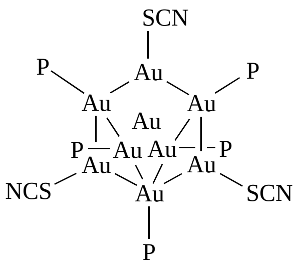


(**25**)

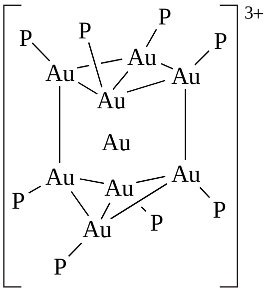


(**26**)

Another Au_9 cluster, $[Au_9(PCy_3)_5(SCN)_3]$, was prepared by $NaBH_4$ reduction of $[Au(PCy_3)SCN]$, and this structure can also be described in terms of a centered icosahedron with different gold atoms missing or as bicapped centered chair as shown in (**27**). The reduction of $[Au_9(PPh_3)_8]^{3+}$ gives $[Au_9(PPh_3)_8]^{+}$ with a distorted centered cubane structure (**28**). On the other hand, the structure of Au_{10} cluster can be described as three trigonal bipyramidal Au_5 cluster sharing a common central gold atom and edge sharing.[5]



(**27**)

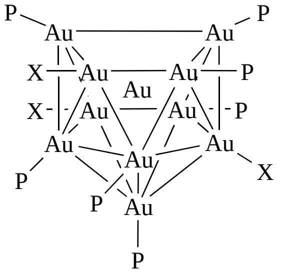


(**28**)

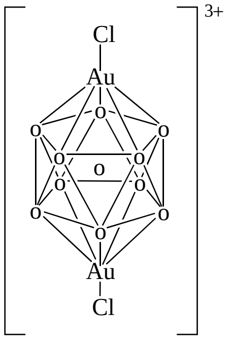
The gold clusters $[Au_{11}X_3L_7]$ (X = SCN, CN or I, L = $P(C_6H_4\text{–}X)_3$ (X = Cl, H, F), PCy_3) were the first gold clusters to be characterized. They are obtained by reduction of

[AuXL] by $NaBH_4$ or [Ti(PhMe)$_2$], or by gold atom reactions with [AuXL]. The structures of these compounds are based on a centered icosahedron of gold atoms, in which a triangle of gold atoms is replaced by a single atom, and each peripheral gold is bound to either a phosphine or a halide or thiocyanate ligand (**29**). The cluster $[Au_{11}(dppp)_5](SCN)_3$ is obtained by the addition of dppp to $[Au_{11}(SCN)_3L_7]$. The skeletal structure is very similar to that of $[Au_{11}X_3L_7]$.

Several clusters are known with the general formula $[Au_{13}X_n(PR_3)_{12-n}]^{(5-n)+}$ (X = halide, $n = 2$ to 4). However, larger gold clusters that have been established by X-ray crystallography[53] are $[Au_{13}(PMe_2Ph)_{10}Cl_2]^{3+}$ and $[Au_{13}(dppm)_6]^{4+}$. The $[Au_{13}Cl_2(PMe_2Ph)_{10}](PF_6)_3$ was prepared by addition of chloride ions to $[Au_{11}(PMe_2Ph)_{10}]^{3+}$, and the $[Au_{13}(dppm)_6](NO_3)_4$ was obtained from $NaBH_4$ reduction of $[Au_2(dppm)](NO_3)_2$. The structures of these clusters are based on a centered icosahedron of gold atoms, as illustrated for $[Au_{13}Cl_2(PMe_2Ph)_{10}]^{3+}$ in (**30**), where o = $AuPMe_2Ph$. This structure is considered to be the parent of structures found for many Au_8–Au_{11} clusters that have different numbers of gold atoms missing from the periphery.



(**29**)



(**30**)

The largest gold cluster claimed is $[Au_{55}Cl_6(PPh_3)_{12}]$, for which the proposed stoichiometry is based on electron microscopy, ^{31}P NMR spectroscopy, analytical, and molecular weight data.[54] The cluster was isolated from the reduction of $[AuCl(PPh_3)]$ with diborane. A two-shell cuboctahedral structure involving an icosahedral Au_{13} unit embedded in an outer layer of 42 Au atoms in a cuboctahedron was proposed. However, the exact nuclearity of the structure is controversial. In the absence of suitable single crystals for X-ray diffraction study, all the experimental data currently available support a cuboctahedral 55-atom gold cluster.[55] However, the largest gold cluster that has been unequivocally characterized in the solid state is $[Au_{39}(PPh_3)_{14}Cl_6]^{2+}$ formed by the reaction of $HAuCl_4$ with PPh_3.[56] Recently, a fourth-generation dendrimer with 96 SH groups has been reacted with $Au_{55}(PPh_3)_{12}Cl_6$ in 3:1 molar ratio to prepare 'naked Au_{55}' clusters.[57]

Of the higher nuclearity gold clusters described above, two classes have been identified. The clusters of the type $[Au\{Au(PPh_3)\}_n]^{x+}$, where the peripheral atoms lie on the surface of a sphere, are characterized by a total of $12n + 18$ valence electrons. The structures $[Au_{13}Cl_2\{P(Me_2Ph)_3\}_{10}]^{3+}$ (162 valence electrons), $[Au_{11}I_3(PPh_3)_7]$ (138 valence electrons), $[Au_9\{P(4\text{-}MeC_6H_4)_3\}_8]^+$ (114 valence electrons), and $[Au_8(PPh_3)_8]^{2+}$ (102 valence electrons) are examples of spheroidal structures. The low nuclearity clusters of the type $[Au\{Au(PR_3)\}_n]^{x+}$, where the peripheral atoms have a ring or torus structure, are characterized by a total of $12n + 16$ valence electrons. Examples for the toroidal structures are $[Au\{Au(PPh_3)\}_8]^{3+}$ (112 valence electrons) and $[Au\{Au(PPh_3)\}_7]^{2+}$ (100 valence electrons).

Both electronic and steric factors influence the geometries and stoichiometries of gold-cluster compounds. The clusters of the type $[Au_{13}L_{12}]^{5+}$, for example, could be formed only for small ligands L. The steric restrictions are further set by the number of ligands L. Calculations of the Kitaigorodski packing coefficients or of cluster cone angles (*see Cone Angle*) are used to understand the steric effects quantitatively. For example, the calculation of Kitaigorodski coefficient would predict that not more than eight PPh_3 can be packed around the metal frame in icosahedral symmetry.[58] As well, it can be shown[59] that an icosahedral gold-cluster $[Au(AuL)_{12}]^{n+}$ could be synthesized with the ligands L having a mean cone angle lying between 70 and 83°.

The gold clusters appear to be ideal models for bulk metals, metal surfaces, and colloidal particles. The gold clusters are used for labelling in electron microscopy studies of biological materials.

14 HETERONUCLEAR GOLD–METAL CLUSTERS[60]

The reagents R_3P–Au–X or $[(R_3P\text{–}Au)_3O]^+$ are commonly used to introduce gold into metal clusters. These gold–metal clusters may contain from one to four gold atoms bound to one or more transition metals. A large number of such clusters have been studied.[61–63] Table 2 gives selected examples of such heteronuclear gold–metal clusters. The structures of the clusters having formula $M(AuPR_3)_x$ (M = a transition metal fragment and $x = 4$–8) can be expressed in terms of a metal-centered icosahedron,[64–66] in which the gold atoms occupy some of the corners as shown in Table 3. Most of these clusters are synthesized by photolysis of Ph_3PAuN_3 with metal carbonyls.

The cluster $[Pt(AuPPh_3)_8]^{2+}$ has a centered crown-like toroidal structure like that of $[Au\{AuP(C_6H_4\text{-}OMe)_3)_8]^{3+}$ (**26**). On treatment with CO or CNR, this cluster cation is converted to $[L\text{-}Pt(AuPPh_3)_8]^{2+}$ (**31**) with a hemispherical geometry.[67]

The reaction of HgX_2 (X = NO_3, Cl, or Br) with the cluster cation $[Pt(AuPPh_3)_8]^{2+}$ yields $[Pt(AuPPh_3)_8(Hg)_2]^{4+}$ (**32**), in which the Pt atom at the center of the cluster is bonded to all Au and Hg atoms.

When a mixture of R_3P–Au–X and $(R_3P–Ag–X)_n$ undergoes reduction by $NaBH_4$, clusters containing 25 atoms ($Au_{13}Ag_{12}$), 37 atoms ($Au_{18}Ag_{19}$), and 38 atoms ($Au_{18}Au_{20}$)

Table 2 Some heteronuclear gold–metal clusters

Cluster type	Skeletal structure	Selected examples
MAu	M-Au-L	$[Co(CO)_4(AuPPh_3)]$ $[Mn(CO)_5(AuPPh_3)]$ $[V(CO)_6(AuPPh_3)]$ $[M(PF_3)_4(AuPPh_3)]$ (M = Rh, Ir)
M_2Au		$[Pt_2(dppm)2(C{\equiv}C\text{-}t\text{-}Bu)_2(AuI)]$ $[Re_2(PPh_3)_4(H)_4(\mu\text{-}H)_3(AuPPh_3)]$ $[\{(C_5Me_5)Rh(\mu\text{-}CO)\}_2(AuCl)]$
M_3Au		$[Pt_3(CO)_3(Pcy_3)_3(AuPCy_3)]^+$ $[CoRu_3(CO)_{13}(AuPPh_3)]$ $[MCo_3(CO)_{12}(AuPPh_3)]$ (M = Fe, Ru)
MAu_2		$[M(CO)_4(AuPPh_3)_2]$ (M = Fe, Ru, Os) $[Pt(PEt_3)_2Cl(AuPPh_3)_2]^+$
M_2Au_2		$[Os_4(\mu\text{-}H)_2(CO)_{12}(AuPPh_3)_2]$
		$[Pt_2(PPh_3)_4(CNR)_4(AuPPh_3)_2]^{2+}$ (R = 2, 6-dimethylphenyl)

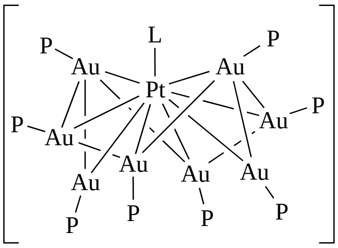
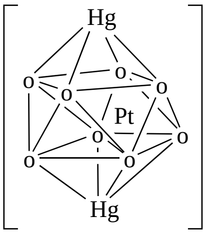
[a] o = LAu, L = phosphine ligand.

have been isolated depending upon the Ag:Au ratio and the nature of R and X.[68,69] Their structures, which have been determined crystallographically, are based on a gold-centered Au_7Ag_6 icosahedron. For example, the metal core in the $[(Ph_3P)_{10}Au_{13}Ag_{12}Br_8]^+$ cluster ion has two Au_7Ag_6 icosahedra sharing one vertex. For this reason, these clusters are termed 'clusters of clusters'. They are among the largest metal clusters to be fully characterized. The basic building block for these 'clusters of clusters', namely, the icosahedral Au–Ag cluster ion, has been isolated[70] from the reaction of equation (16).

$$[Au_{11}(PPh_2Me)_{10}]^{3+} + 4[Ag(PPh_2Me)Cl] \longrightarrow [Au_9Ag_4Cl_4(PPh_2Me)_8]^+ + 2[Au(PPh_2Me)_3]^+ \quad (16)$$



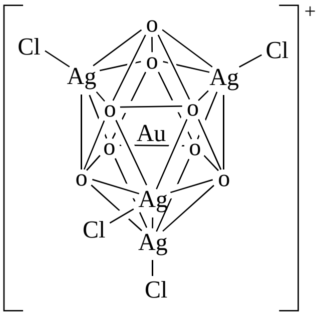
(31)



o = Ph_3PAu

(32)

The structure of the cluster cation $[Au_9Ag_4Cl_4(PPh_2Me)_8]^+$ is shown in (**33**). The largest heteronuclear cluster so far is $[Au_{22}Ag_{24}(PPh_3)_{12}Cl_{10}]$.[71]



o = $PhMe_2PAu$

(33)

15 COMPLEXES OF GOLD(I) WITH Au···Au INTERACTIONS

There are many unusual gold(I) complexes, in which the structures are greatly affected by secondary gold···gold bonding. For example, the gold fragment $[AuPPh_3]^+$ has been used to synthesize several cluster compounds[72,73] of the type $[M(AuPR_3)_x]^{y+}$, where $2 < x < 12$; and M = Cl, Br, I, S ($x = 2$); O, S, or Se ($x = 3$), N ($x = 4, 5$), P ($x = 4, 5, 6$), C ($x = 4, 5, 6$). In all these compounds, there are Au–Au interactions that govern the geometry.

The synthetic routes for these compounds are given in equations (17–26), and the structures are shown schematically as (**34**)–(**39**), in which P = PPh_3. The oxonium salt, $[(Ph_3PAu)_3O]^+$, is a versatile aerating agent that is often used to introduce $AuPPh_3$ units into organometallic and cluster compounds. It is also a useful reagent in organic syntheses.

$$2Ph_3PAuX + AgBF_4 \longrightarrow [(Ph_3PAu)_2X]^+(BF_4)^- + AgX \quad (17)$$

X = Cl, Br, I, SCN

$$2Ph_3PAuCl + Na_2S \longrightarrow [(Ph_3PAu)_2S] + 2NaCl \quad (18)$$

$$3Ph_3PAuCl \xrightarrow{Ag_2O/NaBF_4} [(PPh_3Au)_3O]^+(BF_4)^- + 2AgCl + NaCl \quad (19)$$

$$3Ph_3PAuCl + Se(SiMe_3)_2 \longrightarrow [(Ph_3PAu)_3Se]^+\,Cl^- + 2Me_3SiCl \quad (20)$$

$$4Ph_3PAuCl + N(SiMe_3)_3 + CsF \longrightarrow [(Ph_3PAu)_4N]^+F^- + CsCl + 3Me_3SiCl \quad (21)$$

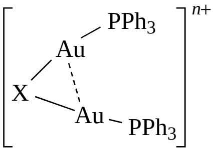
$$4Ph_3PAuCl + As(SiMe_3)_3 \longrightarrow [(Ph_3PAu)_4As]^+Cl^- + 3Me_3SiCl \quad (22)$$

$$[(Ph_3PAu)_4N]^+BF_4^- + Ph_3PAu^+BF_4^- \longrightarrow [(Ph_3PAu)_5N]^{2+}(BF_4^-)_2 \quad (23)$$

$$5Ph_3PAuCl + 5CsF + CH_2[B(OMe)_2]_2 \xrightarrow{HMPA} [(Ph_3PAu)_5C]^+(BF_4)^- + 5CsCl + BF(OMe)_2 + 2MeOH \quad (24)$$

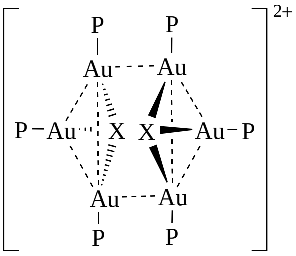
$$6Ph_3PAuCl + 6CsF + C[B(OMe)_2]_4 \xrightarrow{HMPA} [(Ph_3PAu)_6C]^{2+}(MeOBF_3^-)_2 + 6CsCl + 2B(OMe)_3 \quad (25)$$

$$4Ph_3PAuCl + 3CsF + 2Me_3P{=}C(H)SiMe_3 \longrightarrow [Me_3PC(AuPPh_3)_3]^+Cl^- + 2Me_3SiF + 3CsCl + [Me_3PCH_2AuPPh_3]F \quad (26)$$



X = Cl, n = 1; X = S, n = 0

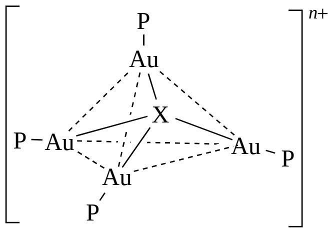
(34)



X = O, S, Se

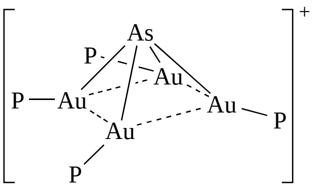
(35)

In some of these mixed gold-main group compounds, the coordination numbers and stereochemistry associated with main group atoms such as carbon and nitrogen are very

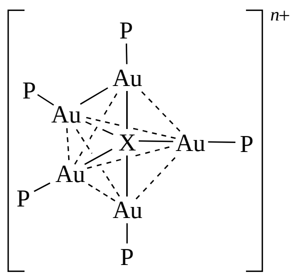


X = C, $n = 0$; X = N, $n = 1$

(**36**)

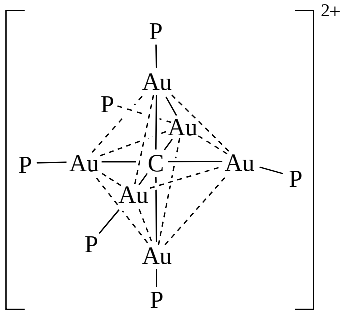


(**37**)



X = C, $n = 1$; X = N, $n = 2$

(**38**)



(**39**)

unusual. For example, in the cations $[C\{Au(PPh_3)\}_5]^+$ and $[C\{Au(PPh_3)\}_6]^{2+}$, the central carbon atoms have trigonal bipyramidal and octahedral geometry, respectively, as shown in (**38**) and (**39**).[74,75] These nonclassical hypercoordinated carbon compounds are stabilized by the strong intermetallic Au–Au interactions.

On the basis of bonding theory, one would expect a tetrahedral configuration (sp^3 hybridization) for the cation $[As\{Au(PPh_3)\}_4]^+$ similar to the nitrogen analog, $[N\{Au(PPh_3)\}_4]^+$, (**34**). However, it was found that the cation preferred the square-pyramidal geometry (**35**), with arsenic atoms capping a square of gold atoms over the classical tetrahedral structure.[76] For a tetrahedral structure, the radius of the central atom arsenic is too large to allow for Au–Au interactions, so the alternative structure is adopted instead. An interesting tetrahedral AuL (L = tri-(2-methylphenyl)phosphine) core incorporating an oxygen atom, namely, $[(\mu\text{-O})(AuL)_4](BF_4)_2$, has been reported by Schimidbaur as the formal analog of H_4O^{2+}.[77] The corresponding sulphur derivative, $[S(AuPPh_3)_4](ClO_4)_2$, as expected, has square-pyramidal structure stabilized by Au–Au interactions.[78]

No Au–Au interactions occur in the monocation $[RP(AuPPh_3)_3]^+$ (R = *o*-tolyl group) in which the central P atom has an ideal tetrahedral geometry. However, by treatment of this compound with $[Ph_3Au]^+(BF_4)^-$ (Scheme (3)), the dication $[RP(AuPPh_3)_4]^{2+}$, which has square-pyramidal geometry with the phosphorus atom at the apex, is formed. The Au–Au interactions are responsible for this unexpected stereochemistry.[79]

This aurophilic property has been used to prepare trimeric and tetrameric gold clusters[80] with 8-aminoquinoline ligands, as shown in Scheme (4).

Finally, octahedral complexes $[P(AuL)_6]^{3+}$ have been prepared by reaction of LAu^+ with $P(SiMe_3)_3$ according to equation (27).[81]

$$6LAu^+BF_4^- + (Me_3Si)_3P + 3KF \longrightarrow 3KBF_4 + 3Me_3SiF + [(LAu)_6P]^{3+}(BF_4^-)_3 \quad (27)$$

(**40**)

16 GOLD-CONTAINING POLYMERS, RINGS, AND DENDRIMERS

Gold(I) compounds are attractive candidates for synthesizing various types of supramolecular systems including polymers,[82–84] rings,[84,85] dendrimers,[86] and so on, with unusual optical or electrical properties making use of the linear coordination geometry and $Au^{I}-Au^{I}$ interactions. An interesting doubly braided[2]catenane containing two 50-membered ring has been found to exhibit fast 'rocking' motion in solution (**40**).[84]

Nanoscale super clusters containing $[Au_2Ru_6C(CO)_{16}]$ has been assembled on the surface of a third-generation dendrite.[87]

17 GOLD COMPOUNDS WITH RARE GASES

Many gold compounds containing rare gases such as Ar–Au–Cl, Kr–Au–Cl, and Xe–Au–Cl have been detected by microwave and mass spectroscopes.[88] The first stable gold–xenon compound, $[AuXe_4]^{2+}$ $(Sb_2F_{11}^{-})_2$, has been isolated and characterized in the solid state by the reaction of AuF_3 and Xe in the presence of HF/SbF_5 medium.[89] In the dark red crystals, the Au^{2+} has square-planar geometry with four terminal Xe atoms. Further, *cis*-$[AuXe_2(Sb_2F_{11})_2]$ has been synthesized by changing the HF/SbF_5 ratio, while the trans isomer was obtained oxidizing finely divided gold in HF/SbF_5 with XeF_2 under pressure of Xe.[90] After Pyykkö, who predicted that $[AuXe_2]^{+}$ ion could exist,[91] the first Au^{I}–Xe compound $[(F_3As)–Au–Xe](Sb_2F_{11})$ was reported recently.[92] The Au^{I}–Xe distance, 2.607 Å, has been found to be shorter than the Au^{II}–Xe bonds, which is ~2.74 Å.

1 DEFINITION, INTRODUCTION, AND HISTORY

Organogold chemistry is defined as the chemistry of compounds containing at least one direct gold-to-carbon bond, regardless of the oxidation state and coordination number of the metal atoms, which may be single in mononuclear complexes or part of aggregates as in polynuclear complexes (*see* ***Polynuclear Organometallic Cluster Complexes***) or in clusters. The only class of compounds with a Au–C bond excluded for systematic reasons is the family of cyanides (*see Cyanides*), which are considered under a separate entry (*see* ***Cyanide Complexes of the Transition Metals***). Although there is also a separate entry on carbonyl compounds (*see* ***Carbonyl Complexes of the Transition Metals***), the few carbon monoxide complexes of gold have been included in this article owing to their very small number, their unusual properties compared to standard transition metal carbonyls, and their use in synthesis. All other types of Au–C species have been reviewed and included where it was found appropriate for a concise treatment of the subject.

Gold forms chemical compounds in the oxidation states −1, 0, +1, +2, +3, and +5. As expected from the position of the element in the periodic table, the oxidation states +1 and +3 are the most common and stable, and this is also borne out in the organometallic chemistry of gold. As is easily derived from the electronic configuration of these two oxidation states, the standard coordination numbers and geometries are linear two-coordinate for Au^{I} and square planar and four coordinate for Au^{III}. Virtually all organogold compounds obey these simple rules. While there are no well-defined organogold derivatives for Au^{-I}, Au^{0}, or Au^{V}, there is some interesting organometallic chemistry for Au^{II}, mainly based on metal−metal bonded dinuclear units $[Au_2]^{4+}$ (*see* ***Dinuclear Organometallic Cluster Complexes***).

Organogold chemistry is a chemistry of metastable compounds: none of the organogold compounds is thermodynamically stable relative to gold metal and any organic component meeting the stoichiometry of the system, like a hydrocarbon, a haloalkane, or an organic oxygen, sulfur, or nitrogen compound. As expected from the ‘noble character’ of gold metal, none of the organogold compounds can be prepared directly from gold metal, and all synthetic pathways for gold organyls have their origin from gold halides or their complexes, which along with a few selenides and tellurides are the only thermodynamically stable binary compounds of gold. Though this situation is not unlike that encountered with elements such as platinum, gold is an extreme case owing to its extreme electrochemical potential. Working in organogold chemistry therefore requires careful control of experimental conditions to avoid the thermal decomposition of the compounds favored by thermodynamics. More often than not, experiments in organogold chemistry are terminated by the appearance of a gold mirror on the walls of the reaction vessel, with nothing but the organic decomposition products remaining in the solution or gas phase.

Historically, organogold chemistry started with the first preparation of dialkylgold(III) halides of the type R_2AuX from tetrahaloauric acids $HAuX_4$ or gold trihalides AuX_3 ($X = Cl$, Br) by treatment with an excess of a Grignard reagent RMgX (*see Grignard Reagents*) by Pope and Gibson[1] in 1907. These experiments were the obvious approach to organogold compounds shortly after the turn of the century, because tetrachlorauric acid and gold trichloride are obtained as the primary products in the treatment of gold with *aqua regia* (a mixture of conc. HCl and HNO_3), and because the first decade of the twentieth century saw the discovery of the Grignard reagents as a major breakthrough for organometallic synthesis in general. Through the following three decades, the dialkylgold halides remained the key intermediates for all further developments in the field, largely by Gibson,[2] and, after World War II, by Tobias.[3] By contrast, alkylgold(I) and trialkylgold(III) chemistry could only be developed much later after the discovery of organolithium reagents and the introduction of tertiary phosphines as almost indispensable stabilizing ligands in the 1950s by Gilman[4] and by Coates.[5]

Arylgold(I) and arylgold(III) chemistry had a late start in the 1960s, but then grew rapidly through the work by Uson[6] and Nesmeyanov,[7] complemented by work on cyclopentadienyl- (*see Cyclopentadienyl*), ferrocenyl- (*see Ferrocene*), and cymantrenyl- (*see Cymantrene*) gold compounds.

Explosive gold acetylide has been known since the mid-nineteenth century, but systematic studies of this type of compounds were initiated by Coates[8] in 1959. The early work on gold carbonyls dates back to 1925, when Manchot[9] discovered (OC)AuCl, while the related isocyanide complexes were prepared only in 1956 by Sacco.[10] Gold−carbene

complexes have been known since 1970, on the basis of the work of Bonati[11] and Raubenheimer.[12]

Alkene complexes of platinum have been well established since the middle of the nineteenth century (*see Zeise's Salt*), but π-complexes of gold were only discovered by Hüttel[13] in 1965, with alkyne complexes following in 1972. All of these complexes have very limited stability, and therefore their chemistry is still poorly developed, even today.

While other gold compounds are recently finding widespread application in modern technology,[14] organogold compounds are not among the prominent classes of compounds in industry. Only for depositing thin gold films on surfaces some of the more volatile organogold derivatives hold a certain potential, which is being exploited for the production of electrical and semiconductor devices or for obtaining specific optical and wear- or chemical-resisting properties. The state of the art is similar for electrolytic or electroless gold plating from solution. In chemotherapy and pharmacology, organogold compounds have shown no major advantages over established gold drugs, which have no organic groups directly attached to the gold center.

In basic research, the chemistry of gold and organogold compounds merits special interest because of the unique position of gold in the periodic table, which is characterized by the highest electron affinity, electronegativity, and redox potential of all metals. These properties have their origin in a pronounced maximum in the relativistic contraction of the valence electron orbitals and associated effects.[15] Several reviews on organogold chemistry have been published.[16–25]

2 GENERAL SYNTHETIC PATHWAYS

Conventional organic groups (alkyl, alkenyl, alkynyl, aryl, cyclopentadienyl, ferrocenyl, and others) are introduced at a given gold(I) or gold(III) center by treatment of the corresponding halide complexes with an organometallic reagent. As a historical example, $AuBr_3$ is reacted with the Grignard compound EtMgBr in diethyl ether (or pyridine) as a solvent to give diethylgold bromide and $MgBr_2$.[1] An excess of the RMgX reagent does not lead to full alkylation, but by employing the more powerful alkyllithium compounds, the trialkylgold species can finally be generated.[4] This product needs a donor ligand L (such as a tertiary phosphine) as a stabilizing ligand. With three equivalents of the LiR reagent, $AuBr_3$ can be converted directly into the trialkylgold complex (equations 1–3).

$$AuBr_3 + 2EtMgBr \longrightarrow 2MgBr_2 + Et_2AuBr \quad (1)$$

$$Et_2AuBr + EtLi + L \longrightarrow LiBr + Et_3Au{\cdot}L \quad (2)$$

$$AuBr_3 + 3EtLi + L \longrightarrow 3LiBr + Et_3Au{\cdot}L \quad (3)$$

Dialkylmercury compounds cannot be used for alkylating gold halides (as already noted by Frankland in 1864), while both alkylzinc and alkylcadmium species can be employed, but offer advantages only for perfluoroalkyl species.[26] The alkylation of AuX_3 or $HAuX_4$ with organotin reagents SnR_4 leads to R_2AuX compounds, but the process is difficult to control, because the separation of the product from the R_nSnX_{4-n} by-products proved to be difficult.[27]

Like trialkylgold compounds (R_3Au), monoalkylgold compounds (RAu) are unstable in the absence of a donor ligand L. Their preparation is therefore carried out by treatment of a suitable complex of a gold(I) halide (L·AuX) with the organolithium reagent.[5] Arylation follows the same pathway (equations 4 and 5).

$$L{\cdot}AuCl + MeLi \longrightarrow LiCl + L{\cdot}AuMe \quad (4)$$

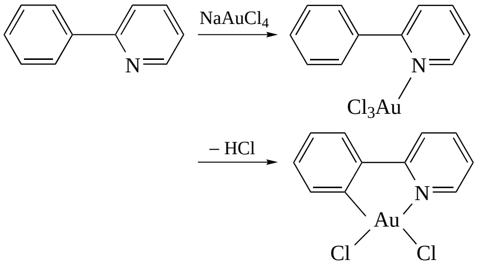
$$L{\cdot}AuBr + PhLi \longrightarrow LiBr + L{\cdot}AuPh \quad (5)$$

A useful method for the formation of Au–C bonds is the insertion of diazoalkanes into the Au–halogen bond (equation 6).[7]

$$Ph_3P{\cdot}AuCl + CH_2N_2 \longrightarrow Ph_3P{\cdot}AuCH_2Cl + N_2 \quad (6)$$

Arylation of gold(III) compounds is not limited to the organometallic route, but can be accomplished in direct 'aromatic auration' of the hydrocarbon by anhydrous $AuCl_3$ with evolution of HCl (equations 7 and 8).[28–30] In special cases, arylation is accomplished by arylthallium reagents (equation 9), or by using arenediazonium salts.

$$(AuCl_3)_2 + 2C_6H_6 \longrightarrow 2HCl + (PhAuCl_2)_2 \quad (7)$$



(8)

$$Ph_3P{\cdot}AuCl + (HC_6Cl_4)_3Tl \longrightarrow (HC_6Cl_4)_2TlCl + Ph_3P{\cdot}AuC_6Cl_4H \quad (9)$$

Alkenylgold compounds, including the cyclopentadienyl and ferrocenyl or cymantrenyl species with σ-bonded alkene ligands, are also generated through treatment of alkenyl-Grignard or alkenyllithium precursors with the corresponding gold–halide complexes. Fluoroalkyl derivatives are obtained through the insertion of fluoroalkenes into the Au–C bond of organogold compounds. A similar insertion has been observed with alkynes and gold(III) halides.[31]

Alkynylgold compounds are readily available from reactions of the parent alkyne and gold(I) halides in the presence of even a very weak base, owing to the enhanced CH acidic properties of alkynes. The donor-free products are oligomeric, probably through a combination of σ- and

π-coordination. In the presence of donors, L, linear 1:1 complexes are generated (equations 10 and 11). Dinuclear complexes LAuC≡CAuL are also readily accessible[32] (equation 12), and are found to be associated into aggregates through aurophilic bonding (Au···Au).[33]

$$n\ \mathrm{RC{\equiv}CH} + n\ \mathrm{base} + n\ \mathrm{AuX} \longrightarrow (\mathrm{RC{\equiv}CAu})_n + n\ [(\mathrm{base})\mathrm{H}]\mathrm{X} \quad (10)$$

$$(\mathrm{RC{\equiv}CAu})_n + n\ \mathrm{L} \longrightarrow n\ \mathrm{L{\cdot}AuC{\equiv}CR} \quad (11)$$

$$\mathrm{HC{\equiv}CH} + 2\ \mathrm{base} + 2\mathrm{L{\cdot}AuX} \longrightarrow \mathrm{L{\cdot}AuC{\equiv}CAu{\cdot}L} + 2\ [(\mathrm{base})\mathrm{H}]\mathrm{X} \quad (12)$$

Alkene and alkyne π-complexes (*see Alkene Complexes* and *Alkyne Complexes*) are known both for Au^{I} and Au^{III}. They are prepared at low temperature from AuCl or $AuCl_3$ with an excess of the alkene or alkyne in the absence of any other potential donor molecules. The products, for example, of the types (MeCH=CHMe)AuCl and MeC≡CMe·$(AuCl_3)_2$, are generally of low stability, and the complexation is reversible in a vacuum or on heating. Representative examples have recently been structurally characterized.[34,35] Strained cyclic alkenes and alkynes give the most stable products. Multiple coordination of monoalkenes or of dialkenes (like butadiene) is known, but information about the products is limited. Alkene coordination to neutral gold atoms has been studied by matrix-isolation techniques at very low temperature.[36] The adduct $(C_2H_4)Au$ appears to be stable only below 40 K.

Carbene complexes of gold are available through the addition of alcohols or amines to isocyanide complexes. The latter are readily prepared from the free isocyanides (*see Isocyanide Ligands*) and other gold–halide complexes containing a weaker ligand such as dimethyl sulphide or carbon monoxide (equations 13–15). Carbeniate derivatives are generated through deprotonation of a suitable carbene precursor by base (equations 16 and 17).

$$\mathrm{Me_2S{\cdot}AuCl} + \mathrm{RN{\equiv}C} \longrightarrow \mathrm{Me_2S} + \mathrm{RN{\equiv}C{\cdot}AuCl} \quad (13)$$

$$\mathrm{RN{\equiv}C{\cdot}AuCl} + \mathrm{R'OH} \longrightarrow \mathrm{(R'O)(RHN)C{\cdot}AuCl} \quad (14)$$

$$\mathrm{RN{\equiv}C{\cdot}AuCl} + \mathrm{R_2'NH} \longrightarrow \mathrm{(R_2'N)(RHN)C{\cdot}AuCl} \quad (15)$$

$$\mathrm{(R'O)(RNH)C{\cdot}AuCl} + \mathrm{KOH} + \mathrm{L} \longrightarrow \mathrm{H_2O} + \mathrm{KCl} + \mathrm{L{\cdot}AuC({=}NR)(OR')} \quad (16)$$

$$3\ \mathrm{(R'O)(RNH)C{\cdot}AuCl} + 3\mathrm{KOH} \longrightarrow 3\mathrm{H_2O} + 3\mathrm{KCl} + [\mathrm{(R'O)(RN)CAu}]_3 \quad (17)$$

Up to two carbene units have been introduced at Au^{I} and up to four at Au^{III} centers.[37] Donor-free Au^{I} carbene complexes are oligomeric and form planar trimeric structures, $[AuC(OR')(NR)]_3$ or $[AuC(NHR')(NR)]_3$.

Carbonyl complexes of gold are only known for Au^{I}. The classical example, (CO)AuCl, is obtained from $(AuCl_3)_2$ and CO at ca. 100 °C, or from AuCl and CO.[9] A more recent preparation from commercial $HAuCl_4$, $SOCl_2$, and CO is more convenient and gives quantitative yields of this important reagent (equation 18).[38]

$$\mathrm{HAuCl_4{\cdot}H_2O} + \mathrm{SOCl_2} + 2\mathrm{CO} \longrightarrow 3\mathrm{HCl} + \mathrm{COCl_2} + \mathrm{SO_2} + \mathrm{(CO)AuCl} \quad (18)$$

The corresponding complexes of AuF, AuBr, and AuI are much less stable and not fully characterized. Gold atoms form CO adducts under matrix-isolation conditions (*see Matrix Isolation*) (below 20 K), but ligand dissociation occurs at a slightly elevated temperature.

Formation of gold–carbon σ-bonds is perhaps most easily accomplished by treatment of gold(I) and gold(III) compounds with phosphorus ylides (phosphonium alkylides, *see Ylide*). Through their strongly nucleophilic carbanionic center, these reagents are able to displace virtually every other ligand attached to gold, even under mild conditions.[39] Phosphonium bis(methylide) reagents, obtained by treatment of an ylide with an organolithium base or through transylidation, lead to multinuclear organogold compounds with open-chain or cyclic structures (equations 19–23).

$$\mathrm{L{\cdot}AuCl} + \mathrm{R_3PCH_2} \longrightarrow [\mathrm{L{\cdot}AuCH_2PR_3}]\mathrm{Cl} \quad (19)$$

$$\mathrm{L{\cdot}AuCl} + 2\mathrm{R_3PCH_2} \longrightarrow \mathrm{L} + [\mathrm{Au(CH_2PR_3)_2}]\mathrm{Cl} \quad (20)$$

$$\mathrm{L{\cdot}AuR'} + \mathrm{R_3PCH_2} \longrightarrow \mathrm{L} + \mathrm{R_3PCH_2AuR'} \quad (21)$$

$$2\mathrm{L{\cdot}AuCl} + 4\mathrm{R_2(Me)PCH_2} \longrightarrow 2\ [\mathrm{R_2PMe_2}]\mathrm{Cl} + [\mathrm{R_2P(CH_2)_2Au}]_2 \quad (22)$$

$$\mathrm{L{\cdot}AuR_3'} + \mathrm{R_3PCH_2} \longrightarrow \mathrm{L} + \mathrm{R_3'AuCH_2PR_3} \quad (23)$$

From carbodiphosphoranes $R_3P{=}C{=}PR_3$ and dialkylgold(III) halides, cyclic ylide complexes containing four Au–C σ-bonds are obtained in a multiple transylidation reaction (equation 24). Related thiophosphorus ylides and sulfonium and sulfoxonium ylides are equally effective in the formation of Au–C σ-bonds, and a series of analogous gold–thiophosphonium and sulfoxonium–methylide complexes is available (equations 25–27).[40]

$$(\mathrm{R_2AuBr})_2 + 4\mathrm{MeR_2'PCPR_2'Me} \longrightarrow 2\ [\mathrm{MeR_2PCH_2PR_2Me}]\mathrm{Br} + 2\mathrm{R_2Au(CH_2PR')_2CH} \quad (24)$$

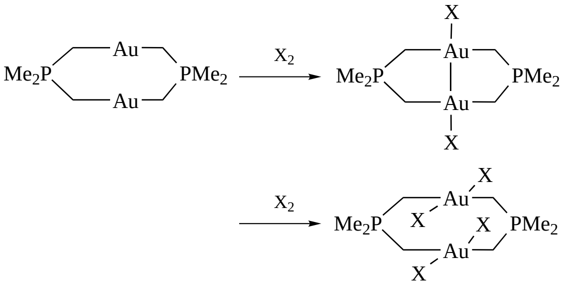
$$2\mathrm{L{\cdot}AuCl} + 2\mathrm{R_2P(S)CH_2^-} \longrightarrow 2\mathrm{L} + 2\mathrm{Cl^-} + [\mathrm{R_2P(S)CH_2Au}]_2 \quad (25)$$

$$\mathrm{R_3Au{\cdot}L} + \mathrm{R_2'S(O)CH_2} \longrightarrow \mathrm{L} + \mathrm{R_3AuCH_2S(O)R_2'} \quad (26)$$

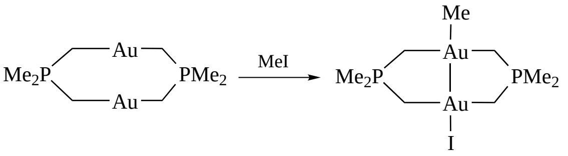
$$\mathrm{R_3Au{\cdot}L} + \mathrm{R_2'SCH_2} \longrightarrow \mathrm{L} + \mathrm{R_3AuCH_2SR_2'} \quad (27)$$

The cyclic gold(I) phosphonium methylide heterocycles are the precursors for the few organogold(II) species reported. Oxidative addition (*see Oxidative Addition*) of halogen and alkyl halides leads to bicyclic compounds containing a transannular Au–Au bond (equations 28 and 29). These reactions are surprisingly facile and are now known to be

reversible and to lead to different regio- and stereoisomers.[39,40]



(28)



(29)

Introduction of more than one gold atom at a given carbon center proved to be very difficult in many early experiments, but later studies have shown that multiauration of a carbon atom is possible and leads to a large, and highly interesting, family of organogold compounds. The syntheses are more facile with increasing C–H acidity of the precursor. Thus, phosphorus ylides can be doubly and triply aurated, and C–H acids, like malodinitrile, malonic acid diesters, and methyloxazoline, are easily aurated. Reactions of metalated or silylated precursors with gold−halide complexes, or treatment of the organic compound with strongly nucleophilic agents such as $[R_3PAu]BF_4$ or $[(R_3PAu)_3O]BF_4$, give high yields of the polygold products (equations 30−32).

$$R_3PCPR_3 + 2L\cdot AuMe \longrightarrow 2L + (R_3P)_2C(AuMe)_2 \quad (30)$$

$$R_3PC(SiR_3{}')_2 + 3L\cdot AuX \longrightarrow 2R_3{}'SiX + [R_3PC(AuL)_3]X \quad (31)$$

$$(NC)_2CH_2 + 2R_3P\cdot AuX + \text{base} \longrightarrow 2\,[(\text{base})H]X + (NC)_2C(AuPR_3)_2 \quad (32)$$

The auration of acetylacetone and other β-diketo compounds affords complexes of the type $[RC(O)]_2CHAuL$ and $[RC(O)]_2C(AuL)_2$, with the gold atoms exclusively C-bonded.[41] The former are useful aurating reagents.[42]

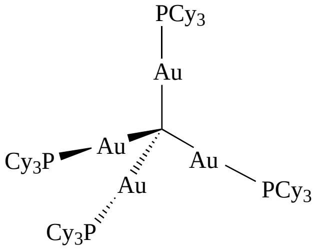
Unexpected reactions are observed in the auration of arylgold(I) complexes. Thus, treatment of (triphenylphosphine)-p-tolylgold with HBF_4 gives one equivalent of toluene and a novel dinuclear compound (equation 33).[7] Similar reactions were found with ferrocenylgold(I) complexes, which give analogous products with one ring carbon atom bonded to two gold atoms (equation 34)

$$2[4\text{-}MeC_6H_4Au\cdot PPh_3] + HBF_4 \longrightarrow PhMe + [4\text{-}MeC_6H_4(Au\cdot PPh_3)_2]BF_4 \quad (33)$$

$$CpFe(C_5H_4Au\cdot PR_3) + [Au\cdot PR_3]X \longrightarrow \{CpFe[C_5H_4(Au\cdot PR_3)_2]\}X \quad (34)$$

Tetragoldmethane complexes are obtained from tetra(boryl)methane compounds upon reaction with gold−halide complexes in the presence of an ionic fluoride (equation 35).[43] Tetragoldmethane species, such as (**1**), can only be isolated with bulky tertiary phosphines, L, which shield the molecule from further attack by $[LAu]^+$ nucleophiles. With smaller ligands L, penta- and hexaauration occurs, leading to hypercoordinate carbon compounds.[33,44,45]

$$[(RO)_2B]_4C + 4L\cdot AuX/F \longrightarrow 4(RO)_2BX/F + (L\cdot Au)_4C \quad (35)$$



(**1**)

Lithiated dicarbaborane clusters yield (organo)gold-substituted clusters on reaction with L·AuX or R_2AuX compounds, also with hypercoordinate carbon atoms (equations 36−38).[46,47]

In all of these clusters, the interaction of the gold atoms is stronger with the boron atoms than that with the carbon atoms of the carborane units.

$$L\cdot AuX + NaC_2B_4H_7 \longrightarrow NaX + L\cdot Au(C_2B_4H_7) \quad (36)$$

$$L\cdot AuX + Li[RC_2B_{10}H_{10}] \longrightarrow LiX + L\cdot Au(RC_2B_{10}H_{10}) \quad (37)$$

$$AuCl_3 + 2Li_2[C_2B_9H_{11}] \longrightarrow 3LiCl + Li[Au(C_2B_9H_{11})]_2 \quad (38)$$

3 CONVERSION OF ORGANOGOLD COMPOUNDS

In Section 2, the principles of formation of gold-to-carbon bonds have been introduced. The primary products can be transformed into other organogold species with the creation of more Au–C bonds than initially present. Au–C bonds are generally retained and only the other substituents or ligands are replaced.

The most common organogold(I) compounds of the type L·AuR can undergo ligand exchange of L, which is known to follow an associative mechanism (equation 39) (*see* ***Mechanisms of Reaction of Organometallic Complexes***).

$$L\cdot AuR + L' \longrightarrow RAu\cdot L(L') \longrightarrow L + L'\cdot AuR \quad (39)$$

Ligands may be classified as forming more or less stable complexes with RAu, with trialkylphosphines being

generally the most stable, followed by triarylphosphines, dialkyl sulfides, or diaryl sulfides, in good agreement with the usual sequence for 'soft' donor ligands. With carbanions as incoming ligands, anionic dialkylaurates(I) are formed (equation 40).[48]

$$\mathrm{L{\cdot}AuR + LiR \longrightarrow L + Li[RAuR]} \qquad (40)$$

A second important reaction of L·AuR species is the oxidative addition (*see Oxidative Addition*) of halogen or alkyl halides, which leads, at least in a first step, to organo(dihalo)gold(III) or diorgano(halo)gold(III) products. The structures are transformed from linear to square planar, and therefore cis and trans isomers are possible. The products may undergo secondary reactions and/or become subject to a reductive elimination (*see Reductive Elimination*) of other substituent combinations (equations 41 and 42).[49,50]

$$\mathrm{L{\cdot}AuR + X_2 \longrightarrow L{\cdot}AuX_2R} \qquad (41)$$

$$\mathrm{L{\cdot}AuR + R'X \longrightarrow L{\cdot}AuR(R')X} \qquad (42)$$

The oxidative addition of stoichiometric quantities of X_2 or RX to cyclic dinuclear gold(I) compounds to give cyclic Au^{II} compounds has already been mentioned.

Treatment of L·AuR species with strong acid or base leads to the cleavage of the Au–R bond, but otherwise these bonds are remarkably robust. Au–R bonds are not readily hydrolized, and they are stable to air at ambient temperature, mainly owing to the low polarity of the Au–C units. In this respect, they resemble organomercurials.

Thermal decomposition of L·AuR species has been carefully studied, and there is agreement that the reaction pathway follows a radical mechanism. Mixtures of alkanes and alkenes (diaryls for R = aryl) are formed, together with free ligand L and elemental gold.

In organogold(III) compounds, L·AuR_3, the ligand L can also be exchanged, but the reactions are generally much slower than for L·AuR. Addition of LiR yields the square-planar tetraalkylaurate(III) (equation 43).

$$\mathrm{L{\cdot}AuR_3 + LiR \longrightarrow L + Li[AuR_4]} \qquad (43)$$

Cleavage of R–Au bonds in L·AuR_3 with HX or X_2 gives (dimeric) R_2AuX and finally (dimeric) $RAuX_2$ compounds that form complexes of the types $R_2AuX{\cdot}L$ and $RAuX_2{\cdot}L$. In the latter, both X and L can be replaced by nucleophiles, following the usual mechanistic pattern of substitution at square-planar complexes. Cis/trans isomerism is common, leading to interesting differences in reactivity according to changes in the trans effect (*see Trans Effect*). 'Soft' ligands X and L are preferred, and a large variety of thiocyanates, thiolates, thiocarbamates, selenolates, phosphides, or arsenides have been prepared, while 'hard' ligands are less common. Tetrameric dimethylgold hydroxide and cyanide, and dimeric dimethylgold trimethylsilyloxide and azide have been prepared, however, and have been fully characterized.

Thermal decomposition of L·AuR_3 compounds proceeds mainly with reductive elimination of R_2 by radical cleavage, as outlined for L·AuR.

4 ANALYSIS AND SPECTRAL CHARACTERISTICS

Organogold compounds have been carefully analyzed by use of the full range of analytical, spectroscopic, and diffraction techniques.

Elemental analysis generally poses no problems because of the limited stability of the compounds and the formation of elemental gold in decomposition and combustion, which does not form carbides, nitrides, or other interstitial phases. Atomic absorption and inductively coupled plasma spectroscopy are presently the methods of choice for Au estimation. Many organogold compounds are sufficiently volatile to allow registration of good mass spectra by gas-phase electron impact. Field desorption, fast-atom bombardment, and chemical ionization mass spectrometry have also been successfully applied.

Gold is not amenable to common magnetic resonance techniques,[51] and to date no ^{197}Au NMR or NQR spectra have been obtained owing to the adverse properties of this nucleus. ^{197}Au is an excellent Mössbauer nucleus, however, and recoil-free γ-resonance spectra have been obtained for a large variety of organogold compounds. Determination of isomeric shifts and quadrupole coupling constants can be used to obtain information on the oxidation state, coordination number, coordination geometry, and environment of the gold atom in solids.[51]

Electron spectroscopy for chemical analysis (ESCA) has also been applied successfully for elucidating oxidation states and coordination numbers of gold compounds, but the number of studies is still very limited.

Proton, carbon, and other standard nuclei in organogold compounds can routinely be studied by NMR spectroscopy. Since virtually all organogold compounds are diamagnetic, the results are generally of high quality, both in solution and solid-state (magic-angle spinning/cross-polarization (MAS/CP)) investigations. Chemical shifts and coupling constants are not unusual and follow general trends in organometallics of heavy late-transition elements. Solution kinetics has been followed by temperature-dependent measurements.

In vibrational studies (IR/Raman, *see Infrared Spectroscopy* and *Raman Spectroscopy*), characteristic frequencies for Au–C bonds have been compiled, which are useful for suggestions regarding molecular symmetries and structures and to calculate force constants for the Au–C bonds. The values have been tabulated in handbooks, and they show consistent results for the individual groups of compounds. Moreover,

there are the expected parallels with data for organometallic compounds of neighboring elements (Hg, Pt).

Only very few organogold compounds are colored. Spectroscopy in the visible region is therefore rarely used. Only a few groups of Au^{III} compounds and the ferrocenylgold(I) complexes have been investigated, and the results have not yet been evaluated in detail. UV absorption studies are also quite limited, except for some more recent luminescence and fluorescence (*see Fluorescence*) work on multinuclear complexes or clusters.

Single-crystal X-ray diffraction (*see X-ray Diffraction*) studies have been carried out on a large number of organogold compounds. Since only very few compounds are sensitive to X-rays, structure determination rarely presents problems, if appropriate corrections are applied, including those for absorption, which are mandatory for the data sets used for calculations.

5 STRUCTURE AND BONDING

As in many gold(I) compounds, the metal atom in organogold(I) species is strictly two-coordinate with a linear array of the two ligands. For example, in crystals of methyl(triphenylphosphine)gold(I), the C–Au–P axis has an angle of 179.1°. The Au–C bond is 2.124 Å long and absorbs in the IR region at 531 cm^{-1} (the Au–P bond is 2.279 Å long). The UV absorption maximum is found at 275 nm, meaning that the compound is colorless. These data are interpreted in terms of covalent Au–C σ-bonding of low polarity. Employing two Au(sp) hybrid orbitals, together with a C(sp^3) and a P(sp^3) hybrid orbital, two localized two-center/two-electron bonds can be constructed with Au^+, CH_3^-, and PMe_3 as the components.

In alkenyl- and arylgold compounds, or in carbene complexes, the ligating carbon atoms are to be taken as sp^2 hybridized, but no other assumptions have to be made. The same scheme is valid for the linear complexes (CO)AuCl, $Me_3CC{\equiv}CAuPMe_3$, or MeNCAuCN, where CO, PMe_3, or MeNC are neutral donors, and Cl^-, $Me_3CC{\equiv}C^-$, and CN^- are the anionic ligands, respectively, the latter with C(sp) hybrids.

Gold(I) appears to be a very weak π-acceptor (*see π-Acid Ligand*), and back bonding (*see Back Bonding*) from filled π-orbitals of the ligands into empty orbitals of the metal is not likely to contribute significantly to the C–Au interactions. Au–C bonds are therefore taken as σ-bonds of unit bond order. The closed-shell $5d^{10}$ configuration of Au^I leaves only the 6p states available for π-interactions. The low stability of the few π-complexes of Au^0 and Au^I reported in the literature also reflects this low-acceptor character of gold(0) and gold(I).

For the same reason, cyclopentadienylgold(I) compounds are exclusively monohapto or σ-bonded (*see Hapticity*). In solution, there is rapid site exchange of the metal at the ring carbon atoms, but at low temperature, a monohapto structure is readily detected by NMR spectroscopy.

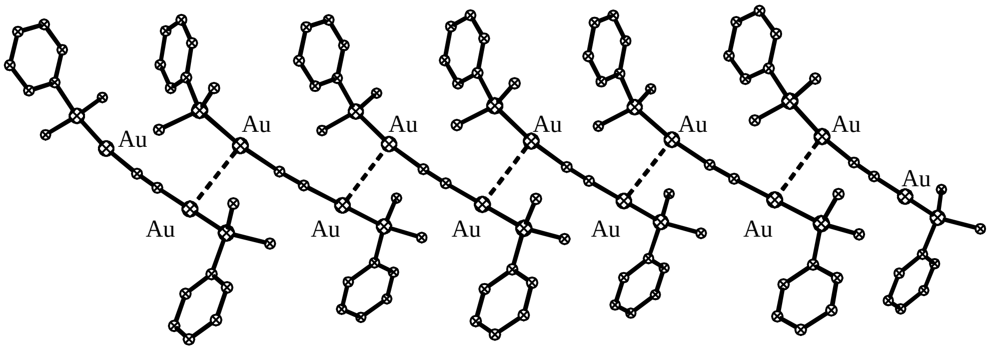
Organogold(II) compounds are only well established for dinuclear cases with direct metal–metal bonding. The metal atoms in these species are square-planar tetracoordinate, and the description of their bonding follows the models for gold(III) complexes with the same coordination geometry (below). The Au–Au distances observed fall in the range 2.60–2.80 Å and are unique cases of localized Au–Au single bonding. The dimeric ylide complex $[(Me_2PCH_2)AuI]_2$ is a representative example for this class of compounds.

Organogold(III) compounds with one to four organic groups attached to Au^{III} are square planar and four coordinate. Complexes having a lower coordination number appear to be inherently unstable. In the absence of independent donor ligands, the organogold fragments associate with the formation of ligand bridges between metal atoms. Organic groups appear to be unsuitable for metal bridging, however, and structures like those of dimeric trialkylaluminium compounds have not been found in organogold chemistry (*see* ***Aluminum: Organometallic Chemistry***).

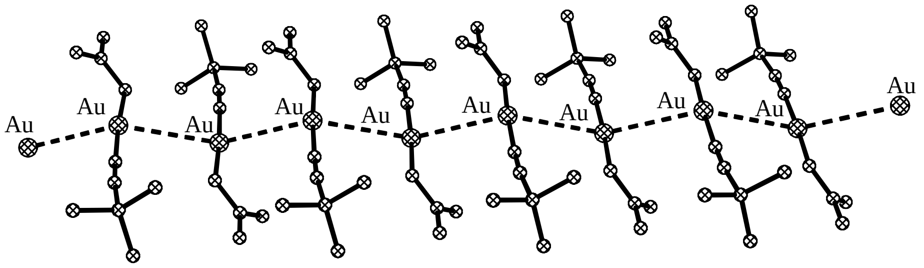
Thus, 'naked' R_3Au compounds are unknown (as are 'naked' RAu), but $R_3Au{\cdot}L$ compounds are stable. For R_2AuX systems, oligomerization occurs if X has donor capabilities, to give X-bridged aggregates, while the addition of donor ligands leads to mononuclear complexes $R_2AuX{\cdot}L$. $RAuX_2$ species appear as unsymmetrical dimers. In a redistribution of the ligands R and X, compounds of the type $R_2AuX{\cdot}AuX_3$ are formed.

In $Me_3Au{\cdot}PPh_3$, the two cis Au–C bonds are longer than the trans Au–C bond owing to the trans influence (*see Trans Effect*) of the tertiary phosphine: Au–C (cis) = 2.100 and 2.168 Å; Au–C (trans) = 1.923 Å (Au–P = 2.350 Å). All angles at Au are close to 90°. The structure of the complex is configurationally stable, and two different methyl groups can be distinguished in the proton or carbon NMR spectra of solutions (intensity ratio 2:1). IR absorption bands at 512 and 530 cm^{-1} can be ascribed to the Au–C stretching vibrations of the complex.

For a description of the chemical bonding, Au^{III} can be introduced as dsp^2 hybridized, and a set of localized σ-bonds can be constructed with the σ-orbitals of the three carbon atoms and the phosphorus atom. In the more symmetrical case of $[AuMe_4]^-$, four equivalent Au–C bonds arise from this model. In a different approach, crystal or ligand field theory may also be successfully employed for a description of bonding in this anion. With CH_3^- anions as extremely strong ligands, a low-spin d^8 state is obtained, which accounts very well for the diamagnetism observed with all organogold(III) compounds. Like gold(I), gold(III) is also a weak π-acceptor, and R–Au^{III} bonds are probably of pure σ-character. π-Complexes of Au^{III}, for example with alkenes, are unstable in most situations, that is, in nonforcing structures.



(**2**) $[PhMe_2P\cdot AuC{\equiv}CAu\cdot PMe_2Ph]_n$



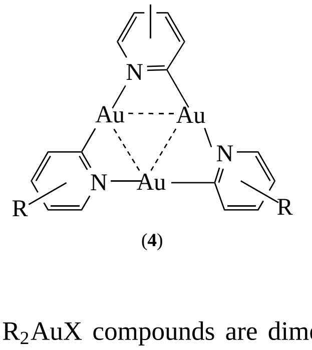
(**3**) $[(NO_3)AuC{\equiv}N^tBu]_n$

For multinuclear structures, and for details of energy levels as related to optical properties, the theoretical treatment of organogold compounds has to be modified to include relativistic effects (*see Relativistic Effects*), which are particularly strong for gold.[15] With two, three, or more gold atoms attached to a given carbon atom, significant metal–metal bonding arises, which leads to unusually small Au–C–Au angles (<109°; for aliphatic carbon) and short Au···Au contacts (ca. 2.80 Å). These structural effects can be accounted for by calculations with relativistic Au(6s) contraction and Au(5d) expansion, which lead to a mixing of states. Hypercoordinate (*see Hypercoordination*) carbon, as in $[C(AuL)_5]^+$ and $[C(AuL)_6]^{2+}$, adopts a trigonal bipyramidal and octahedral structure, respectively, with similar geometrical characteristics and with both radial and peripheral (Au···Au) bonding. Pertinent examples are given below.[33]

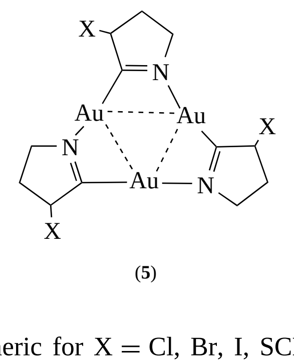
The same phenomenon is responsible for the aggregation of independent RAu·L species via Au···Au contacts in the solid state, or of RAu·L units in polynuclear compounds, which leads to unusual conformations. Illustrative examples are the oligomeric gold(I) acetylide and isonitrile (isocyanide) complexes (**2**) and (**3**), where the slim ligands give unlimited access to the gold atoms.[32,52,53] Generally, however, this effect is weaker for organogold compounds than for other gold(I) complexes, probably due to the strong electron-donating capabilities of the organic substituents. Au···Au interactions are also less common for Au^{III} pairs than for Au^I pairs or Au^IAu^{III} mixed-valence systems, although examples are known for these combinations as well.

6 SELECTED INDIVIDUAL COMPOUNDS

Very much like the RCu and RAg analogs, simple organogold(I) compounds of the type RAu are generally unstable. 2,4,6-Trimethylphenylgold(I) was shown to form pentamers with mesityl-bridging of the gold atoms.[54] If R contains a donor center E, as in α-pyridyl, the RAu compounds also oligomerize with the formation of linear R–Au–E units (see **4** and **5**). The α-pyridylgold trimer is an example in case, and also the numerous carbene–gold compounds. In most of these oligomers, the Au···Au contacts are short enough to allow transannular bonding interactions.

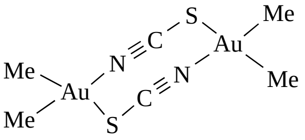


(**4**)

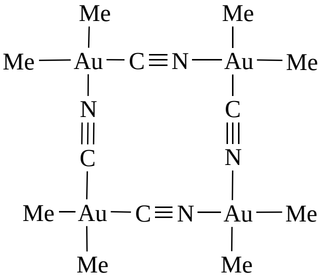


(**5**)

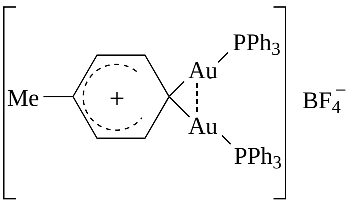
R_2AuX compounds are dimeric for X = Cl, Br, I, SCN, RCO_2, $OSiR_3$, SR, SeR, NR_2, PR_2, or AsR_2 (see **6**), and tetrameric for X = OH or CN (see **7**). Fluorides R_2AuF have not been reported, but are likely to have a larger ring or chain structure, like AuF_3. Sulfates and phosphates are also associated but most of their structures are unknown.



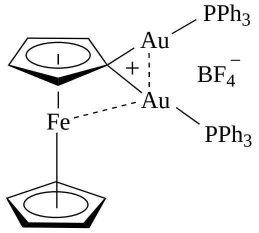
(**6**)



(**7**)

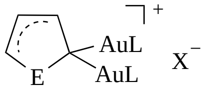


(**11**)

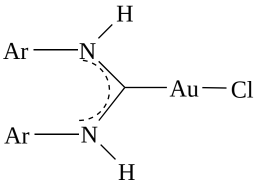


(**12**)

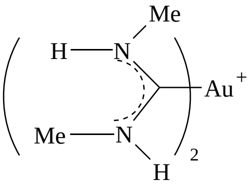
The chemistry of carbene complexes is well advanced, and numerous examples have been synthesized and structurally characterized. Prototypes are represented by structures (**8**–**10**).



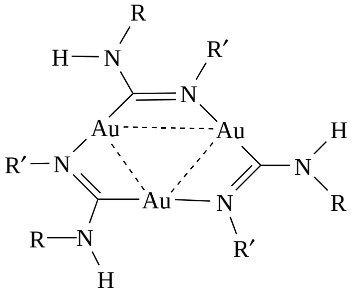
(**13**)



(**8**)



(**9**)

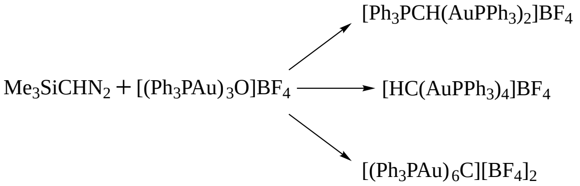


(**10**)

Gold compounds with hypercoordinate (*see Hypercoordination*) carbon atoms are a rapidly growing class of multinuclear organogold compounds with very special features of structure and bonding. It is important to note in this context that gold does not form any ligand-free carbide phases Au_mC_n. Clustering of gold around carbon is thus unique to this chemistry developed out of the addition of LAu^+ acceptors to organogold precursors. Neighboring elements in an isoelectronic state, such as Hg^{II} or Pt^0, do not form similar clusters.

Early examples for this phenomenon are the addition reactions of Ph_3PAu^+ to *p*-toly(triphenylphosphine)gold(I) (**11**) and to ferrocenyl(triphenylphosphine)gold(I) (**12**) to give cationic species with *p*-tolyl and cyclopentadienyl ring carbon atoms engaged in bonding to a pair of gold atoms. This reaction pattern was confirmed for heteroarenes such as furan and thiophene (**13**).[55]

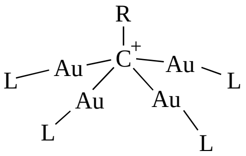
R-C$(AuL)_3$ moieties are present in onium cations $[P_3P–C(AuL)_3]^+$, obtained from silylated ylides $R_3P{=}C$-$(SiR_3)_2$ on treatment with L·AuCl and CsF. Polyborylmethanes or -ethanes are the precursors not only for tetragoldmethane complexes[56,57] but also for penta- and hexagoldmethanium cations and of 1,1,1,1-tetragoldethanium cations, (**14**)–(**16**).[33] Another route uses the silyldiazomethane Me_3SiCHN_2 as a source for the interstitial carbon atom of the clusters (equation 44).[58] Owing to the high stability of the salts containing these novel cations, the compounds are readily identified by elemental analyses, field desorption mass spectrometry, NMR spectroscopy, and X-ray diffraction of single crystals, and rationalized by theoretical calculations.[59] The presence of the interstitial carbon atom has been confirmed by ^{13}C NMR using material enriched in ^{13}C. Up to four gold atoms could also be attached to the carbon atom of sulfur ylides (**17**).[60,61]



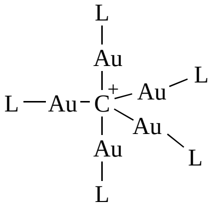
(44)

7 USAGE OF ORGANOGOLD COMPOUNDS

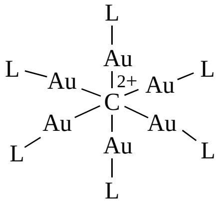
For several decades, many organogold compounds have been tested as potential drugs for the treatment of rheumatoid arthritis and related diseases, for venereal diseases, and, more recently, for cancer therapy. None of these investigations has led to a medical breakthrough, and such efforts have largely been discontinued. Current research is oriented toward an improvement of existing drugs (none of which is an organogold chemical), regarding side effects and administrational aspects.



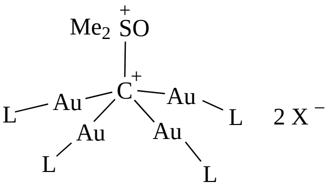
(**14**)



(**15**)



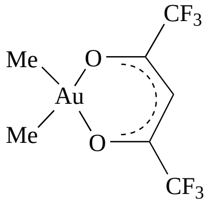
(**16**)



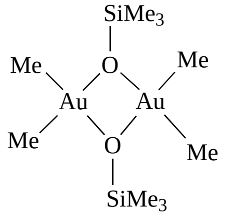
(**17**)

L = PR_3; R = alkyl, aryl, $S(O)R_2^+$

Volatile organogold compounds are candidates for new ways of depositing gold films on surfaces (*see* ***Metallic Materials Deposition: Metal-organic Precursors***). The most promising materials are dimethyl(acetylacetonato)gold(III) and its hexa- (**18**) or trifluoro derivatives, dimethyl(trimethylsilyloxy) gold(III) (**19**), methyl(trimethylphosphine)gold(I) (**20**), and methyl(methyl isocyanide)gold(I) (**21**). Thermal as well as plasma and photodecomposition experiments have been very successful for all of these compounds. The major disadvantage of the dimethylgold(III) compounds is the high cost of their production, caused by low yields in the preparation of any Me_2AuX precursor (<35%). The volatility of the compounds, and of the fluorinated acac compounds in particular, is quite satisfactory as already demonstrated in earlier analytical studies using gas/liquid chromatography. With the isocyanide complex, incorporation of carbon into the gold films has been reported, and with the phosphine complex, some environmental concern is becoming apparent. Therefore, usage of organogold compounds is still rather limited, even on the small scale required for the microelectronics industry.



(**18**)



(**19**)

$\mathrm{Me{-}Au{-}PMe_3}$

(**20**)

$\mathrm{Me{-}Au{-}C{\equiv}N{-}Me}$

(**21**)

A rather new field emerging in organogold research is the study of luminescence and phosphorescence phenomena, associated in most cases with Au···Au secondary bonding. The optical properties and the mechanism of the excitation and emission are still poorly understood, but may provide a new basis for applications[62–64] (*see* ***Photochemistry of Transition Metal Complexes***).

Gold(I) complexes of alkenes and alkynes appear to play an important role as intermediates of the gold(I)-catalyzed addition of water, alcohols, carboxylic acids, or amines to these substrates. The effect of this π-complexation (**22**) is superior to the performance of mercury(II) in this type of reactions.[65–67] In a similar way, gold(III) salts have found applications in homogeneous catalysis.[68]

1 INTRODUCTION

Halides have been known since earliest times and archeological evidence for the use of rocksalt, the most generally known halide, dates back thousands of years. The trade with this salt was the origin of wealth and prosperity in many regions around the globe, but other halides also have had a tremendous impact on all aspects of our world's history. In particular, during the past 200 years, the halogens and their compounds have significantly contributed to the development of both experimental and theoretical chemistry.

The immense number of chemical compounds formed by the halogens provides chemists with an extraordinary database from which numerous chemical and physical phenomena can be correlated with respect to various periodic trends.[1,2] From databases like *Inorganic Crystal Structure Data* (ICSD, 'http://www.fiz-karlsruhe.de') and *International Centre for Diffraction Data* (ICDD, http://www.icdd.com) with ~67 000 and ~25 000 entries, respectively, one can easily make out that halides are one of the dominant classes of compounds besides oxides. Even within the subset of inorganic solids, there is tremendous diversity of composition, structure, and properties and to summarize this would create its own encyclopedia. Therefore, the discussion in this article is limited primarily to binary halides, their structures, and some of their properties, except halides of elements which are nonmetals. Binary actinide halides are discussed elsewhere (*see* ***Actinides: Inorganic & Coordination Chemistry***). Complex halides (solid phases containing two or more kinds of metal ions),[3] mixed halides, halides containing other anions (H^-, O^{2-}, S^{2-}, $N^{3-}C^{4-}$, B^{n-}, etc.), and polyhalides[4] will also not be addressed.

2 THERMODYNAMIC ASPECTS OF HALIDE FORMATION

2.1 Halide Formation from Elements

A dominant feature of the chemistry of the halogens is the facility with which their atoms acquire an electron from a metal to form the uninegative ion X^-. The main reason for that lies in the electronic structure of the free atoms, [A]ns^2np^5 (A = previous noble gas), which accounts for the strong affinity for electrons and reducing capabilities in order to achieve the electronically stable closed-shell (octet) configuration. As the oxidation potentials of Table 1 and other data suggest, however, this uninegative oxidation state becomes progressively less stable with respect to the free element of atomic number (I < Br < Cl < F), and fluorine is indeed the most reactive of all elements.

Thermodynamic stability of a general metal–halide MX_n with respect to its elements under ambient conditions is assessed according to $\Delta G^\circ{}_f(MX_n)$, which necessarily has a large entropic contribution for solid fluorides and chlorides. Basic knowledge for the understanding of the existence and stability of halides is wonderfully described by D.A. Johnson.[5] One can break down a chemical reaction, such as $M(s) + (n/2)X_2 \rightarrow M^{n+}(g) + nX^-(g) \rightarrow MX_n(s)$, into a series of hypothetical steps known as a Born-Haber cycle (equation 1).[5] The enthalpy change for the first process is given by $\Delta H^\circ{}_f(M^{n+}, g) + n\Delta H^\circ{}_f(X^-, g)$. Table 1 contains values of $\Delta H^\circ{}_f$ (X^-, g) for the halogens. $\Delta H^\circ{}_f(M^{n+}, g)$ will have large positive values due to both sublimation and subsequent atomic ionization energies for each metal, so the first process is endothermic.

The energetics of the second step has received a tremendous amount of theoretical attention.[6,7] The enthalpy change is defined as the negative of the lattice energy for the solid MX_n, which itself is defined as the energy needed to separate a solid into its constituent gaseous ions. Since the forces holding atoms together in molecules and solids are largely electrostatic, and the thermodynamic values in Table 1 suggest that a large degree of charge transfer takes place in metal halides, the lattice energies for these compounds are generally large, positive, and usually outweigh the enthalpy term for the first reaction. Therefore, $\Delta H^\circ{}_f(M^{n+}$; s) for most metal halides adopts large negative values. Moreover, $\Delta G^\circ{}_f(MX_n$, s) will also be negative, except at very high temperatures, at which point entropic effects are influential.

Table 1 Contributions to the standard enthalpies of formation of gaseous halide ions at 298.15 K

Property	F	Cl	Br	I
Ionic radius, X^-/pm	133	165	181	199
van der Waals radius/pm	135	180	195	215
$1/2\Delta H_f^\ominus(X^-, g)$/kJ mol^{-1}	0	0	15.5	31.2
$1/2D(X_2)$/kJ mol^{-1}	79.0	121.7	96.4	75.6
$-Ea(X)$/kJ mol^{-1}	−343.5	−361.5	−339.6	−297.2
$5/2RT$/kJ mol^{-1}	−6.2	−6.2	−6.2	−6.2
$\Delta H^\circ{}_f(X^-, g)/(\text{kJ mol}^{-1})^a$	−270.7	−246.0	−233.9	−196.6

$^a\Delta H^\circ{}_f(X^-, g) = \Delta H^\circ{}_f(X_2, g) + 1/2D(X_2) - E_a(X) - 5/2RT$.

2.2 Stability of Halides Containing High and Low Metal Oxidation States

Many elements exhibit several different oxidation states, and the relative stabilities of MX_n and MX_m are often more difficult to assess. Assuming the lattice energy to be inversely proportional to the shortest M–X distance in the structure, then, since halide ion radii increase from F^- to I^-(Table 1), fluorides generally have the largest values and iodides the smallest values for lattice energies. However, one has to consider the stabilities of fluorides or iodides with respect to each other, for example, a solid salt MX_{n+1} decomposing into another, MX_n, and $1/2X_2$. From the Born-Haber cycle (with some approximations) one obtains for such a reaction

$$\Delta H_m^\ominus = L(MX_{n+1}) - L(MX_n) - I_{n+1} - \Delta H_f^\ominus(X^-, g) \tag{1}$$

where I_{n+1} is the $(n+1)$th ionization potential and $L(MX_{n+1})$ and $L(MX_n)$ are the lattice energies of the salts MX_{n+1} estimated by the Kapustinskii equation[8] with

$$L_0 = \frac{W\nu}{r_+ + r_-} \quad (W = 1.079 \times 10^5 \text{kJ} \times \text{mol}^{-1}\text{ pm}, \; r_+ = \text{cation and } r_- = \text{anion radius}) \tag{2}$$

$$\Delta H_m^\ominus = \left[\frac{W(n+1)(n+2)}{r(M^{(n+1)+}) + r(X^-)} - \frac{Wn(n+1)}{r(M^{n+}) + r(X^-)}\right] - I_{n+1} - \Delta H_f^\ominus(X^-, g) \tag{3}$$

If the term in the bracket is put equal to x, while n and the cation radii are kept constant, one obtains for the change of x with the size of the anion as

$$\frac{\partial x}{\partial r(X^-)} = -W(n+1)\left[\frac{(n+2)}{[r(M^{(n+1)+}) + r(X^-)]^2} - \frac{n}{[r(M^{n+}) + r(X^-)]^2}\right] \tag{4}$$

In most of the cases, $r(M^{(n+1)+})$ will be less than $r(M^{n+})$, although it is not necessarily crucial. Consequently, as n is positive $\partial x/\partial r(X^-)$ will be less than zero, and x will become more negative as the size of the anion is increased. Now the changes in $T\Delta S$ from halogen to halogen are small compared to $\Delta H^\circ{}_f$. Thus the variations in both $\Delta H^\circ{}_f$ (X^-, g) and the difference in lattice energies place the capacities to stabilize the higher oxidation states in the order F > Cl > Br > I. The stabilities of lower or medium oxidation states can be derived in a similar manner for the large anions. For example, the fluorides are the only halides of dipositive silver, trivalent cobalt or tetravalent manganese, cerium, praseodymium and terbium or pentavalent gold which have been prepared. On the other hand, the fluorides are the only unknown halides of gold(I) and copper(I), presumably because they are unstable with respect to the formation of Au and AuF_3 and Cu and CuF_2, respectively. That the iodides of copper(II) and iron(III) have not been obtained pure, because they are unstable at room temperature, decomposing into CuI and FeI_2 can also be understood by such an approach. To summarize, within the series iodides, bromides, chlorides, and fluorides the difference in the stabilities of the halide with metal atoms in high oxidation states and the corresponding reduced halide increases and therefore the tendency for disproportionation reactions is maximal among fluorides.

3 COMPOSITION, COORDINATION NUMBER, AND POLYHEDRA CONNECTIVITY

The compositions of metal halides are dominated largely by the stable oxidation states for the metal component. It is important at this point to realize that thermodynamics, when applied to solid-state systems, treats compounds as solid solutions. Thus, most of the compounds to be discussed in this article are considered as ‘line’ compounds, which have extremely narrow (but nonzero) ranges of homogeneity because extremely large variations of chemical potential accompany negligible changes in chemical composition.[9] Nevertheless, significant crystal chemical information can be derived from a simple empirical formula for an inorganic solid. In fact, the empirical formula provides information on the possible topologies (connectivities) of structural networks

available for a given composition. Like for any compound the number and kind of possible crystal structures of halides can be easily derived from a given formula, especially when using graph theoretical tools.[10] In particular, if the average coordination number (C.N.) of M by X in the halide MX_n is C.N. (M: MX_n), then the coordination number of X by M is C.N.(X; MX_n) $= 1/n$ C.N. (M: MX_n). Therefore, for large n, the topology of metal halides is generally low dimensional for small cations, higher dimensional for larger cations. As a simple example, Al^{3+} is large enough to coordinate 6 F atoms and the crystal structure of AlF_3 consists of a 3D framework of connected AlF_6 octahedra. The neighboring tetravalent elements Si and Ge are smaller, their coordination number in the tetrafluorides MF_4 is 4, equal to the anion/cation ratio, and a molecular structure (0D) with isolated MF_4 tetrahedra is found. As a consequence AlF_3 melts at 1254 °C whereas SiF_4 and GeF_4 are gaseous at room temperature. The larger Sn has a C.N. of 6 in SnF_4, which on the other hand is a solid at room temperature containing a condensed network of SnF_6 octahedra.

Another aspect that will become clear in the following chapters is the fact that condensation via corners is favored in fluorides whereas condensation via edges or faces is more common among the higher homologues. Short M–F distances in fluorides lead to short M–M distances and electrostatic repulsion of the higher charged metal atoms makes corner sharing much more favorable. This changes gradually from chlorides via bromides to iodides, besides direct metal–metal bonding as stabilizing factor for edge sharing or face sharing. For example, face-sharing polyhedra are not found among fluorides and one finds condensation of polyhedra via corners, edges, or faces correlated with the size of the halide.

4 MAIN GROUP HALIDES

Information about the binary main group metal halides abounds in numerous texts and tabulations.[1,3,4,11,12] Table 2 gives a qualitative listing of many of the halide stoichiometries adopted by the main group metals. All solid-state compounds tend to behave as salts with very low electrical conductivity. Many of the pure compounds with metals in their higher

Table 2 Representative binary halides of the main group metals[a]

Group	Fluorides	Chlorides	Bromides	Iodides
	LiF	LiCl	LiF	LiF

15	BiF_5, BiF_3	$BiCl_3$, Bi_6Cl_7	$BiBr_3$, BiBr Bi_6Br_7,	BiI_3, BiI, Bi_7I_2, Bi_9I_2

[a]Structures are discussed in the text.

possible oxidation states are colorless, while lower oxidation states develop yellowish, orange, or red colored crystals. Iodides and some bromides often show red/lustrous dark brown colors. There are also relatively few examples of metal–metal bonding in any of the reduced binary halides.

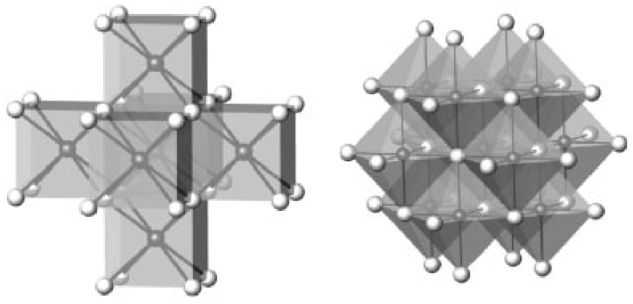
Vertical trends are affected by both the metal and the halide. As one goes down a column, larger cation radii lead, in general, to larger coordination numbers. On the other hand, increasing anion radii from fluoride to iodide (Table 1) generates increased anion–anion repulsions and smaller coordination numbers. Furthermore, oxidation states two less than their maximum allowed values (the 'inert-pair effect') are prevalent for the heavier atoms in a group, and are manifested in the relative stabilities of, for example, TlCl and $TlCl_3$.

Recent efforts involving these systems include: (i) high-pressure studies and structural phase transformation; stabilization of mixed valence main group metal halides; (iii) synthesis of low oxidation state halides; and (iv) characterization of mixed metal halides.

4.1 Alkali Metal Halides

At ambient conditions, the crystalline alkali halides CsCl, CsBr, and CsI have the CsI structures whereas all others adopt the rocksalt structure (*see* ***Alkali Metals: Organometallic Chemistry***); see Figure 1.

Radius ratio rules would ascribe the differences to the increased size of the cations, since Cs^+ is eight-coordinate cubic in CsCl, whereas Na^+ is six-coordinate octahedral in NaCl. However, these 'rules' are not successful for some of the alkali metal halides. For example, LiCl should adopt the zinc blende structure with four-coordinate tetrahedral Li^+ ions rather than the observed NaCl type. It is, therefore, not so surprising that mixed metal halides like $RbLiBr_2$ show significant differences from the parent rock salt structure.[13] Nevertheless, these halides nearly fit the classical conception of ionic bonding. Their heats of formation are reproduced using Born-Haber cycles with the lattice energy evaluated from Madelung terms, short-range repulsions, and van der Waals attractions.[7] However, precise electron density plots obtained from careful diffraction experiments on LiF, NaCl, and KCl indicate some electron density between cation and anion (the ions are not hard spheres) and, for example, the Li centers in LiF are not spherically symmetric.[14] Ionic radii obtained from these plots give larger cation and smaller anion values than those found in standard tables. Therefore, the M^+X^- formulation is an extreme description of the bonding in these traditional ionic materials, and even in the simple rocksalt structure type there must be an intricate balance between nearest neighbor (cation–anion) and next nearest neighbor interactions (anion–anion, cation–cation), which cannot simultanously be satisfied in a given structure. Therefore, if the cation is small and the anion is large or vice versa, unusual properties are observed, for example, the solubility of LiI in organic solvents or the strong hydrophilic properties of RbF or CsF compared to their lighter homologues NaF and KF. CsF also reacts with bromine under the formation of $CsFBr_2$,[15,16] which exhibits a distorted CsF structural framework with embedded neutral molecular Br_2 units. This situation is completely different from $CsBr_3$, which is a polybromide with $[Br_3]^-$ units or CsI_3or RbI_3 with linear $[I_3]^-$ anions.[4]



(a) (b)

Figure 1 Polyhedral representation of the structures of (a) CsI and (b) NaCl

Under elevated pressures, the rocksalt structure transforms into the CsCl structure.[3] Changes in lattice constants and measurements of other physical properties have provided much quantitative information for empirical fits to equations of state. Modern theoretical tools are used for obtaining a deeper understanding of charge being transferred back from the anion towards the cation in the alkali halides. However, as can be seen from calculations of their cohesive properties,[17] even nowadays there are problems to be solved for such simple structures. The data for the halide ions, in particular, are quite useful and may be transferred to other halide systems, and give good predictive values for more complex systems.

4.2 Alkaline Earth Metal Halides

All of the alkaline earth metals form saltlike MX_2 dihalides (*see* ***Alkaline Earth Metals: Inorganic Chemistry***). Within this group, we observe structural effects owing to both cation sizes and properties of the halide ions. From Be to Ba, coordination numbers monotonically increase from four (tetrahedral) in Be dihalides to eight (cubic) or nine (tricapped trigonal prismatic) in the Ba systems.

BeF_2, which is best made by thermal decomposition of $(NH_4)_2BeF_4$, is a glassy compound that crystallizes with difficulty. Like SiO_2, BeF_2 shows various frameworks of corner-sharing tetrahedra, both crystalline and amorphous. With the larger chlorine there is an α-modification of $BeCl_2$ which adopts an unusual tetrahedral framework,[18] whereas the β-modification of $BeCl_2$,[19] is isotypic to SiS_2, like $BeBr_2$ containing chains of edge-sharing tetrahedra $^1_\infty[BeX_{4/2}]$ (this notation indicates the dimensionality (1) of a quasi-infinite extended network; Figure 2). The X–Be–X angle within each

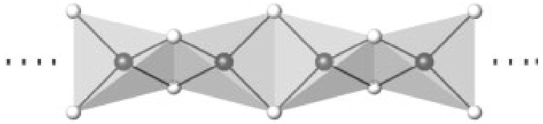


Figure 2 Chain structure of $BeCl_2$. In every figure, open circles represent halides, filled circles represent metal atoms

X–Be–X–Be rhombus is substantially smaller than 109.5°, suggesting that the local coordination at Be tries to diminish the repulsions between Be^{2+} ions. The highly moisture sensitive BeI_2 has been known for more than a century, but its structure is still unknown and the question arises whether the coordination number of Be by I is still four and not three as one might expect.[20]

The MgX_2 have Mg^{2+} ions in octahedral coordination, and their structures reflect the properties of each halide ion, especially with respect to polarizability. MgF_2 adopts the rutile structure, whereas layered morphologies occur for the heavier halides: $CdCl_2$ and CdI_2. A fundamental difference between these structures is that in rutile each F^- is nearly trigonal planar coordinated by Mg^{2+} (but planar), and in CdI_2 the I^- ions have trigonal pyramidal environment. The heavier metal dihalides of Ca, Sr, and Ba reveal an interesting effect of optimizing cation coordination number and anion–anion repulsion.[21] Moreover, these two forces need to be coupled with the covalent character and polarizability of the anion. Thus, the MF_2 compounds adopt fluorite structures, whereas other geometries are found for chlorides, bromides, and iodides.

The $CaCl_2$ structure for $CaCl_2$, $CaBr_2$, and $SrCl_2$ is slightly distorted from rutile, but the anion coordination is pyramidal rather than planar. In fact, whereas the anion packing in rutile is a distortion of hexagonally close-packed anions (hcp), the anion arrangement in $CaCl_2$ is nearly ideal hcp. Compounds of the type BaX_2 (X = Cl, Br, I) all show the complex $PbCl_2$ structure (Figure 3) with nine-coordinate Ba^{2+}. There are two symmetry inequivalent anions whose coordinations are nearly tetrahedral for one and nearly square pyramidal for the other. The forces we mentioned earlier lead to an interesting trend in the SrX_2 series: maximum coordination around Sr^{2+} occurs in $SrBr_2$, approximately nine ($PbCl_2$-type). SrI_2, on the other hand, adopts a unique structure in which each Sr^{2+} is seven coordinate: the polyhedral arrangement is a hybrid between a cube and a trigonal antiprism.[22] A metastable form of SrI_2 was recently isolated with seven-coordinate Sr as well.[23] n

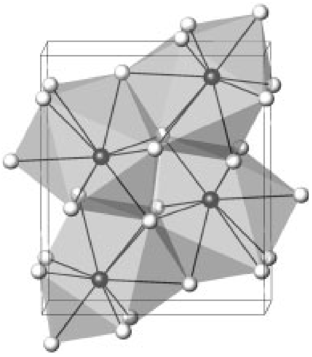

Figure 3 Structure of $PbCl_2$

Recent high-pressure experiments on alkaline earth metal dihalides indicate that most of the observed transitions can be interpreted in purely geometric terms by considering ion compression, radius ratios, and increase in coordination and packing efficiency.[24] The Sr and divalent rare earth halides undergo transitions to the $PbCl_2$-type. Crystal chemical analysis of compounds adopting the orthorhombic $PbCl_2$-type structure show that there are two adjustable parameters, that is, the a/b and c/b ratios, that separate these compounds into 'ionic' and 'non-ionic' regions.[25] SrI_2, SmI_2, and EuI_2 fall in a region which indicates a low ionicity, unlike the saltlike BaX_2 phases at normal pressure.

On the other hand, the high-pressure phase BaI_2-II, which can be quenched and retained at ambient conditions, forms the *anti*-Fe_2P structure (Figure 4a). This modification is structurally related to the $PbCl_2$-type formed at normal pressures (Figure 4b) but slightly more dense.[26] Surprisingly, neither $BaCl_2$ nor $BaBr_2$ will undergo a similar transformation under pressures up to 3.0 GPa in a belt apparatus. However, solvolytic decomposition of mixed halide precursors have led to the *anti*-Fe_2P type for these two systems.[27]

At one point, Ca, Sr, and Ba were believed to adopt monohalides as well.[28] Their geometries, based upon X-ray powder diffraction, suggested a distortion of the rocksalt structure, but without significant metal–metal bonding. With nine valence electrons per formula unit, simple models

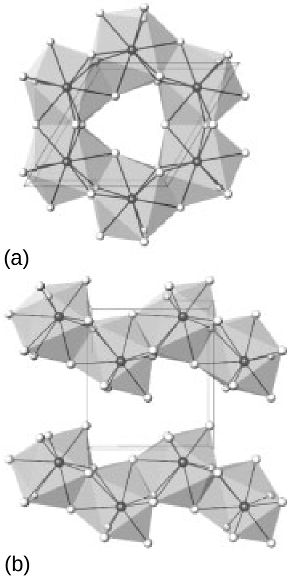

Figure 4 Projection of layers of condensed MX_9 polyhedra together with the unit cells in the structures of (a) BaI_2-II and (b) $PbCl_2$

predicted metallic character, yet ‘these compounds’ are colorless insulators. The monohalides are, in fact, hydride halides MXH.[29] Treating each hydrogen atom as H^- provides a rationale for their insulating behavior.

4.3 Group 13 Metal Halides

The lightest element of the group 13, boron, exhibits aspects of covalent metal–halide interactions. It is the first element to form reduced halides in which the access valence electrons are localized in boron–boron bonds. As a consequence the chemistry of reduced boron halides chemistry is very rich, consisting of numerous phases containing polymeric boron units embedded in a halide matrix (*see* ***Boron: Inorganic Chemistry***). The group 13 metals are the first main group elements to show multiple stoichiometries in their halides (*see* ***Aluminum: Inorganic Chemistry***; ***Gallium: Inorganic Chemistry***; ***Indium: Inorganic Chemistry***; ***Thallium: Inorganic Chemistry***). Most of the structures show evidence for both $M^I$and M^{III}, both of which are closed-shell configurations and adopt typical lone pair structures. However, few of them indicate strong metal–metal bonding.

The variation in cation size from Al^{3+} to Tl^{3+} in MX_3 leads to structures that range from three-dimensional (3D) frameworks to packings of molecular species. Most of the trihalides are made by direct combination of the elements. The trifluorides, on the other hand, are obtained from thermal decomposition of NH_4MF_6 or $(R_4N)AlF_6{\cdot}H_2O$. Also, HF reacts at 970 K with Al_2O_3 to give AlF_3.

The fluorides, AlF_3, GaF_3, and InF_3, adopt structures related to ReO_3. In ReO_3, each metal ion is octahedrally coordinated and each anion is linearly coordinated. In these MF_3 systems, however, the M–F–M angles are around 150°, which suggests some polar covalent character to the metal–fluoride interaction, although these observations are not well understood. A recent investigation reports a new corner-sharing octahedral 3D network for τ-AlF_3.[30] With the heavier halides, these three metals form either the layered $AlCl_3$-type (Figure 5) with six-coordinate metals or the molecular Ga_2Cl_6-type (Figure 6) with tetrahedrally surrounded cations. In $AlCl_3$, the anions are cubic closest packed (ccp) with metals in 1/3 of the octahedral holes. Each MX_6 octahedron shares three edges with neighboring octahedra according to ${}^2_\infty[(\square X_{6/3})(MX_{6/3})_2]$. Near the melting point of $AlCl_3$ (465 K), the Al^{3+} ions must diffuse in the chloride matrix from the octahedral to tetrahedral interstices because Al_2Cl_6 molecules are formed in both the liquid and gaseous states. In addition, the conductivity of $AlCl_3$ drops dramatically near the melting point, unlike most other ionic salts.[31] The dimers consist of two edge-sharing MX_4 tetrahedra to give $MX_2X_{2/2}$ and distort in a similar fashion as $BeCl_2$ to minimize cation–cation repulsions.

The halides TlX_3 (X = I, Br, Cl, I) provide an interesting series which couples both anion packing forces and the electronic stability of Tl^I against Tl^{III}. TlF_3 adopts the YF_3 structure: a 3D framework with Tl^{III} in a distorted tricapped trigonal prism of F^- ions.[32] $TlCl_3$ is isomorphous with YCl_3 and can be described as an ordered defect rocksalt structure. It is hygroscopic and easily forms hydrates. $TlBr_3$ presumably contains Tl_2Br_5 dimers. TlI_3, however, contains I_3^- ions, another indication of larger anions stabilizing low oxidation states of metals. In fact, $TlCl_3$ and $TlBr_3$ lose X_2 (X = Cl, Br) at around 320 K to give TlCl and TlBr.

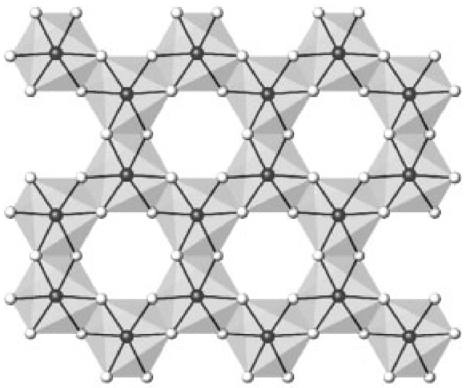

Figure 5 Part of a layer from the structure of $AlCl_3$

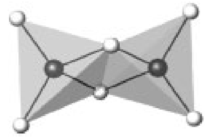

Figure 6 Edge-sharing tetrahedral molecules in Ga_2Cl_6

The heavier group 13 metals In and Tl form stable monohalides, owing to the inert-pair effect, which can be attributed to relativistic effects on the electronic motion in atoms and ions. These can be obtained in different ways: (1) by heating the elements directly; (2) by heating stoichiometric mixtures of M(s) and MX_3(s); or (3) by halogenation of the metal using HgX_2 or Hg_2X_2. InCl at temperatures below 390 K (α-InCl) adopts a yellow modification that is a distorted rocksalt structure.[33] With an electronic configuration [Cd]$5s^2$, In^I ions show stereochemically active lone pairs within the ccp Cl matrix. In α-InCl, distortions of the $InCl_6$ octahedra suggest these lone pairs to be directed towards either an edge or a face. Although concurrent shifts in In^+ positions create a range of In–In distances, there is neither direct experimental evidence nor theoretical conclusions supporting In–In bonding. Red InCl ($T > 390$ K), InBr, InI, and TlI have the layered TlI structure (Figure 7),[3] which is related to the NaCl structure by displacing two adjacent (001) planes in NaCl by 1/2 [110] relative to the next two planes. This transformation creates five-coordinate square pyramidal Tl and the formation of zig-zag chains of weakly interacting Tl ions. At 4.7 kbar, TlI converts to a red modification (cubic CsCl

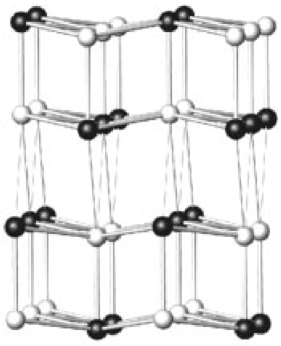

Figure 7 Structure of TlI

structure type), as found under normal conditions for TlCl and TlBr. All three compounds become metallic conductors at even higher pressures.

TlF adopts a distorted rocksalt structure, which transforms at 81 °C to a tetragonal distorted variant, slightly more dense than the room temperature form. A high-pressure phase appears at 12.6 kbar.[34]

Although there is no example of a purely binary M^{II} halide among the group 13 metals, Ga, In, and Tl do form dihalides, which can be prepared using the same techniques as for the monohalides. These compounds contain M^+ besides MX_4^- ions. $TlCl_2$, for example, is isostructural with scheelite ($CaWO_4$), which can be derived from fluorite by distorting the anion array.[35] The topology of $GaCl_2$ and $TlBr_2$ is different. It has been extremely difficult to rationalize the absence of metal–metal bonds for these stoichiometries, but one again finds large anions stabilizing low oxidation state cations. A wonderful example of this occurs in Ga_3Cl_7,[36] which contains Ga^+ besides $[Ga_2Cl_7]^-$ vertex-sharing tetrahedra (like $Si_2O_7{}^{6-}$, $P_2O_7{}^{4-}$or $S_2O_7{}^{2-}$). The larger In^{3+} and Tl^{3+} ions can also accommodate octahedral coordination, and the complex ions, like $[InCl_6]^{3-}$ or $[TlBr_6]^{3-}$, can form numerous intermediate halides. Thus, compounds like In_2Cl_3 are formulated as $(In^+)_3[InCl_6]^{3-}$ and In_7Br_9 as $(In^+)_6[In_2Br_6]^{3-}$ $(Br^-)_3$.

Dimers of M^{II} centers occur in the mixed valent compounds Ga_2X_3 (X = Br, I) = $(Ga^+)_2$ $[Ga_2X_6]^{2-}$ which contain ethane-type $[Ga_2X_6]^{2-}$ units with Ga–Ga single bonds.[37] As in the dihalides, mixtures of complex and simple ions combine also in $In_5X_7 = (In^+)_3[In_2Br_6]Br$, which contains the ethane-like units with M–M single bonds as well.[38–40]

4.4 Group 14 Metal Halides

Moving across a row of the periodic table to the right electronegativities increase. The lighter homologues of group 14 elements C, Si, and partly Ge are nonmetals and begin to exhibit aspects of covalent metal–halide interactions and homonuclear bonds, as observed for the reduced B halides (*see* ***Boron: Inorganic Chemistry***). Classical ionic forces, which were incorporated to evaluate and analyze the energetics of alkali and alkaline earth metal halides, become interwoven with covalent orbital interactions. Thus, the global structures of these inorganic solids minimize ionic contributions, in general, while local coordination geometries are well described using the valence shell electron pair repulsion (VSEPR) model.[41] The fullerene halides and the graphite halides are excluded from this discussion of main group metal halides, although graphite is poorly metallic. Silicon forms volatile tetrahalides and with fluorine and chlorine numerous halopolysilanes (*see* ***Silicon: Inorganic Chemistry***) which will also not be addressed.

Germanium, tin, and lead form numerous complex ternary halides that involve interesting anionic fragments. Within the set of purely binary compounds, MX_2 and MX_4 compounds predominate, and there is tremendous structural diversity. In terms of thermodynamic stabilities, dihalides PbX_2 are preferred over tetrahalides PbX_4, whereas the reverse is true for Ge, especially for the higher homologues of the halogens. The number of reported intermediate compositions is limited, and those, which have been characterized, are mixed valent compounds (*see* ***Germanium: Inorganic Chemistry***; ***Tin: Inorganic Chemistry***; ***Lead: Inorganic Chemistry***).

The tetrahalides of Ge and Sn are all known, but only the iodides and SnF_4 are crystalline solids at room temperature. The iodides consist of ccp iodine with Ge^{4+} or Sn^{4+} in one-eighth of the tetrahedral holes. When $SnCl_4$ condenses,[42] the chlorine atoms adopt hcp. In other words, these solids are packings of $SnCl_4$ tetrahedral molecules, like GeF_4.[43] On the other hand, SnF_4 and PbF_4 are both tetragonal with MF_6 octahedra sharing four vertices to give a flat two-dimensional analog to the ReO_3 structure (see Figure 8). The checkerboard-like $MX_{4/2}X_{2/1}$ sheets with four shared equatorial and two terminal anions which are connected via van der Waals interactions are also found in many complex fluorides and oxides, for example, K_2NiF_4 or the cuprate network in the

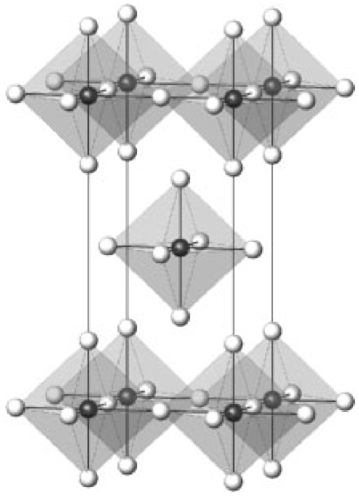

Figure 8 Structure of SnF_4

high-temperature superconductors $La_{2-x}Sr_xCuO_{4-y}$.[35] $PbCl_4$ is a yellow liquid at room temperature, decomposes at 50 °C into $PbCl_2$ and Cl_2 and solidifies at −15 °C. Its structure is still unknown. $PbBr_4$ and PbI_4 do not seem to be stable at all, which can be considered in terms of the oxidizing power of Pb^{4+} which is reduced to Pb^{2+} by Br^- and I^-, respectively.

Various synthetic methods produce the dihalides, the simplest of which involves heating stoichiometric mixtures of M(s) and MX_4. SnI_2, however, forms by heating Sn with I_2 in 2M HCl. Its structure shows two types of Sn sites: two-thirds of them occupy sites similar to those in $SnCl_2$ ($PbCl_2$-type) and the remaining are in rutile-type chains.[44] As in the reduced group 13 halides, there is no evidence for Sn–Sn bonding, but the regular geometry around one set of Sn atoms in SnI_2 suggests a degree of electron delocalization of the lone pair into a low lying crystal band (orbital).[45]

More generally, for the element halides $:MX_n$ the stereochemical activity of a free electron pair (:) decreases with increasing period number of M within an element group and in the series $:MF_n > :MCl_n > :MBr_n > :MI_n$ due to the space required by the anion near the lone pair atom. Thus SiF_2 should show this activity most effectively, however, it polymerizes after milliseconds to a Teflon analogue. GeF_2 crystallizes with a typical lone pair structure[46] in which channels provide space for the lone pairs (see Figure 9). A comparable structure can also be expected for $GeCl_2$, although it is not yet determined. SnF_2, which exists in three polymorphs[47] and $SnCl_2$, also demonstrate a stereochemically active lone pair at Sn. At low temperatures, α-SnF_2 contains two kinds of Sn atoms: three-coordinate $[SnF_3E]$ (E = lone pair) pyramids and 3 + 2 coordinate $[SnF_5E]$ tetragonal pyramidal units, which are linked together to form tetrameric molecules. Between 150 and 190 °C the α form transforms into γ-SnF_2, which contains $[SnF_4E]$ trigonal bipyramids. Upon subsequent cooling, the second order displacive transformation to β-SnF_2 ensues giving $[SnF_4F'E]$ coordination that is intermediate between trigonal bipyramidal and octahedral as found for the isotypic GeF_2. The fluorides with intermediate compositions, Ge_5F_{12},[48] Ge_7F_{16},[49] and Sn_3F_8,[50] are mixed valence compounds and their structures show features of both MF_2 (stereochemically active lone pairs) and MF_4 with octahedral coordination for the M^{IV}. $Ge_5F_{12}$and Ge_7F_{16} are less hygroscopic than either GeF_2 or GeF_4, and both thermally decompose into these two phases. Another mixed valency example is $SnF_3 = Sn[SnF_6]$ and in this case the high-temperature modification has an ordered ReO_3 type structure with octahedral coordination of both Sn atoms by F ($Sn^{II}-F = 2.29$ Å and $Sn^{IV} = 1.86$ Å)[51] indicating the absence of a stereochemical effectiveness of the free electron pair at Sn^{II}.

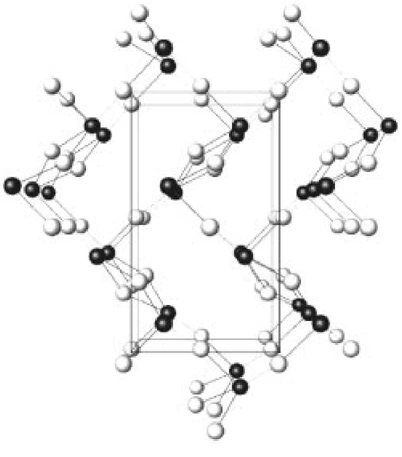

Figure 9 Structure of GeF_2

The dihalides PbX_2 (except PbI_2) occur in the orthorhombic $PbCl_2$ structure type[3] (see Figure 3), and their structural parameters are consistent with an ionic formulation. In particular, with Pb the relativistic effect plays an additional role and therefore the s-character of the free electron pair is in addition favorized over the p-character, that is, the stereochemical effectivity is less pronounced. This is reflected by PbF_2 which undergoes an irreversible transition to the cubic fluorite structure at 648 K. At temperatures near 973 K, well below the melting point of PbF_2 (ca. 1200 K), it becomes a good F^- ion conductor.[52] PbI_2 is isotypic with CdI_2, showing several polymorphs and no stereochemical activity of its lone pair, which parallels observations in SnI_2 and other complex Sn^{II} and Pb^{II} halides.[45] The intermediate stoichiometry, PbF_3, is mentioned but not well characterized.[53]

4.5 Group 15 Metal Halides

Many halides of the group 15 elements, which are molecular species,[3,4] have received a great deal of attention (*see* ***Arsenic: Inorganic Chemistry***; ***Antimony: Inorganic Chemistry***; ***Bismuth: Inorganic Chemistry***). Only the halides with antimony and bismuth, which form binary compounds of the type MX_3, subhalides with the larger anions, and compounds of the type MX_5 with smaller anions, will be discussed here. With Sb, the two pentahalides SbF_5 and $SbCl_5$ are known; however, among the Bi trihalides, only BiF_3 can be oxidized by F_2 (∼500 °C) to BiF_5, which is an extremely strong fluorinating agent. In $SbCl_5$, the coordination number of Sb is five and the $SbCl_5$ trigonal bypyramids are packed in a molecular structure,[54] which is isotypic to AsF_5.[55] With the smaller F, the coordination numbers of Sb and Bi are six and the structure of SbF_5 contains tetrameric rings of cis corner-sharing SbF_6 octahedra,[56] whereas BiF_5 crystallizes with chains of trans corner-sharing BiF_6 octahedra[57] (see Figure 10). The pentahalides $BiCl_5$, $BiBr_5$, and BiI_5 are not known and obviously the equilibrium is on the BiX_3 and X_2 (X = Cl, Br, I) side.

Discrete pyramidal molecules of SbX_3 and BiX_3, except BiF_3 and BiI_3, can be detected in the solid phase. β-bismuth

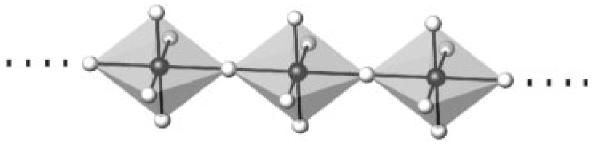

Figure 10 Chains of corner-sharing octahedra in the structure of BiF_5

trifluoride has a distorted uranium trichloride structure, in which the Bi^{3+} cations are surrounded by nine F^- ions in a triply capped trigonal prismatic structure. One fluorine cap is somewhat farther away from the bismuth, giving Bi the coordination number $8 + 1$. This may be a result of the steric effect of the free electron pair on the bismuth. The trichlorides and tribromides of antimony and bismuth have analogous structures and differences are based on the size effect.[58] Of particular crystal chemical interest are SbI_3 and BiI_3, which occur in the layered BiI_3 structure with hcp iodide ions and M^{III} in the octahedral holes. Each of the layers, which are stacked via van der Waals interactions, is topologically equivalent to the sheets in $AlCl_3$ (Figure 5). Although crystallographic symmetry does not demand that the cations lie exactly on the center of the octahedral interstices, Bi nearly centers this site whereas Sb is shifted away from the center resulting in $3 + 3$ coordination.

Similar to the mixed valent Ge fluorides there is also a large chemistry of Sb halides with intermediate compositions, see Table 2. These compounds are adducts according to $n\mathrm{SbX_3}\cdot m\mathrm{SbX_5}$ $(n, /m = 1, 2, 3\ldots)$ and their structures are built from anionic units $\mathrm{SbX_6}^-\cdot(n-1)\mathrm{SbX_5}$ and cationic building units $\mathrm{SbX_2}^+\cdot(m-1)\mathrm{SbX_3}$.

With Sb only one subhalide, Sb_2I_4, is known so far, which is formed by the reaction of elemental Sb in molten SbI_3 below 230 °C. Besides the BiX_3 phases, several subhalides with the larger halides are known, for example, BiBr, BiI,[59] Bi_7I_2 and Bi_9I_2, which contain Bi clusters with strong metal–metal bonding. A subchloride of bismuth has also been isolated from Bi/$BiCl_3$ mixtures and was determined to be Bi_6Cl_7: $[(\mathrm{Bi_9}^{5+})_2(\mathrm{BiCl_5}^{2-})_4(\mathrm{Bi_2Cl_8}^{2-})]$,[60] a compound built from Zintl cations and units known from complex salts like $KBiCl_4$. The $\mathrm{Bi_9}^{5+}$ polycation is a tricapped trigonal prism, and corresponds to a closo system in Wade's scheme of counting valence electrons in clusters, whereas the other complex ions do not show close Bi–Bi contacts.[61]

4.6 Group 16 Metal Halides

The prevalent solid-state examples contain tellurium and polonium (*see* ***Tellurium: Inorganic Chemistry***; ***Polonium: Inorganic Chemistry***). The lower halides of Te are polymeric. A recent review covering the chalcogen halides, which includes aspects of their solid-state chemistry, provides an excellent overview of these materials.[62]

5 TRANSITION METAL HALIDES

Few classes of inorganic solids can surpass the diverse chemical and physical properties of the transition metal halides.[63–65] Through countless studies in the literature, each transition metal provides a fascinating individual collection of structures and properties, although, as chemists, we are always trying to ascertain periodic trends and relationships from one metal to the next. Much of the current research efforts involve stabilizing reduced metal halides in order to probe their potentially interesting electronic and magnetic properties.

From a theoretical perspective, these compounds have provided a basis for testing various crystal field and ligand field theories due to the large electronegativity and size of the halide anions with respect to the transition metal cations.[66,67] The increased size factor of the second and third row metals provides additional forces that compete with the omnipresent attractive cation–anion and repulsive anion–anion interactions, and present special challenges for an understanding of their structures. Chemical bonding in these systems can also be characterized from magnetic susceptibility measurements due to the open shell configurations of these metals, in contrast to the main group elements.

Most of the commonly observed compositions are listed in Table 3. As mentioned above (see Section 3) fluorides, in general, occur for the higher oxidation states, chlorides through iodides for the lower ones. However, the relative stability of higher oxidation states increases down a particular group, and thus we find WF_6, WCl_6, and WBr_6, MoF_6 and $MoCl_6$, and just CrF_6, which forms only above 200 atm at temperatures of 400 °C. For the largest part, beyond group 3, the transition metals are coordinated by an octahedron of halide ions. Exceptions occur usually when metal–metal bonding takes place, as in $ReCl_3$ or Nb_6F_{15}, or when the metal's electronic configuration prefers another geometry, as in d^8 square-planar $PdCl_2$.

Synthetic approaches are numerous, but many of the halides can be obtained by allowing the halogen to react directly with the pure metal under mild conditions. In general, fluorides require special handling and procedures, and we refer the reader to other articles in this volume (in particular ***Fluorides: Solid-state Chemistry***). Heavier halides can be obtained from the lighter halides by exchange reactions with the heavier anhydrous hydrogen halide, for example, TaI_6 results from treating $TaCl_6$with dry HI.[68–70] A very successful preparative route to numerous transition metal halides, in particular reduced metal halides, involves chemical transport.[71] In order to control reactions to obtain desired products, an enormous amount of thermodynamic data for these heterogeneous systems are required.

In the set of main group metal halides, we could readily systematize the solid-state examples according to group number. Since, in general, several oxidation states are observable for each transition metal, it is more convenient to discuss these halides according to their empirical formulas,

[a]Structures are discussed in the text.

which also allows us to correlate structure (topology) and properties with d electron concentration at the metal atoms.

5.1 MX_6 and Higher Halides

The MX_6 series represents a set of molecular solids and liquids at ambient conditions, owing to the octahedral coordination of the transition metals. Many of the other second and third row metal hexafluorides show the same phenomenon.[72] $MoCl_6$ and WCl_6 have Cl^- ions in hcp with 1/6 of the octahedral holes occupied. The fluorides are volatile solids with low melting and boiling points, while WCl_6 and WBr_6 melt around 570 K.

ReF_7 is the only thermally stable binary heptahalide, and crystallographic studies indicate a high-temperature, body-centered cubic (bcc) lattice which transforms to a lattice with lower symmetry at lower temperatures.[72] Spectroscopic evidence suggests pentagonal bipyramidal geometry. Only within ternary systems, hepta-anions are more often found, for example, in K_3ZrF_7 or K_2TaF_7.[3] The $[TaF_7]^{2-}$ ion is a monocapped trigonal prism rather than a pentagonal bipyramid. There are speculations about the existence of OsF_8, however, there is simply not enough space for eight ligands of the size of F^- and with Os^{VIII} only the oxyfluorides OsO_2F_4 and OsO_3F_2 could so far be prepared.[73]

5.2 MX_5 Halides

The relatively high +5 oxidation state for these compounds parallels the frequency of fluorides relative to the heavier halides. In contrast to the structure of BiF_5 (see Figure 10), all of the reported transition metal pentafluorides occur as tetramers composed of four MF_6 units sharing two cis ligands (see Figure 11). The ring formation via common corners (any ring size) is another way of realizing the composition $MX_4X_{2/2}$. An interesting trend is observed for the M–F–M bridging angle as the metal d count changes: for d° and d^1 systems, this angle is 180°; for d^2, ca. 150°; and for

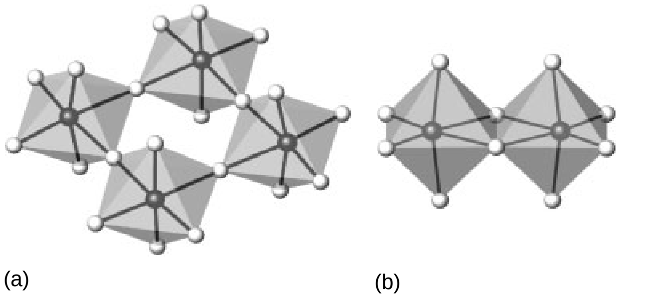

Figure 11 Connection of MX_6 octahedra in MX_5 type halides of the transition metals (a) for X = F and (b) for X = Cl, Br, I

d^3–d^5; nearly 132°, which equals the M–X–M angle when metal atoms occupy adjacent octahedral holes in a hcp anion array.[3] This bending can be assigned to the occupation of M–F π^* orbitals,[66] but trends in bond distances are not that conclusive.[74]

The heavier halides form molecular solids by sharing edges of the MX_6 octahedra, and thus dimers (Figure 11b). The corresponding angles at the bridging halides are close to 90°, indicating the greater polarizability of these halides relative to F^-. Although electron counts vary from d^0 to d^6, their structures and properties negate strong metal–metal interactions. Each metal atom shifts away from the center of the octahedron and increases the metal–metal separation and, as expected, bridging ligands lie farther from the metals than the terminal ligands. An exception among the heavier halides is NbI_5 which crystallizes with a close packing arrangement of the anions and a polymeric structure based upon NbI_6 octahedra sharing cis vertices to form a complex skew chain $[NbI_4I_{2/2}]$ is found.[31]

The magnetic susceptibility measurements of halides containing non-d^0 metal atoms are a useful indicator for the presence or absence of metal–metal interactions. They show Curie-Weiss behavior and effective magnetic moments are in reasonable agreement with spin-only values: $MoCl_5$ ($1.67\mu_{eff}$), WCl_5 ($1.00\mu_{eff}$), $ReCl_5$ ($2.21\mu_{eff}$), $OsCl_5$ ($3.39\mu_{eff}$). Only when spin-orbit coupling is considered, these values are somewhat high. $OsCl_5$, for example, also has a Weiss constant that suggests antiferromagnetic coupling between Os atoms,[75] but strong metal–metal bonding can be excluded. This is also valid for the red-colored AuF_5, whose diamagnetism results from the low-spin ground state.

5.3 MX_4 Halides

At this stoichiometry, the numbers of two- and one-coordinate halides are equal, and their solid-state structures begin to exhibit 1D, 2D, and 3D characteristics. Furthermore, as the oxidation states now become lower, effects due to metal–metal bonding become observable, especially for the 4d and 5d transition metals. Moreover correlations in M–X–M angles continue to differentiate fluorides from the rest of the halides.

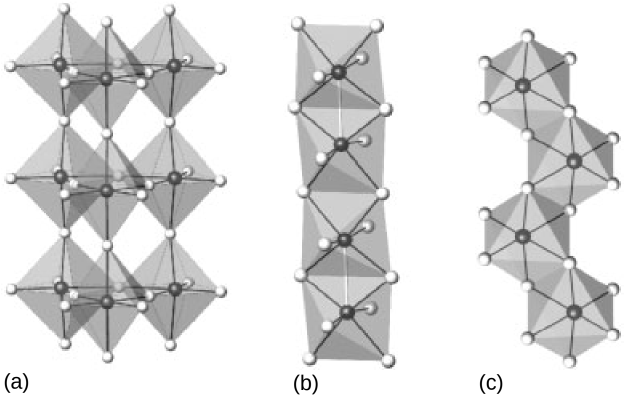

Figure 12 (a) Chains of MX_6 octahedra in MX_4 type halides of the transition metals, for example, (a) TiF_4, (b) NbI_4, and (c) $TcCl_4$

The tetrafluorides all have six-coordinate metals and adopt either 1D, 2D, or 3D structures, all of which involve sharing four vertices among adjacent metal centers. TiF_4[76] adopts a unique 1D structure with triple chains of TiF_6 corner-sharing octahedra with two shared ligands in cis position (see Figure 12a). In VF_4,[77] NbF_4,[78] and RuF_4,[74] the unshared ligands are trans to each other. NbF_4 is isotypic to SnF_4 (2D) with linear Nb–F–Nb bridging angles (see Figure 8), whereas VF_4 and RuF_4 crystallize as distorted variants of this structure type with V–F–V[79] and Ru–F–Ru angles[75] of approximately 151° and 135°, respectively. The structures of MoF_4 and WF_4 have not yet been elucidated, to our knowledge. In α-MnF_4[79] and the remaining systems MF_4 (M = Os, Rh, Ir, Pd Pt)[80–83] cis vertices remain unshared. Their structures are 3D and closely related to rutile, from which alternate metal atoms along each of the edge-sharing octahedral chains are removed. Again, the M–F–M angles approach 132°, in accordance with the occupation of M–F π^* orbitals.

The dimers found in MX_5 systems now develop into chains for the heavier tetrahalides.[3] However, close metal–metal contacts, as well as low values for magnetic susceptibilities, provide the rationale for metal–metal bonding. The tetrahalides Nb (α-forms), Ta, Mo (α-forms), W, Re (α-forms), and $OsCl_4$ adopt trans edge-sharing octahedral chains (Figure 12b).[84] In general, the metal atoms shift to form distinct pairs along the chain, that is, metal–metal distances alternate between short and long. $TcCl_4$, $ZrCl_4$, $OsBr_4$, and PtX_4 form zig-zag metal chains without bond distance alternation (Figure 12c).[85] In general, there is an indefinite number of ways that these types of chains can grow.[86] ZrI_4 and HfI_4 show two of these more complex configurations. Lastly, such chains can also close upon themselves in the way that benzene is related to polyacetylene. $MoCl_4$ shows a hexameric ring,[87] as well as a random arrangement of metal vacancies in the layered $MoCl_4$ structure.[88] β-$ReCl_4$ with d^3 Re^{4+} adopts another modification involving two face-sharing

$ReCl_6$ octahedra which form a quasi-infinite chain by sharing one vertex at each metal center.[3] Such dimeric units are observed in the complex salts $A_3M_2X_9$ with trivalent atoms (M = Tl, V, Nb, Cr, Mo, W).[4]

5.4 MX_3 Halides

The transition metal trihalides have mostly structures based upon close packings of halide atoms with the metal ions in octahedral holes. Exceptions include those of W and Re with the metal atoms in a five-coordinate square pyramidal environment,[89] and the series AuX_3 with square-planar coordinated Au atoms.[31] The stoichiometric ratio in the transition metal trihalides provides structures that can range from 1D to 3D arrangements. The most common general structure types are: VF_3, BiI_3, $AlCl_3$, and TiI_3. The differences occur in either the three-dimensional anion packing modes or the distribution of occupied metal sites.

All known trifluorides are related to the VF_3 structure, which represents an intermediate geometry between the cubic ReO_3-type and the rhombohedral RhF_3-type.[90] RhF_3 contains a hcp arrangement of fluoride ions. These materials consist of an array of rigid octahedra that have been rotated around their trigonal axes.[91,92] The MF_6 octahedral units remain virtually regular throughout the series, while the M–F–M angle varies from 180° in NbF_3 to 132° in RhF_3. Figure 13 illustrates the geometrical relationships between the three varieties of MF_3 structures, which is reminiscent of cubic perovskites $A[BO_{6/2}]$ and distorted variants, such as $GdFeO_3$, where the size of the A cation determines the skewing of the octahedral framework. The structures of PdF_3 and PtF_3 contain two differently sized $[MF_6]$ octahedra comparable to what has been found for the high-temperature modification $SnCl_3$ (see above) indicating mixed valency according to $M^{2+}M^{4+}F_6$, in which both M atoms remain octahedrally surrounded by F atoms.[90] For the M^{2+}, this is quite unusual as Pd^{2+} and Pt^{2+} with d^8 configuration normally prefer a square-planar coordination.

The trifluorides occur as three-dimensional networks, whereas the heavier trihalides crystallize as either layer or chain structures.[31] The commonly observed layer structures are BiI_3 and $AlCl_3$, which correspond to ordered defect derivatives of the CdI_2 and $CdCl_2$ types, respectively. Both consist of ${}^2_\infty[(\square X_{6/3})(MX_{6/3})_2]$ sheets ($\approx M_2X_6$; see Figure 6), in which the metal atoms form a honeycomb network. The complete structures of BiI_3 and $AlCl_3$ form by stacking this two-dimensional motif in two different ways: for rhombohedral BiI_3, the halide ions are hcp and, moreover, the vacancies in the metal layers spiral trigonally along the stacking direction; in the monoclinic $AlCl_3$ structure, the anions are ccp and the metal vacancies are ordered along the monoclinic a axis. In each case, the planes of possible metal atom sites alternate with 66% and 0% occupancy along the stacking direction. The structure of TiI_3, unlike $AlCl_3^-$, and BiI_3 is quasi one-dimensional.[93,94] The anions in TiI_3 form a hcp arrangement, but the metal atoms occupy 1/3 of each plane to form quasi-infinite one-dimensional chains, $[MX_{6/2}]$, of face-sharing MX_6 octahedra (see below).

Besides vertical trends exhibited by the transition metal trihalides, they also vary systematically with the number of d electrons. We begin our summary with the trifluorides.[90] The d° compounds generally do not adopt structures based upon octahedral coordination of the metal. No d^1 (except TiF_3) or d^4 systems have been noted. For $d^2$and d^3 compounds, older literature reports the cubic ReO_3-type with a M-F-M angle of 180°; these were in fact oxyfluorides, $MO_{3x}F_{3-3x}$.[95] The highest purity of NbF_3 has been obtained by high-pressure synthesis (High-Pressure Synthesis of Solids), and retains the cubic structure.[96] Careful neutron diffraction investigation on MoF_3 shows the VF_3-type and antiferromagnetic ordering of three unpaired spins per Mo atom.[97] In the d^4 fluoride MnF_3[98] with ccp of the anions and in the d^5 and d^6 systems with hcp-based RhF_3 structure type the M–F–M angle bends significantly away from linearity. We have already referred to the interesting case of PdF_3, which, in addition, shows ferromagnetic ordering with T_C of 10 K.[99]

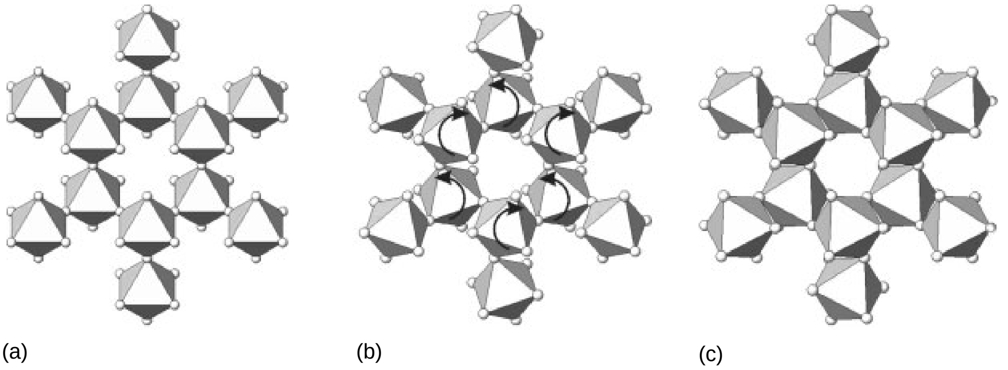

Figure 13 Projections of the structures of (a) NbF_3, (b) RhF_3, and (c) VF_3. The arrows in (b) indicate the skewing of the framework of MF_6 octahedra for the hypothetical transition from (a) via (b) to (c)

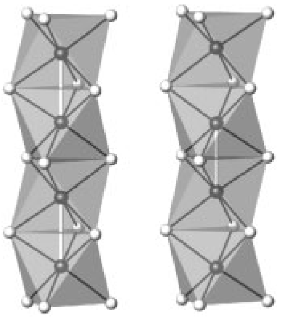

Figure 14 Chains of face-sharing octahedra in TiI_3. Alternating metal–metal bonding within chains is indicated

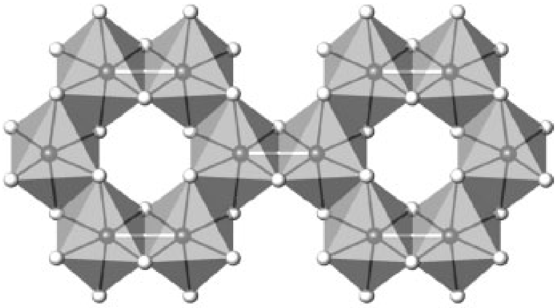

Figure 15 Honeycomb-like (6^3) network of edge-sharing octahedra in β-$MoCl_3$. Alternating metal–metal bonding is indicated

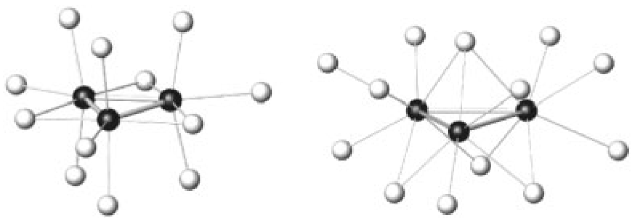
The heavier trihalides show their own intrinsic structural systematics. For the group 4(d^1) metals, distorted TiI_3 structures are found.[100–102] Most compounds assigned to this structure class actually crystallize in an orthorhombic space group in which the metal atoms move away from their regular octahedral sites to form one-dimensional chains with alternating short and long metal–metal distances (Figure 14). In addition, the anions shift to form two different isosceles triangles bridging pairs of metal atoms. In group 5 (d^2), NbI_3 is the only reported compound. A recent X-ray diffraction study indicates that it also adopts the distorted TiI_3 structure with an extremely short Nb–Nb bond distance. All of the other trihalides of this transition metal group, that is, Nb and Ta, are thermodynamically not stable, but rather homogeneous mixtures of M_3X_8 and MX_4.[103,104]

The group 6 trihalides form three different kinds of structures. α-$MoCl_3$ crystallizes in a distorted $AlCl_3$ structure with Mo–Mo dimers.[105] β-$MoCl_3$, which also contains Mo–Mo pairs, is related to the BiI_3 phase.[88] Figure 15 illustrates the distortion of the metal arrangement in β-$MoCl_3$ from a regular honeycomb (6^3) net. The heavier halides, $MoBr_3$ and MoI_3, however, crystallize in the distorted TiI_3 structure with pairing of Mo atoms along the c axis.[102,105] WCl_3 and WBr_3 are exceptional cases which also show metal–metal bonding.[106,107] (see Section 5.5). Metal clusters continue into the higher homologues of group 7 (d^4) compounds as well. Although nothing is yet reported for the Tc system, all of the rhenium trihalides ReX_3 contain triangular rhenium clusters, Re_3X_{12} (see Figure 16a), which are connected to three other neighboring clusters through bridging halogen atoms to form a buckled two-dimensional layer.[108–110] In lower transition metal halides with fewer d electrons, such as Nb_3Cl_8 (see Section 4.5), metal–metal bonded triangular M_3 units with a higher coordination by the ligands are found (see Figure 16b).

The group 8 (d^5) metal trihalides in some cases are very similar to the d^1 systems. Distorted face-sharing octahedral chains, $^1_\infty[MX_{6/2}]$ have been found for all Ru trihalides.[111,112] In addition, another modification of ruthenium trichloride, α-$RuCl_3$, is believed to belong to the $AlCl_3$ type by an X-ray powder diffraction study. It exhibits ferromagnetic



(a) (b)

Figure 16 (a) Re_3X_{12} cluster as found in ReX_3 and (b) M_3X_{13} cluster in Nb_3X_8 (X = Cl, Br, I)

coupling of Ru^{III} atoms within a layer, and antiferromagnetic coupling between layers. A recent structural investigation on α-$RuCl_3$ by means of scanning tunneling microscopy showed distortions of $RuCl_6$ octahedra on the surface of the crystal.[113] The images have been interpreted as a shift in surface chloride positions owing to the formation of Ru–Ru pairs. Although the structural arrangement in the crystalline bulk is still not clear, the distortion found on the surface of the crystal may indicate a similar distortion within the crystal. For the group 9 metals (d^6), we again find the regular $AlCl_3$ structure for all of the trihalides,[114] with numerous examples of stacking disorder. Pd does not form stable trihalides beyond the fluoride, but both $PtCl_3$ and $PtBr_3$ have been reported.[115,116] As in PdF_3, these compounds apparently contain Pt in two different oxidation states: 50% as Pt^{2+} square planar surrounded and 50% as Pt^{4+} in $[PtX_2X_{4/2}]$ cis edge-sharing octahedral chains.

Finally trifluorides are found among the group 11 elements. AgF_3 contains highly elongated AgF_6 octahedra which are connected to a 3D framework.[117] It is one of the few metallic fluorides known so far. Au forms a stable molecular trihalides with each of the halides, Au_2X_6, with square-planar coordinated Au atoms.[31]

The structural preference within the series of trifluorides is dominated by the nature of the M–F covalent interaction. As we move to the heavier halides, that is, as the anion polarizability increases, lower dimensional structures become prevalent. For these materials, three major interatomic

interactions influence the observed geometries: (1) the ligand field effects of halide ions on the d orbitals of the transition metal; (2) direct (through-space) metal–metal interactions; and (3) the matrix effect of halide ions.[118] Furthermore, the later transition elements tend to form mixed valence compounds, like groups 13 and 14 metals, rather than metal–metal bonded units.

5.5 MX_n Halides ($n < 3.0$)

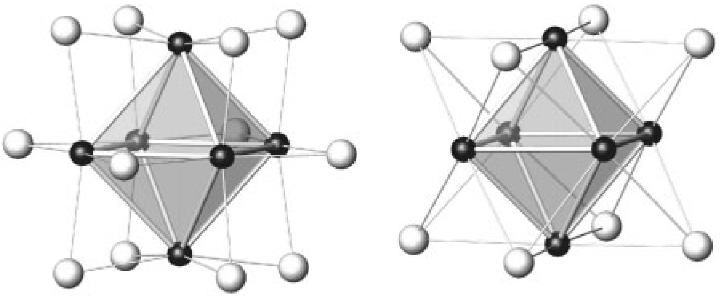
These types of halides comprise the MX_2 type compounds of the 3d metals, halides of the 4d and 5d metals with strong metal–metal bonding, and the Cu and Zn families. TiF_2 can only be prepared under high pressure and crystallizes in the fluorite-type structure.[119] The other 3d difluorides are isotypic to rutile, except CrF_2 and CuF_2 which show distortions arising from a first-order Jahn-Teller instability of the high-spin d^4 and d^9 configurations in an octahedral field.[3] The chlorides, bromides, and iodides, when they exist, adopt either CdI_2- or $CdCl_2$-type structures. First principle calculations show that interactions of occupied t_{2g} levels of transition metal atoms with the ligand orbitals often play an essential role for the stability of the CdI_2 type over the rutile type.[120]

Other than 3d element dihalides are found with Ru which are thought to occur as intermediates in the reduction of RuX_3 with H_3PO_2. α-PdX_2 show chains of edge-sharing square-planar PdX_4 units, while the β-form contains octahedral clusters, which are cuboctahedrally surrounded by 12 X (see Figure 17(a)).[4] However, metal–metal distances preclude any strong bonding between the metal centers, like in the isostructural β-$PtCl_2$ which is built from Pt_6Cl_{12} molecules. The Pt atoms are slightly shifted outside the Cl_{12} cuboctahedron indicating Pt–Pt repulsive interactions.[121] With silver, there exists only one dihalide, the fluoride AgF_2, which contains highly distorted AgF_6 octahedra and Ag_3F_8 which according to $Ag^{2+}(AgF_4)_2{}^-$ is a mixed valent Ag(II)Ag(III)fluoride.[122]

Much recent research has centered on the chemistry of reduced 4d and 5d metal halides (Zr, Nb, Mo, Hf, Ta, W, and Re), and has contributed a great deal to our knowledge of metal–metal interactions as well as the relationship between geometrical and electronic structure.[123–127] These phases are generally prepared using synproportionation reactions involving a high oxidation state halide and either the metal or a lower halide, when appropriate,[126] and most of them have noninteger anion/cation ratios (see Table 3).

Transition elements that form triangular metal clusters in reduced halides are Ti, Nb, Mo, W, and Re. In contrast to the clusters in halides ReX_3, in many other cases the M_3 triangles are surrounded by 13 X atoms to form M_3X_{13} clusters (see Figure 16b). These units contain 6–9 valence electrons. The structures of the halides Ti_7X_{16} (X = Cl, Br) are built from $TiCl_6$ octahedra and Ti_3Cl_{13} clusters. However, among the 3d elements such halides are exceptions, as metal–metal bonded M_3X_{13} units are more frequently found with the 4d and 5d transition elements. They have first been observed in the Nb_3X_8 (X = Cl, Br, I) type compounds, in which the metal–metal bonding within the Nb_3 clusters containing seven valence electrons is indicated by an effective magnetic moment corresponding to one unpaired electron per formula unit.[103]

However, most of the halides with metal–metal bonding are based on one of two types of octahedral metal cluster: (i) M_6X_{12} and (ii) M_6X_8 (Figure 17). In (i), the 12 edges of the cluster are bridged by ligands and the M–X distances are approximately $1/2\cdot\sqrt{2}$ times shorter than the M–M distances, whereas in (ii), the ligands cap the eight faces and the M–X distances are nearly the same as the M–M distances. Therefore, one finds M_6X_{12} clusters preferably among fluorides and chlorides, whereas for iodides only the M_6X_8 cluster is observed. Bromides lie somewhere in between and depending on the kind of transition element both types can be found. However, besides geometrical aspects there are certain valence electron counts for the metal cluster that maximize stability, as could be shown by numerous molecular orbital calculations.[123–125] For the M_6X_8 cluster, 20–24 valence electrons are optimal, whereas for the M_6X_{12} cluster, 14–16 valence electrons are found. These valence electrons occupy orbitals that are concentrated largely on the metal atoms of the cluster. Thus, these counts represent the



(a) (b)

Figure 17 (a) M_6X_{12} and (b) M_6X_8 cluster

number of valence electrons in excess of the number required for each halide ligand to achieve a closed-shell configuration. In addition, McCarley and coworkers have demonstrated that $TaBr_3$ is a metastable phase ($TaBr_{2.80}$) that probably contains $[Ta_6Br_8]$ cluster units.

MoX_2 and WX_2 (X = Cl, Br, I) are all isomorphous.[87] Their structural formulas are $[M_6X^i_8]$ $X^a_2X^{a-a}_{4/2}$, using a special notation,[128] where X^i are ligands belonging to either the M_6X_8 or M_6X_{12} cluster (i = innen = inner), and X^a are ligands coordinated radially (axially) to a metal atom (a = ausser = outer). X^{a-a}, therefore, indicates that this ligand is shared between two clusters and adopts ausser positions with respect to both clusters. These axial ligands are important components to the complete structures of these cluster compounds, and are responsible for the diversity of observed arrangements. The $[Mo_6Cl_{12}]^{4+}$ cluster unit has 24 valence electrons in agreement with its diamagnetic behavior and stability. In these dihalides, four axial ligands bridge two clusters to give a 2D system. These clusters can be formally oxidized, as seen in the series W_6Br_{14}, W_6Br_{16}, and W_6Br_{18}, all of which contain M_6X_8 clusters.[11] All of these clusters, however, have formally 22 electrons because some of the axial ligands involve the polybromide ion $Br_4{}^{2-}$. Thus, for example, $W_6Br_{16} = [W_6Br_8]Br_4(Br_4)_{2/2}$. Although a M_6X_8 cluster occurs in Nb_6I_{11},[124] with one less valence electron in the group 5 atoms, M_6X_{12} clusters are more common. Therefore, compounds like Nb_6Cl_{14} and Ta_6Br_{15}, with 16 and 15 valence electrons, respectively, are optimal for the M_6X_{12} system. The observed M_6X_{15} systems have magnetic moments corresponding to one unpaired electron per cluster.

Cluster systems have also been observed with group 4 metals, but they adopt low valence electron concentrations. Upon careful synthetic and crystallographic investigations, Zr dihalides were found to be exceptionally stabilized by interstitial species like H, C, B, and Be, and this has opened a rich chemistry in this field.[129,130] $ZrCl_2$, when synthesized by allowing $ZrCl_4$ and ZrCl to react, leads to MoS_2-type phases, with Zr in trigonal prismatic coordination.[131] Like the d^1 dichalcogenides (and unlike d^2 systems), there are also phases which are nonstoichiometric according to the description $Zr_{1+x}Cl_2$ with excess Zr atoms in the van der Waals gaps. ZrI_2 also forms a distorted variant of the CdI_2 structure with zig-zag chains of Zr atoms within each planar sheet of metals.[31]

The monohalides ZrCl, ZrBr, HfCl, and HfBr (Figure 16) are formed by high-temperature reduction of ZrX_4 with the metal.[126] These are layered compounds constructed of two adjacent close-packed sheets of metal atoms surrounded by similar arrangements of halide ions (see Figure 18). These four-atom slabs then stack differently to give the 3D structures. The corresponding iodides are unknown and probably the iodide ion is too large to allow such a topology. As expected, there is strong metal–metal bonding within the slabs and the monohalides of Zr and Hf show 2D electrical conductivity. The systematic studies of these reduced Zr and Hf halides have stressed the relationships between such layer structures and the M_6X_{12} clusters via cluster condensation.[123–130]

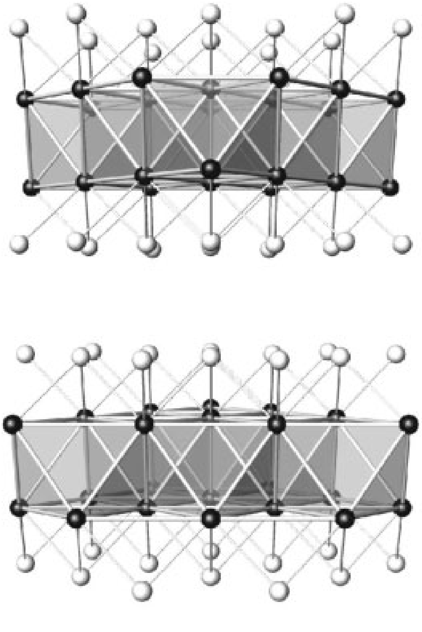


Figure 18 Structure of ZrCl

Moving to the right across the rows of the periodic table, we again find monohalides. All of the group 11 element monohalides, except CuF, CuI_2, and AuF, are known. The monofluorides CuF and AuF are unstable with respect to disproportionation into the metals and CuF_2 and AuF_3 respectively, whereas CuI_2 is unstable because iodide ions reduce Cu^{2+}. The silver monohalides crystallize all, except AgI, in the rocksalt type structure, whereas AuCl, AuBr, and AuI are chain polymers which feature two-coordinate Au. Finally, we should mention the metallic, bronze colored silver subfluoride, Ag_2F, which is formed in the reaction between finely divided Ag powder and AgF in hydrogen fluoride or by electrochemical reduction of AgF. It has an *anti*-CdI_2 structure in which double layers of Ag alternate with layers of F. The compound is rather unstable and decomposes at temperatures above 100 °C into AgF and Ag. Strong metal–metal bonding is found in the mercury monohalides Hg_2X_2 (X = F, Cl, Br, I) which are formed by the reduction of the dihalides with elemental Hg. They contain single bonded Hg–Hg dumbbells ($d^{10}s^1$ configuration) with distances ranging from 2.51 Å (X = F) to 2.69 Å (X = I). With the lighter homologues Zn and Cd only the dihalides could be obtained so far.

6 RARE EARTH HALIDES

Rare earth metal halides have received a great deal of attention during the past 50 years.[132–135] The lanthanide trihalides are colored, magnetic salts, which have provided

a stockpile of structural parameters and spectroscopic transitions. These data helped to develop both crystal field theory and the angular overlap method. In recent years, their optical and magnetic characteristics due to the $4f^n$ configurations of these ions have contributed to widespread applications (*see* ***Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry***). Rare earth halide salts have compositions MX_3 and MX_2, besides a few more reduced ones, some with intermediate compositions and very few with rare earth elements in oxidation states higher than +3.

The trihalides MX_3 are well known and well characterized for all rare earth elements with the exception of EuI_3. Most of them are colored as a result of $f \rightarrow f$ and/or $f \rightarrow d$ transitions. The lanthanide contraction as well as anion–anion repulsions contribute to the observed trends in the structures of the trihalides at ambient conditions (see Figure 19). The trifluorides with the larger rare earth ions adopt the tysonite type structure (LaF_3) with 11-fold coordination of the metal ion, the highest one known in a binary ionic solid (see Figure 20). The coordination polyhedra can be described as a trigonal prism squeezed along the threefold axis and capped on the two triangular and the three rectangular faces.

For the smaller rare earth ions the YF_3 structure type with nine-coordinated metal atoms occurs. This first coordination sphere is similar to the $PbCl_9$ polyhedra in $PbCl_2$, however, its connection leads to a much more complicated arrangement. For ScF_3 with the smallest rare earth element, the ReO_3 type structure with octahedral metal coordination is found. Four major structure types occur for the heavier halides: UCl_3, with nine-coordinated metals (tricapped trigonal prisms as in the $PbCl_2$ and BaI_2–II type structures, however, less condensed;

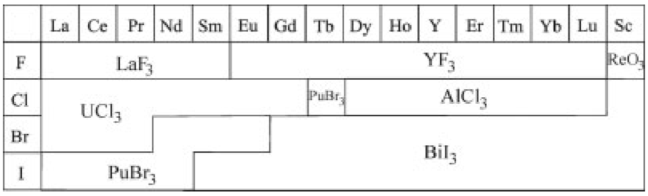

Figure 19 Structures of the rare earth trihalides at ambient conditions

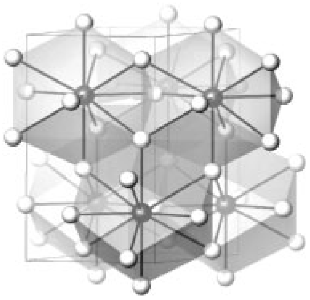

Figure 20 Structure of LaF_3

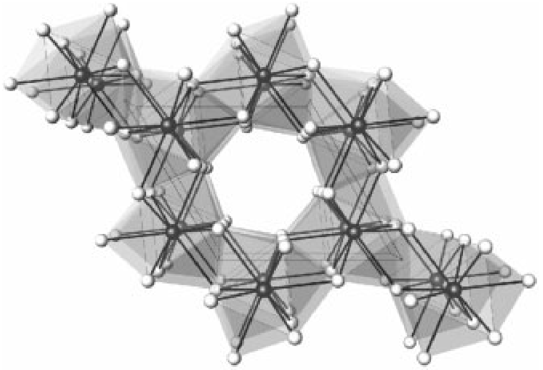

Figure 21 Structure of UCl_3

see Figure 21), $PuBr_3$, with 8 + 1 coordinate metals, $AlCl_3$ (YCl_3) with six-coordinate metal atoms (defect rocksalt) and BiI_3 ($FeCl_3$), also with six-coordinate metal atoms.

Rare earth dihalides REX_2 are all known for RE = Sm, Eu, Yb, with RE = La, Ce, Pr, Nd, Gd, Tm, and Sc only chlorides, bromides, or just the iodides have been obtained, whereas it seems that with Ho, Er, Lu, and Y, the dihalides do not to exist. Most of them can be synthesized by the reduction of the trihalides with the corresponding metals in Ta ampoules or other preparative routes. However, care should be taken as hydrogen is easily incorporated and indeed some of the dihalides reported in literature are in fact halide hydrides.[136] The binary dihalides are either saltlike compounds according to $RE^{2+}(X^-)_2$ or metallic with one delocalized electron per formula unit according to $RE^{3+}(X^-)_2{\cdot}(e^-)$. Their structures follow mainly the crystal chemical principles outlined for the alkaline earth dihalides[3] and reflect effects of size relations between cations and anions and covalent interactions. The ionic difluorides SmF_2, EuF_2, and YbF_2 crystallize in the fluorite structure. Their stability with respect to disproportionation into the trivalent oxidation state and metal can be attributed to the stabilities of the f^6 configuration (thermal excitations of low lying states),[137] the half-filled f^7 shell, and the filled f^{14} shell. Chlorides and bromides crystallize in the $PbCl_2$, MoS_2, $SrBr_2$, and iodides mainly in the $MoSi_2$, $CdCl_2$, and CdI_2 type structures.[135] NdI_2 undergoes a pressure induced phase transformation from the $SrBr_2$ type to the $MoSi_2$ type which is accompanied by an insulator $\rightarrow$ metal transition ($Nd^{2+} \rightarrow Nd^{3+}{\cdot}(e^-)$). Examples, where owing to the nonclosed-shell configurations of the rare earth atoms unusual properties are found, are numerous. Already in 1961 the use of rare earth lasers began with Sm^{2+} in CaF_2,[138] shortly after the ruby laser was discovered. SmI_2, a dark blue salt with remarkably good solubility in tetrahydrofuran (THF), is widely used as reducing agent in organic chemistry.[139] Structures based on the MoS_2 phase are particularly susceptors for the incorporation of hydrogen, as in CeI_2 109 or LaI_2.[140] Magnetic ordering has been found for GdI_2[141] below 313 K which is accompanied by

a large change of the electrical resistivity, that is, GdI_2 shows a giant magneto resistance effect near room temperature.[142]

The chemistry of phases with intermediate compositions REX_n ($2.0 < n < 3.0$), which are complex mixed valent RE(II)/RE(III) halides, reminds on the AX_2/REX_3 systems (A = Ca, Sr, Ba). In fluorides REF_n ($n \approx 2.0-2.2$) divalent ions and trivalent ions occupy the sites within a fluorite-type variant, in which, for charge compensation, interstitiell halides are incorporated into the primitive anion sublattice and solid solutions REX_2/REX_3 are observed. For higher n, the anions form clusters and line phases are formed which crystallize as so-called anion ordered excess fluorite-type variants or in other complicated structure types.

Highly reduced binary rare earth halides (more than one electron per metal atom) are relatively rare.[143] Similar to the early transition metal systems, their structures are derived from M_6X_8 or M_6X_{12} clusters, which can be either isolated in a halide matrix, or condensed to form metal frameworks with 1D, 2D, and 3D characteristics. Since these clusters are even more electron deficient than the corresponding Zr systems, interstitial species, which include H, small main group atoms and fragments (C_2^{n-}), and even transition metals,[130] are often critical for their formation.[123–125] Therefore, only few binary halides are found which belong to this class of compounds, such as the sesquihalides RE_2X_3 for RE = Y, Gd, Tb and X = Cl, Br. They are isostructural and contain chains of trans vertex-sharing octahedral clusters (see Figure 22). Using simple chemical ideas to predict properties, the metal networks, coupled with the formal oxidation state of +1.5, would suggest metallic behavior for the RE_2X_3 type compounds. However, Gd_2Cl_3 and Gd_2Br_3 are semiconductors. Determinations of the band structures for these materials agree with experiments and predict a band gap. A neutron diffraction study for Tb_2Cl_3 shows that there is strong antiferromagnetic ordering between the basal Tb atoms which is accompanied by a high degree of frustration of the apical Tb atoms.[144] Further examples of highly reduced rare earth halides are Sc_7Cl_{12} and RE_7I_{12} (RE = La, Pr, Tb) which contain discrete M_6X_{12} clusters. Characteristic building units in Sc_5Cl_8 are single chains of edge-sharing metal octahedra along with parallel chains of edge-sharing $ScCl_6$ octahedra

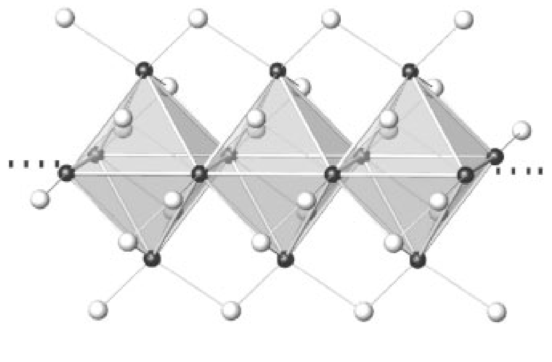

Figure 22 Structure of a condensed cluster chain in Gd_2Cl_3

and in Sc_7Cl_{10} double chains of edge-sharing metal octahedra. There is also a recent report on a most metal-rich rare earth halide, LaI;[145] however, this compound could be synthesized only in the presence of other metals (Cr, Mn) so that its existence remains at least doubtful.

Higher oxidation states of the rare earth element halides are only found among the fluorides.[146] Three binary examples are known, CeF_4,[147] PrF_4,[148] and TbF_4,[149] which all crystallize in the ZrF_4 type structure. They decompose thermally into fluorine and the corresponding trifluorides. All attempts to prepare other rare earth tetrafluorides, for example, NdF_4 and DyF_4, have proved unsuccessful and only the deep-orange complexes, Cs_3NdF_7 and Cs_3DyF_7 could so far be prepared.

7 SUMMARY

Binary metal halides are crystalline solids that demonstrate an enormous richness of structural topologies as well as compositions.

1 INTRODUCTION

Catalysis refers to the phenomenon by which the rate of a chemical reaction is accelerated by a substance (the catalyst) not appreciably consumed in the process. The term 'catalysis' was coined by Berzelius in 1835 and scientifically defined by Ostwald in 1895, but applications based on catalysis can be traced back to thousands of years ago with the discovery of fermentation to produce wine and beer.[1] Nowadays, catalysts are used in 80% of all chemical industrial processes, and create annual global sales of about 1500 billion dollars and contribute directly or indirectly to approximately 35% of the world's GDP.[2] Catalysis is central to a myriad of applications, including the manufacture of commodity, fine, specialty, petro-, and agro- chemicals as well as the production of pharmaceuticals, cosmetics, foods, and polymers. Catalysis is also an important component in new processes for the generation of clean energy, and in the protection of the environment both by abating environmental pollutants and by providing alternative cleaner chemical synthetic procedures.

Most catalytic processes are heterogeneous in nature, typically involving a solid catalyst and gas or liquid phase reactants. When compared with homogeneous catalysts, heterogeneous catalysts offer inherent advantages because of their ease of preparation, handling, separation from the reaction mixture, recovery, and reuse, and also in terms of their stability, low cost, and low toxicity. Heterogeneous catalysts are most commonly made out of metals and metal oxides, although metal sulfides, nitrides, carbides, phosphates and phosphides, ion-exchange resins, and clays are also employed in selected applications. Metal catalysts, especially those containing transition metals, have proven particularly useful in industrial catalysis, because they have the ability to easily activate key molecules such as H_2, O_2, N_2, and CO as well as polyatomic organic molecules with C–H, C–O, C–N, and C–Cl bonds.[3] Table 1 summarizes some of the most important metal-based catalytic processes developed since the 1870s.[1,4]

In the following sections, the basic chemical concepts behind heterogeneous metal catalysis will be introduced. Then, typical examples of practical catalytic systems related to the generation of energy, the production of chemicals, the preparation of materials, and the cleaning of the environment will be provided. Finally, several promising directions related to heterogeneous metal catalysis will be highlighted.

2 FUNDAMENTALS OF HETEROGENEOUS METAL CATALYSIS

2.1 Kinetics Versus Thermodynamics, Active Centers, Catalytic Cycles

Catalysis relies on changes in the kinetics of chemical reactions. Thermodynamics acts as an arrow to show the way to the most stable products, but kinetics defines the relative rates of the many competitive pathways available for the reactants, and can therefore be used to make metastable products from catalytic processes in a fast and selective way. Indeed, catalysts work by opening alternative mechanistic routes with lower activation energy barriers than those of the noncatalyzed reactions.[5] As an example, Figure 1 illustrates how the use of metal catalysts facilitates the dissociation of molecular oxygen, and with that the oxidation of carbon monoxide. Thanks to the availability of new pathways, catalyzed reactions can be carried out at much faster rates and at lower temperatures than noncatalyzed reactions. Note, however, that a catalyst can shorten the time needed to achieve thermodynamic equilibrium, but cannot shift the position of that equilibrium, and therefore cannot catalyze a thermodynamically unfavorable reaction.[6]

The new mechanistic routes opened by the introduction of a catalyst to the reaction mixture typically start with the adsorption of the reactants. Because of the heterogeneous nature of the surface of the catalyst, both the adsorption and the subsequent conversion reactions may take place preferentially at particular ensembles of surface sites, often called active sites or active centers.[7,8] An atomic ensemble may become active because of a specific structural arrangement of those atoms. Alternatively, the electronic properties of metal atoms may also influence the adsorption and activation of reactants. Typically, the performance of catalytic active sites depends on both structural and electronic effects.

After diffusion towards and adsorption on the surface-active sites, the reactants are converted to products. Those products then desorb and diffuse out of the catalyst, leaving the active centers available for new incoming reactants.[7] That way, the catalytic cycle can be repeated many times on each active site. For this to work, however, the bond strength between the adsorbed surface species and the active sites

Table 1 Important industrial heterogeneous catalytic processes promoted by metals[1,4]

Process	Year	Main uses	Key reaction scheme	Typical catalyst
SO_2 oxidation to sulfuric acid	1875	Chemicals, Metallurgic processing	$SO_2 + 1/2O_2 \rightarrow SO_3$	Pt on asbestos, $MgSO_4$, or SiO_2 (replaced by $V_2O_5 - K_2SO_4/SiO_2$ since the 1920s)
Methanol to formaldehyde	1890	Resins for adhesives	$CH_3OH + 1/2O_2 \rightarrow HCHO + H_2O$	Ag wire gauze or Ag crystals
Olefin hydrogenation	1902	Oil refining	$C_2H_4 + H_2 \rightarrow C_2H_6$	Ni, Pt
Hydrogenation of edible fats and oils	1900s	Food production	unsaturated fatty acids → partially saturated acids	Ni on a support
Methanation	1900s	Fuels	$CO + 3H_2 \rightarrow CH_4 + H_2O$	Ni on Al_2O_3 or other oxide supports
Ammonia synthesis (Haber)	1913	Fertilizers	$N_2 + 3H_2 \rightarrow 2\,NH_3$	Fe promoted with Al_2O_3, K_2O, CaO, and MgO
Ammonia oxidation (Ostwald)	1906	Nitric acid production	$4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O$	90%Pt-10% Rh wire gauze
Fisher–Tropsch synthesis	1938	Fuels	$CO + H_2 \rightarrow$ paraffins	Fe or Co with promoters on support
Steam reforming	1926	Synthesis gas	$C_nH_m + nH_2O \rightarrow nCO + [n + (m/2)]H_2$	Ni on support promoted by K_2O
Ethylene to ethylene oxide	1937	Antifreeze	$C_2H_4 + 1/2O_2 \rightarrow (CH_2)_2O$	Ag on α-Al_2O_3, promoted by Cl and Cs
Hydrogen cyanide synthesis	1930s	Chemicals	$CH_4 + NH_3 + 3/2O_2 \rightarrow HCN + 3H_2O$	90%Pt-10% Rh wire gauze
Catalytic reforming	1940s	Fuels	e.g., n-$C_6H_{14} \rightarrow i$-C_6H_{14}	Pt, Pt–Re or Pt–Sn on acidified Al_2O_3 or zeolite
Benzene to cyclohexane	1940s	Nylon	$C_6H_6 + 3H_2 \rightarrow C_6H_{12}$	Ni, Pt, or Pd catalysts
Vinyl acetate synthesis	1968	Polymers	$C_2H_4 + CH_3COOH + 1/2O_2 \rightarrow CH_3COOCH{=}CH_2 + H_2O$	Pd on SiO_2 or α-Al_2O_3
Automobile three-way catalysis	1970s	Pollution control	$CO + H.C. + NO_x + O_2 \rightarrow CO_2 + H_2O + N_2$	Pt, Pd, Rh on monolith support

needs to be neither too weak nor too strong: too weak and the reactants cannot be readily activated; too strong and either the reactants are completely decomposed on the surface or the products cannot desorb.[6] This relationship between adsorption energy and catalytic performance is epitomized by volcano plots such as those in Figure 2.[9–12] In many instances, the adsorption energy can also be correlated to specific properties of the metals such as their d-band occupancy (%d) character (Figure 2b).[12]

2.2 Activity, Selectivity, Stability

Three key parameters, activity, selectivity, and stability, can be used to evaluate catalyst performance. Achieving good and sustainable activity and selectivity at low cost is an everlasting goal in catalyst design and development. Activity refers to the rate at which a given reaction proceeds. In practice, activity can be expressed in absolute terms, but is often reported using relative units such as specific rate (rate divided by catalyst weight), areal rate (rate divided by surface area), turnover frequency (molecules converted per active center per unit time), conversion after specified time (fraction of reactants converted per fixed time), or required temperature for a given conversion under specific conditions.[13] In industry, activity is often expressed by space-time yield, the amount of product formed per unit time per unit volume of reactor. Regardless of the parameters adopted to express activity, however, it needs to be appreciated that such activity depends on the catalyst load in the reactor, the concentration of the reactants, and the temperature, pressure, and flow during operation.

In addition to activity, the design of catalytic processes needs to consider their selectivity towards the desirable products.[14] In fact, selectivity is arguably the most important criterion to take into account to decide on a particular catalytic process. Selective reactions consume less reactant, avoid the need of costly separations, and do not produce potentially polluting by-products. Unfortunately, it is not easy to design selective catalytic processes from first principles. For one, a catalyst active for a given reaction may be inactive for a closely related one. In addition, given a set of reactants, the use of different catalysts may lead to different products. For example, ethanol is dehydrogenated to acetaldehyde on Cu

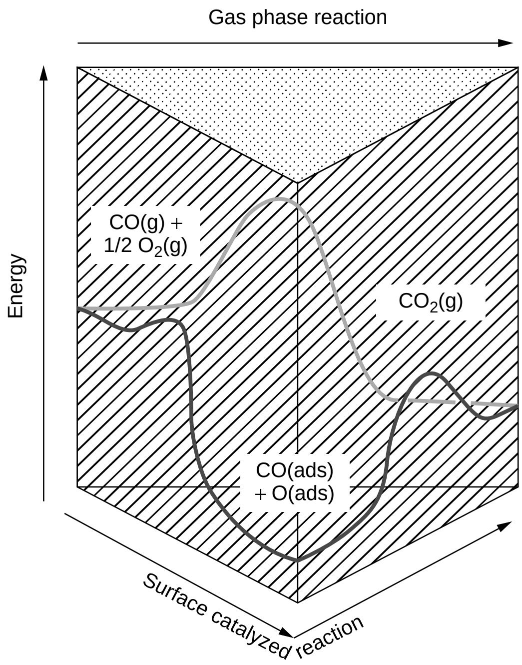

Figure 1 Energy diagram illustrating how solid catalysts facilitate reactions by opening new mechanistic routes. This example corresponds to the oxidation of carbon monoxide, a conversion that can be accelerated by previous dissociation of the molecular oxygen on many transition metal surfaces

but dehydrated to ethylene or ethyl ether on γ-Al_2O_3.[4] Many competing reactions may also be promoted by one particular catalyst, in which case the distribution of the resulting products may depend on experimental conditions such as reaction temperature, pressure, and contact time.

Finally, there is the issue of stability. Ideally, catalysts are expected not to be consumed and to maintain a constant level of performance during the course of the reaction. In reality, however, both catalytic activity and catalytic selectivity may deteriorate during operation. The lifetime of most industrial catalysts is finite, ranging from months to years. The most common reasons for this catalyst deactivation include the evaporation, washout, reduction, corrosion or other transformation of the active catalytic species during reaction, the formation of carbonaceous deposits (coking), the poisoning due to strong adsorption of impurities such as sulfur or carbon monoxide on the surface of the catalyst, and/or the coalescence of metal particles (sintering).[4,13] Some of these processes are reversible, in which case the catalysts can be regenerated by special treatments in situ in the reactor such as burning off of the coke deposits or other in situ chemical treatments, but many are irreversible and require the replacement of the catalyst. Fluctuations in processing conditions may influence the stability of catalysts as well, so engineering optimization is also crucial in the design of catalytic processes.

2.3 Supports, Promoters

As mentioned above, heterogeneous catalysis is centered around the chemistry of adsorbed species on solid surfaces. Consequently, it is important to maximize the surface-to-volume ratio of the active phase to minimize cost and

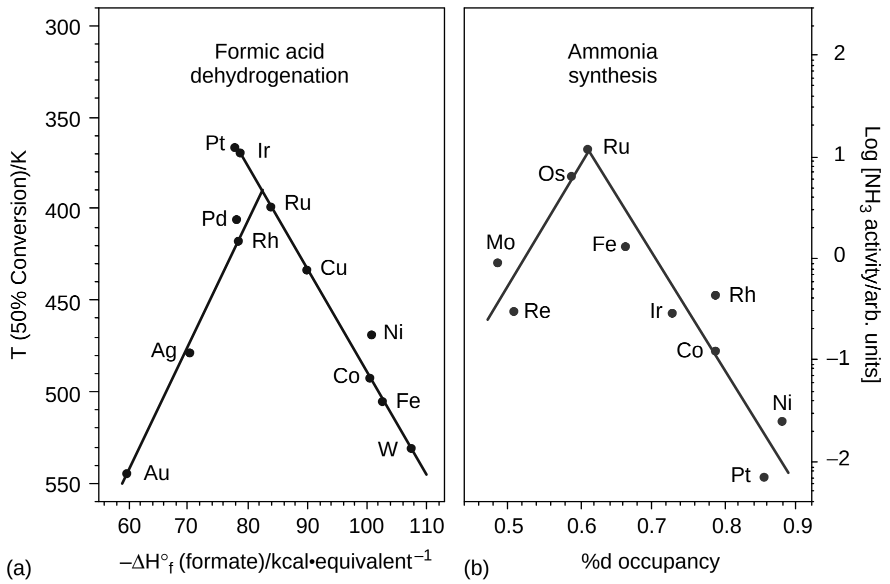

Figure 2 Volcano plots illustrating how catalytic activities depend on the nature of the metal used as catalyst. (a) Correlation between catalytic activity for formic acid dehydrogenation and enthalpy of formation of metal formates. (Ref. 10. Reproduced by permission of John Wiley & Sons, Inc.)[9,10] (b) Correlation between catalytic activity for ammonia synthesis and degree of d-band filling in the metal used as catalyst. (Ref. 12. Reproduced by permission of John Wiley & Sons, Inc.)[11]

improve performance. Because of this, the direct use of metal wires, gauzes, and foils in industrial catalysis is rare. The surface area of bulk metals is rather small, with only a few active sites exposed, and pure metals in high surface area forms are generally not thermally stable under catalytic conditions. Instead, metals are typically dispersed onto high surface area refractory supports such as alumina, silica, zeolites, activated carbon, titania, zirconia, or mixed oxides. Pillared clays, mesoporous materials, ceramics, silicon carbide, graphite, carbon nanofibers, magnesia, metal fluorides, calcium carbonate, and barium sulfate have also been used occasionally for this purpose. Figure 3 shows a transmission electron microscopy (TEM) picture of a typical catalyst; in this case silver particles approximately 10–20 nm in diameter are deposited on a porous alumina support.[15] The choice of support is primarily based on its surface area, but thermal and chemical stability, chemical properties, mechanical strength, and price also need to be considered.[13] Although most supports are used primarily to disperse a catalytic active phase, they often add to the overall chemistry of the catalytic process. In particular, supports with different acid-base or redox properties often exert marked influence on catalytic behavior. Zeolites (*see* ***Zeolites***) can also provide unique shape selectivity, since the uniformity of their pores can regulate the relative flows of the entering reactants, the leaving products, and the transition states of the reaction based on their sizes, thus determining the product distribution.[16] Last but not least, strong interactions between metal catalysts and supports such as titania (SMSI) can significantly modify the electronic and chemical properties of the former.[4]

To further optimize the performance of metal catalysts, promoters are often added. Textural promoters work by separating metal particles from one another to minimize sintering, whereas electronic and structural promoters change the electronic or crystal structure of the active metal. For instance, a small amount of potassium acetate is added to the Pd/SiO_2 or $Pd/\alpha\text{-}Al_2O_3$ catalysts used in the synthesis of vinyl acetate to promote the adsorption of acetic acid and lower the barrier to vinyl acetate formation, thus increasing the overall activity and minimizing the yield of CO_2.[17] The addition of potassium compounds or other alkaline substances to nickel catalysts during steam reforming can facilitate both the adsorption of water and the removal of carbonaceous deposit.[4] In ammonia synthesis, Al_2O_3, CaO, and MgO are added to the iron catalyst as textural promoters to minimize the sintering of Fe, and K_2O as an electronic promoter to increase the activity for the dissociative adsorption of N_2.[4] Nowadays, almost all catalytic processes in industry involve the incorporation of promoters during catalyst preparation and/or the feed of additives with the reaction mixture.

2.4 Preparation and Characterization of Metal Catalysts

Because of the complexity of solid catalysts, where the active phase is dispersed onto a high surface area solid and promoted with a number of additives, the preparation of catalysts is still somewhat of an art. Numerous methods have been developed over the years for the preparation of metal catalysts. For example, some iron-based catalysts for ammonia synthesis are manufactured by fusion of Fe_3O_4 with small amounts of K_2CO_3, Al_2O_3, and other ingredients.[4] The porous Raney nickel catalysts used for the selective hydrogenation of organic chemicals are prepared by alloying Ni with Al and then leaching away the Al in a boiling NaOH solution.[17] The silver catalyst used in the partial oxidation of methanol is made electrochemically using an $AgNO_3$ electrolyte.[17] However, the most common way to prepare supported metal catalysts is by impregnation, where a porous support is soaked into a solution containing a metal precursor such as $HAuCl_4$ or H_2PtCl_6.[18] Coprecipitation is another traditional method where a solution containing a soluble metal salt and a precursor for the support such as $Al(NO_3)_3$ or $ZrOCl_2$ are thoroughly mixed with an aqueous inorganic base to precipitate the cations as hydroxides or carbonates.[19] Sol-gel methods (*see* ***Sol–Gel Synthesis of Solids***) involving the hydrolysis of metal alkaloids such as $Si(OC_2H_5)_4$ and $Al(i\text{-}OC_3H_7)_3$ can also be used to form high surface area supports.[20] In all of these three cases, the resulting materials need to be calcined and reduced in order to expose the metallic phase. Decarbonylation of metal carbonyls adsorbed on appropriate supports, oxidative transformation of amorphous alloys into supported metal catalysts, and flame spray pyrolysis, are also viable routes to catalyst preparation.[17] Finally, for industrial applications, the powder catalysts obtained are further shaped into tablets, pellets, rings, extrudates, spheres, shells, or granules (Figure 4).

The processes used for the preparation of heterogeneous catalysts are not only versatile, but also complex; even subtle changes in preparation conditions often lead to clear differences in catalyst performance. Therefore, it is highly desirable to develop a microscopic understanding of the

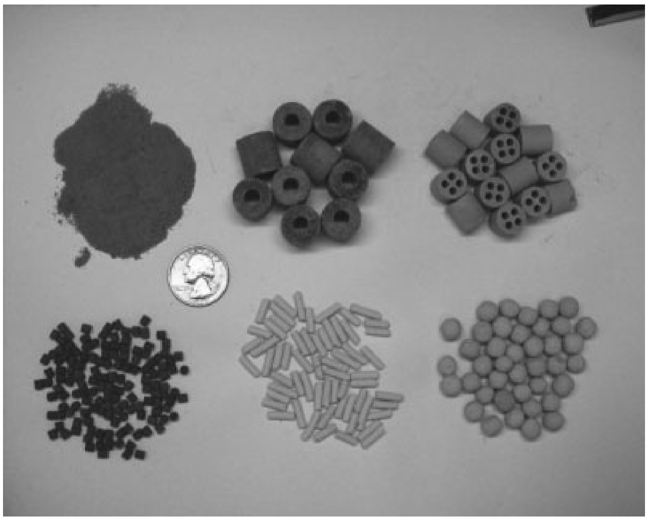

Figure 4 Examples of the final forms of the catalysts used in industrial processes. Shown are powders, rings, four-hole cylinders, tablets, pellets, and spheres of different supported metal catalysts

relation between structure and reactivity in catalysts. For now, however, the design of catalyst preparation from first principles is still not possible. Luckily, a number of analytical methods are available for the characterization of the final solids.[21] X-ray diffraction (XRD) provides information on the bulk structure, degree of crystallinity, and average crystal size of supported catalysts. Electron microscopy, in either transmission (TEM) or scanning (SEM) modes, aids in the determination of individual metal particle sizes and morphology, and of metal dispersion. Nitrogen adsorption isotherms are used to derive surface areas, pore size distributions, and pore volumes. X-ray photoelectron spectroscopy (XPS) facilitates the identification of surface species and their oxidation states. Infrared spectroscopy of probe adsorbates such as CO, NO, NH_3, C_2H_4, CH_3OH, and pyridine gives information on the nature of adsorption sites and reaction mechanism on catalyst surfaces.[22] Finally, chemical titration can be used to identify specific properties of active sites. For instance, temperature programmed desorption (TPD) of NH_3 or CO_2 can provide an indication of the acidic or basic nature of the solid catalysts. The use of these and other characterization methods such as nuclear magnetic resonance (NMR), X-ray absorption fine structure, and in situ Raman spectroscopy have already been well documented.[23–25]

3 APPLICATIONS OF HETEROGENEOUS METAL CATALYSIS

Metal catalysis is widely used in processes related to energy production, chemicals manufacture, materials synthesis, and environmental controls, among others. In this section, both traditional and recent examples highlighting the role of metal catalysts in each of these areas are provided.

3.1 Metal Catalysis Related to Energy Production

Metal catalysis plays a key role in the utilization of fossil fuels such as petroleum, coal, and natural gas. Petroleum technology has been identified as one of the 20 most world-shaping engineering achievements of the 20^{th} century, supplying 40% of the global energy and 90% of the industrial organic chemicals.[26,27] However, crude oil consists of a vast mixture of hydrocarbons (together with small amounts of sulfur and nitrogen-containing organic compounds) and therefore cannot be used efficiently without extensive processing. Components with different boiling point ranges are first separated via fractional distillation, and the naphtha fractions are then treated with hydrodesulfurization (HDS) and hydrodenitrogenation (HDN) catalysts (*see **Hydrodesulfurization & Hydrodenitrogenation***) to remove impurities, the precursors of environmental pollutants such as SO_2 and NO_x, and with reforming, cracking, and hydrocracking catalysts to produce high quality fuels.

Metals, metal oxides, zeolites, and metal sulfide catalysts are at the heart of these oil conversion processes. HDS and HDN are commonly carried out on molybdenum sulfide catalysts. Catalytic cracking uses zeolites to breakdown large hydrocarbon molecules into branched or cyclic hydrocarbons and alkenes. More to the point of this review, catalytic reforming uses noble metals to promote isomerization and cyclization reactions without significantly changing the molecular weight of the naphtha fraction.[4,28] Reforming catalysts are almost exclusively based on a platinum metallic phase. Indeed, the most common processes used nowadays are the UOP Platforming, based on Pt/Al_2O_3-SiO_2, and the Chevron Rheniforming, which employs Re–Pt/Al_2O_3-SiO_2. Typical reforming processes are carried out at temperatures between 480 and 540 °C, and with hydrogen-rich reaction mixtures under several atmospheres of pressure. The reforming catalyst is believed to rely on its dual functionality, with hydrogenation-dehydrogenation steps taking place on the metallic phase and isomerization reactions on acid sites furnished by the support, although it has been shown that platinum alone can perform all reforming steps.[29] Platforming and Rheniforming processes are currently used in more than 170 plants worldwide.[27]

Coal and natural gas are also major sources of energy. Coal supplies 27% of the energy used worldwide, and natural gas, which is mainly composed of methane, provides another 23%.[27] At present, both coal and natural gas are primarily burned to produce energy. However, in order to fully exploit their energy and chemical potential, they are also increasingly being converted to synthesis gas, a mixture of CO and H_2, via gasification ($C + H_2O \rightarrow CO + H_2$), steam reforming ($CH_4 + H_2O \rightarrow CO + 3H_2$), or direct oxidation ($CH_4 + 1/2O_2 \rightarrow CO + 2H_2$), and further transformed into

heavier hydrocarbons and into alcohols via Fischer–Tropsch (F-T) type processes.

Again, most of the conversions enumerated above require the use of heterogeneous catalysts. F-T synthesis, for instance, uses Fe-, Co-, or Ru-based catalysts dispersed onto high surface area Al_2O_3, SiO_2, or TiO_2 supports. This process was initially commercialized in Germany to produce transportation fuels during World War II, and later employed in South Africa to cover their domestic fuel demands during apartheid. More recently, new F-T plants have been built in New Zealand, Malaysia, South Africa, and the Netherlands.[30,31] The classical F-T process follows an overall reaction stoichiometry of $2n\mathrm{CO} + 2n\mathrm{H_2} \rightarrow (-\mathrm{CH_2}-)_n + n\mathrm{CO_2}$, and typically yields a mixture of hydrocarbons with a range of hydrocarbon chain lengths. The most accepted mechanism for those reactions requires three main types of steps, namely, the initial formation of C_1 intermediates by CO dissociation and hydrogenation, the growth of hydrocarbon chains by successive insertion of C_1 building blocks into the growing hydrocarbon surface chains, and the termination and desorption of surface species.[30,32]

Small amounts of oxygenated products such as alcohols may also be made in F-T processes depending on the catalyst used, and various parameters, including catalyst composition and operation conditions, can be used to influence the distribution of the various paraffins, olefins, and oxygenates produced. For instance, iron-based catalysts, which can be operated at high temperatures and are relatively tolerant to impurities such as sulfur in the feedstock, tend to produce straight hydrocarbon chains. Cobalt-based catalysts are even more selective, producing a much higher ratio of paraffins to olefins and much less oxygenated products. Rhodium-containing catalysts, on the other hand, yield high fractions of alcohols, allegedly because of the slow dissociation of CO on that metal. Nowadays, F-T based gas-to-liquids (GTL) processes are used to produce diesel fuels for urban local transportation. It has been estimated that this process will supply 10% of the global diesel demand within the next 15 years.[31]

Metal catalysts are not only useful for producing gasoline, oil, diesel, and jet fuels, but also promise to contribute to the next generation of environmentally friendly energy production technology. For instance, the room temperature decomposition of liquid hydrazine (N_2H_4) to N_2, H_2, and NH_3 over a commercial Ir/γ-Al_2O_3 catalyst is already used as a propellant to control and adjust the orbit and attitude of satellites.[33] Perhaps more promising is the use of H_2-fuelled electrochemical energy converters (fuel cells) in cars, space shuttles, and other power systems. This application has already been demonstrated on a commercial scale, and is predicted to reach a market in excess of 23 billion dollars by 2010.[34] The reaction involved, $2\mathrm{H_2} + \mathrm{O_2} \rightarrow 2\mathrm{H_2O}$, is quite simple and thermodynamically favorable, but kinetically nonviable for practical applications without the use of catalysts. Figure 5 shows a typical fuel cell setup indicating the Pt-coated anode used to catalyze the oxidation of H_2 ($2\mathrm{H_2} \rightarrow 4\mathrm{H^+} + 4e^-$) and the also Pt-based cathode that catalyzes the combination of the resulting protons with O_2 from air ($4\mathrm{H^+} + 4e^- + \mathrm{O_2} \rightarrow 2\mathrm{H_2O}$).[35] The two electrodes are separated by an ion-conductive electrolyte to allow for the proton transfer. The overall combination of H_2 and O_2

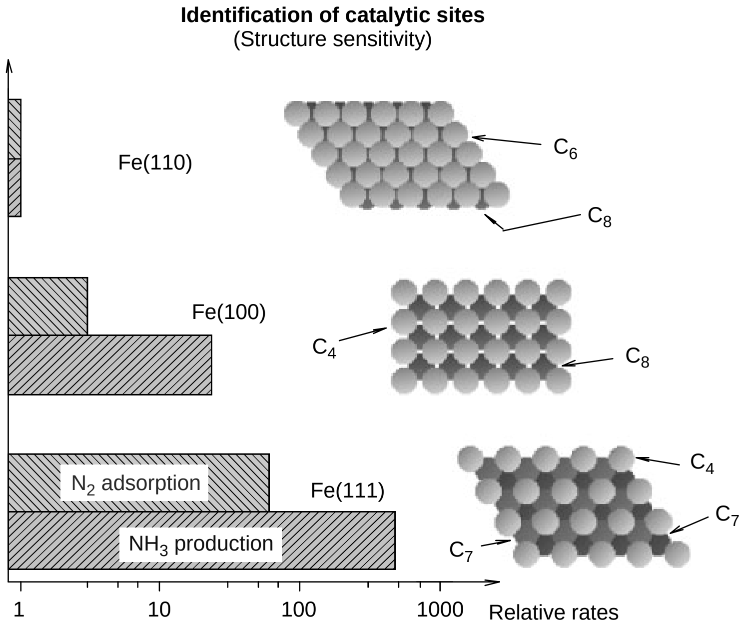

Figure 6 Correlation between both N_2 adsorption and NH_3 production rates and the structure of the catalytic surface, as determined by studies with various single crystals of iron.[38] These results explain the strong dependence of the performance of commercial ammonia synthesis catalysts on their method of preparation[39]

is fast, generating an electrochemical current and additional heat. Some technical problems related to surface poisoning by CO and to fuel storage have so far limited the widespread use of fuel cell technology, but solutions to these roadblocks are already underway.[36] It is clear that metal catalysts will continue to play a crucial role in most future energy generation technologies.

3.2 Metal Catalysis Related to the Manufacturing of Chemicals

Metal catalysts play a pivotal role in the production of most commodity, fine, and specialty chemicals. In fact, a large number of hydrogenation and oxidation processes would not be viable without the use of heterogeneous catalysis. Perhaps the most important and mature example of a catalytic process for the production of chemicals is the synthesis of ammonia from nitrogen and hydrogen, a process that was initially commercialized in 1913 and is nowadays responsible for the production of more than 100 million tons of synthetic ammonia and associated chemicals such as nitric acid, fertilizers, explosives, caprolactam, acrylonitrile, and hydrogen cyanide each year.[27,37] A typical ammonia synthesis catalyst is made by combining Fe_3O_4, Al_2O_3, K_2O, CaO, and MgO, and reducing this mixture in the reactor before operation to expose metallic iron sites. Surface science studies have indicated that this reaction is particularly sensitive to the structure of the active metal phase, with the dissociative adsorption of N_2, the rate-limiting step, being a couple of orders of magnitude faster on Fe(111) planes than on Fe(100) or Fe(110) surfaces (Figure 6).[38,39] The efficiency of the ammonia-producing process is limited by thermodynamic considerations, and reaches yields of only about 14% under the optimized reaction conditions of temperature (around 450 °C) and pressures (~100 atm). Recirculation of the reaction mixture, however, allows for ammonia yields of up to 98% under industrial settings. Supported ruthenium catalysts promoted by alkali metals have been introduced since the early 1970s to synthesize ammonia at lower temperature and pressures, and have resulted in the commercialization of the ruthenium-based Kellogg Advanced Ammonia process in Canada in 1992. Nevertheless, because of the high cost of Ru, most of the industrial ammonia plants still rely on iron catalysts.[11,17]

Successful examples of selective oxidation catalysis in industry include the conversions of ethylene to ethylene oxide and of methanol to formaldehyde, both on silver catalysts. Ethylene oxide, with an annual worldwide production capacity over 11 million tons, is an important intermediate for the production of glycols (antifreeze agents), ethoxylates (additives in washing powder), cosmetics, polyester fibers, and pharmaceuticals.[27] The partial oxidation of ethylene to ethylene oxide is carried out on silver metal particles supported on α-Al_2O_3 or SiC and promoted by alkaline earth or alkali metals. Trace amounts of ethylene dichloride are also fed continuously into the reactor to suppress deep oxidation. Selectivities of about 75–85% are typical nowadays for this process. Formaldehyde, with a production capacity of

30 million tons per year, is employed for the production of the resins used as adhesives in various boards and other miscellaneous products.[27] This chemical is commercially produced by oxidation of methanol on electrolytic silver while feeding water vapor, nitrogen, and/or trace amounts of additives to promote methanol adsorption and inhibit deep oxidation. In addition, silver catalysts supported on low surface area pumice, ceramics, sol-gel derived SiO_2, SiO_2-TiO_2, and SiO_2-Al_2O_3 have been used to inhibit sintering. At present the formaldehyde yield in industrial plants is 86–90%, the main by-products being carbon oxides, formic acid, and methyl formate.[27]

The key to the success of the oxidation examples cited above is the ability of the catalysts used to exert proper kinetic control on the possible side reactions. Without it, thermodynamically favorable but undesired products such as CO_2 and H_2O are made instead. Controlling oxidation kinetics to stop at the desired oxygenated products is quite difficult, and has yet to be solved for many other systems. For instance, although many attempts have been made to develop a commercial process for the oxidation of propylene to propylene oxide, both the activity and the selectivity of the systems proposed to date, mostly based on silver catalysts, are still too low to be of industrial interest;[40] propylene oxide is presently manufactured by processes based on chlorohydrin or hydrogen peroxide instead.[27] In spite of these difficulties, though, recent advances in selective liquid phase oxidation of fine chemicals on supported metal catalysts have shown some promise, offering high yields (close to 100%) under mild reaction conditions.[41]

Other commercial approaches to the production of chemicals use selective hydrogenation of unsaturated bonds, dehydrogenation, or coupling reactions promoted by various metal catalysts.[42] One old example related to food production is that of the manufacture of margarine by hydrogenation of unsaturated vegetable oils on nickel catalysts.[4,17] Table 2 provides a list of other key catalytic conversion processes of commercial value in the chemical industry.[42–46] These reactions are particularly useful for the production of 'building blocks' for the manufacturing of pharmaceuticals, agrochemicals, and other fine and specialty chemicals of high added value. For instance, aromatic haloamines, important intermediates in the synthesis of agrochemicals, drugs, dyestuffs, and pigments, can be manufactured via hydrogenation of aromatic halonitro compounds on supported Pt catalysts.[43] Ethyl (R)-2-hydroxy-4-phenylbutanoate, an intermediate for the production of benazepril, a drug used to treat high blood pressure, can be made by chiral hydrogenation of the corresponding α-ketoester on Pt/Al_2O_3 modified by chiral cinchona alkoloids.[44] Iminostilbene, a key intermediate in producing Carbamazepine, a medicine to treat psychiatric disorders, is made by dehydrogenation of iminodibenzyl on Pd/C catalysts.[43] Octyl p-methoxy cinnamate, the most common UV-B sunscreen in the market, can be produced via Heck coupling also using Pd/C catalysts.[45] Metal catalysts play a central role in these and many other processes, providing highly selective pathways toward the making of desired products by activating specific functional groups in the presence of other potentially reactive moieties.

3.3 Metal Catalysis Related to the Synthesis of Materials

Heterogeneous catalysis is also extensively used for the manufacture of materials such as polymers, plastics, fibers, and carbon filaments. For example, Ziegler-Natta catalysts, based on $TiCl_4$, $Al(C_2H_5)_3$ and $MgCl_2$, are commercially used to fabricate many polymers, including polyethylene, polypropylene, polybutadiene, and polystyrene.[13] Metallocene complexes have also been developed to control molecular weight and tacticity in polymerization processes. Most polymerization catalysts are homogeneous in nature (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***), but are sometimes anchored on solid supports to facilitate the catalytic process. A more direct example of the use of heterogeneous metal catalysts in this area is that of the commercial production of caprolactam, the precursor to nylon-6 and nylon-66. This is done by using the Allied-Signal process, which involves the liquid phase hydrogenation of phenol to cyclohexanone on a palladium catalyst. That product is then converted to cyclohexanone oxime, and further to caprolactam via Beckmann rearrangement.[27] An alternative route for this synthesis is the Snia Viscosa process, which involves the hydrogenation of benzoic acid to hexahydrobenzoic acid on a Pd/C catalyst followed by direct conversion to caprolactam via nitrosation with nitrosylsulfuric acid.[27] Another practical example of the synthesis of precursors for the manufacture of materials is the hydrosilylation process, in which silicon hydrides undergoes an addition reaction with an unsaturated reactant. This reaction is particularly useful for the catalytic production, curing, and functionalization of polysiloxanes and other organosilicon polymers. Although homogeneous metal complexes are often used for these hydrosilylation reactions, supported Pt catalysts are preferred in many applications.[46]

Carbonaceous deposits have been long regarded as unwanted side products during catalysis.[47] However, with the advent of nanotechnology, there has been a renewed interest in the use of metal catalysts for the production of filamentous carbon materials such as carbon nanotubes (*see* ***Carbon: Nanotubes***) and nanofibers because of their potential applications in electron emission devices, hydrogen-storage materials, fuel cell electrodes, and catalyst supports.[48] Physical synthetic methods such as arc-discharge and laser ablation are already available for the production of carbon filaments, but their yields are relative low. Metals such as Fe, Co, and Ni, on the other hand, can be used to convert CH_4, CO, synthesis gas, C_2H_2, C_2H_4, or C_2H_6 efficiently to carbon nanofilaments or composite materials in good quantities. Figure 7 provides

Table 2 Important hydrogenation, dehydrogenation, and coupling processes catalyzed by metals[42–46]

Process		Example reaction scheme	Metal catalyst
Hydrogenation of alkenes and alkynes		$—C{\equiv}C— + H_2 \longrightarrow —C{=}C—$	Pd, Rh, Pt
Hydrogenation of aromatic rings			Rh, Ru, Pt
Hydrogenation of aldehydes, acetones, and carboxylic acids to alcohols			Pt, Ru, Pd, Ir
Hydrogenation of nitro and nitroso compounds to amines			Pd, Pt
Hydrogenation of nitriles to amines			Rh, Pt, Pd
Hydrogenation of oximes to amines, hydroxyamines or imines	$>C{=}NOH + H_2 \longrightarrow >CHNH_2$	$>C{=}NOH + H_2 \longrightarrow >CHNHOH$	Rh, Pt, Pd
Hydrogenation of imines to amines	$—CH{=}NNH_2 + H_2 \longrightarrow —CH_2NHNH_2$		Pt
Enantioselective hydrogenation of α- or β-ketoesters			Cinchona-modified Pt, Pd, or tartaric acid-modified Ni

(cont'd overleaf)

Table 2 cont'd

Process		Example reaction scheme	Metal catalyst
Hydrodehalogenation		Rosenmund reduction	Pd
Dehydrogenation			Pd, Pt, Rh
Hydrogenolysis of sulfides			Re
Reductive alkylation			Pt, Pd
Arylation or vinylation of alkenes with aryl or vinyl halides (Heck coupling)			Pd
Suzuki coupling of aryboronic acids and aryl halides to biarys			Pd
Hydrosilyation	$-CH{=}CH_2 + SiHR_3 \longrightarrow -CH_2CH_2SiR_3$		Pt

an example of the nanofibers that can be grown this way.[49] It shows both the grown carbon fibers and the capping metal particles that catalyze the carbon deposition process. The rate-determining step in most of those catalytic reactions is thought to be the diffusion of carbon atoms through metal particles, and the properties of the resultant products are believed to depend on the composition and nature of the catalyst as well as on operational parameters such as temperature, reaction time, composition of reactant mixture, and gas flow rate.[4] Other carbon materials such as diamond can also be synthesized with the aid of metal alloy catalysts.[50] Unfortunately, full understanding of these processes is at present limited, and the production and practical use of well-defined carbon fibers and diamond materials by catalytic means are still in the future.

3.4 Metal Catalysis Related to Environmental Control

Metal catalysis is not only good for the production of chemicals, but has also been increasingly employed for the control of pollutant emissions and for the removal of contaminants. In fact, a third of the 9–10 billion dollars market for world catalyst consumption nowadays is related to environmental catalysis.[2,51] One of the most prominent uses of environmental catalysis is in the control of automobile exhausts. Stringent regulations on car gas emissions have now been imposed by numerous governments around the world to minimize the buildup of noxious CO, NO_x, and hydrocarbon gases in the troposphere. To meet these standards, modern internal combustion engines are fitted with commercial catalytic converters designed to transform those pollutants to less toxic N_2, H_2O, and CO_2. The typical so-called three-way catalyst used for this in most countries is composed of a combination of Pt, Rh, and Pd metal particles supported on a γ-Al_2O_3 washcoat stabilized with La_2O_3 or BaO and modified with CeO_2 or CeO_2/ZrO_2. These catalysts are set onto a ceramic honeycomb or monolith to obtain high thermal stability, high heat and mass transfer rates, low pressure drops, and long catalyst life (Figure 8).[52]

The conversion of automobile exhaust gases involves a number of complex oxidation and reduction reactions, which with today's catalysts requires careful control of the air/fuel ratio within a narrow window around the stoichiometric value of 14.6. Direct injection gasoline engines, however, operate best with a large excess of air, and that compromises the reduction efficiency for NO_x. In order to address this problem, alkaline metal oxides such as BaO are being incorporated into new catalytic designs to adsorb NO_x; periodic brief incursions into rich fuel-burn operation conditions are then induced to release and reduce the trapped NO_x on the metal catalyst.[53] Another technical problem in the present systems is their ineffectiveness during the so-called cold start, right after the engine is turned on; this is the time when most of the polluting hydrocarbon emissions takes place. The challenge here is to either develop ways to achieve fast heating of the catalyst to its light-off temperature or to design catalysts more active under lower operating temperatures.[53] New metal-based formulations have already been incorporated in the new generations of automobile catalytic converters.

Three-way catalysts are mainly used to treat gaseous pollutants from mobile engines. In stationary sources such as power generators and industrial plants for the production of nitric acid and other chemicals, the most important requirements in terms of environmental control are the removal of NO_x and volatile organic compounds (VOCs) from gas discharges. In general, NO_x is selectively reduced (SCR) on either V_2O_5-WO_3/TiO_2 or metal-exchanged zeolite catalysts with NH_3 or urea. However, the use of nitrogen-containing reducing agents can lead to the production of other pollutants, so recent attempts have been made to use metal catalysts such as Pd/TiO_2 together with methane as the reducing agent instead.[54] In terms of the treatment of VOCs, they are often burned over Pt/Al_2O_3-BaO or Pd/Al_2O_3 catalysts in order to lower the temperature of the process well below those used in conventional flame combustion (up to 2000 °C).[51]

Customized catalysts are also available for more specialized environmental uses. For instance, Pt/mordenite catalysts are used for the treatment of air pollutants in spray painting and coating workshops, and also to control emission in benzoic anhydride manufacturing industries. Pt–V_2O_5–SO_4^{2-}/mordenite is sometimes employed to purify flue gases containing sulfur compounds. Metal-based catalysts are ideal for such applications, because they work at low reactant concentrations (4–6 g/m^3), high space velocities

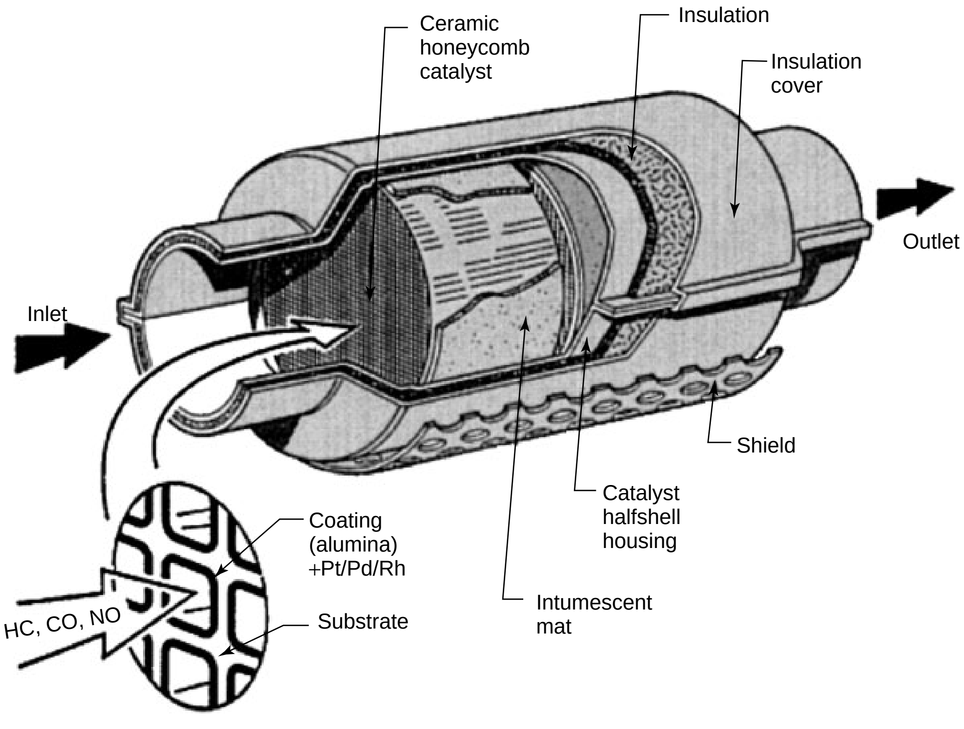

Figure 8 Typical design of a three-way catalyst for automobile exhaust control. Highlighted here are the honeycomb support and the mounting can used. So-called three-way catalysts, consisting of a combination of Pt, Rh, and Pd particles dispersed on high surface area alumina, are spread on the honeycomb structure to oxidize the carbon monoxide and unburned hydrocarbons and to reduce the nitrogen oxides released by the engine of the car. (Reprinted from Ref. 52, © 1998, with permission from Elsevier)

(4500–20 000 h^{-1}), and low temperatures (150–400 °C). Processes such as those mentioned above have been adopted in more than 1000 factories in China and Japan alone.[55]

Another use of environmental catalysis is in the hydrodechlorination of chlorine-containing pollutants such as chlorinated olefins, chlorobenzenes, chlorophenols, and chlorofluorocarbons. Thermal combustion of these chemicals has been demonstrated on a commercial scale, but the required high temperatures for incineration lead to the formation of toxic dioxins. Alternatively, supported Pd, Pt, Rh, Ni, Pd–Au and Pd–Re catalysts can be used to remove the chlorine atoms from those molecules via hydrogenation reactions.[56,57] Hydrodechlorination is also one of the purifying steps needed to improve the quality of drinking water and to clean waste water.[58] In another example, zero-valent iron has been used as an electrocatalyst for the removal of both organic chlorinates and inorganic salts such as arsenates from groundwater.[59] Wet air oxidation is used to remove dissolved organic pollutants, and hydrodenitrification is used to abate inorganic salts such as nitrates and nitrites in water.[58] Other applications of metal catalysis in this area include the indoor detection and room temperature oxidation of carbon monoxide, the elimination of odors in indoor environments, and the decomposition of aqueous ozone.[51]

4 PROMISING NEW DIRECTIONS IN HETEROGENEOUS METAL CATALYSIS

The field of catalysis is a mature one, with a history over 100 years old. Nevertheless, new opportunities keep on developing in this area. Below, some of the new directions that we believe will lead the near future of heterogeneous catalysis are advanced.

4.1 Novel Catalytic Materials

One of the main problems of traditional metal catalysts is that they are fairly ill-defined, in that the shapes of the metal particles on the supports are often irregular, that their particle size distributions are broad, and that no strict control can be exerted on interparticle distances. Recent developments in material technologies promise to provide new metallic materials, new supports, and new methodologies for the fabrication of better defined catalysts.

One family of new materials with potential use in metal catalysis is that of metal nanostructures such as metal nanoparticles (*see* ***Metal Nanoparticles, Synthesis of*** and ***Metal Nanoparticles, Organization & Applications of***), nanoshells, nanowires, nanorods, nanotubes, nanobelts, and nanoplates.[60–62] For instance, it has been recently shown that Ag nanowires and nanoparticles can be produced by

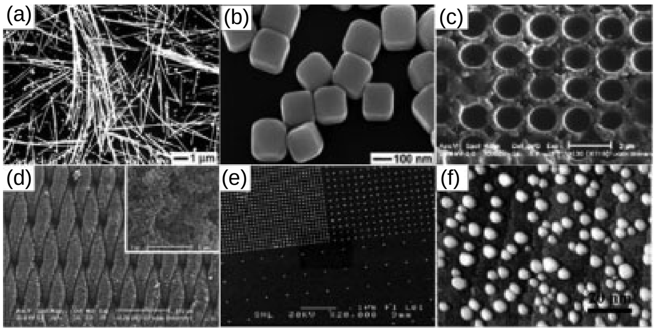

Figure 9 Examples of novel materials with potential catalytic applications. From left to right and top to bottom, these pictures represent: (a) Ag nanowires. (Reprinted with permission from Ref. 63. © 2002 American Chemical Society); (b) Ag nanoparticles. (Reprinted with permission from Y. Sun and Y. Xia, *Science*, 2002, **298**, 2176. © 2002 AAAS (www.sciencemag.org)); (c) zeolite monolith. (Ref. 67. Reproduced by permission of Kluwer Academic/Plenum Publishers); (d) zeolite coatings on stainless steel grids. (Ref. 68. Reproduced by permission of Wiley-VCH); (e) arrays of Pt nano lithography-made particles on SiO_2. (Ref. 70. Reproduced by permission of Kluwer Academic/Plenum Publishers); and (f) Ag nanoparticles vapor deposited on an Al_2O_3 thin film[71]

nucleation and growth on nanoseeds produced by first reducing $PtCl_2$ or $AgNO_3$ with ethylene glycol (Figures 9a and 9b).[63,64] Moreover, those Ag nanowires can be further used as templates to grow Au, Pt, or Pd nanotubes with hollow interiors.[62] The controlled growth of other metals with various nanostructures have been reported in the recent literature, but their uses in catalysis are still in the embryonic stages. One tantalizing result in this direction is that of the use of palladium nanoshells and nanotubes to catalyze the Suzuki coupling reaction with up to 100% yield.[61,62]

Because of their ordered pore structures and adjustable acid-base properties, zeolites have long been used as supports for many catalysts. However, the small size of the micropores in zeolites (diameter < 1 nm) limits their application when dealing with bulky molecules.[16,65] The recent development of mesoporous metal oxides (*see* ***Porous Inorganic Materials***) with ordered nano channels promises to allow for the engineering of ‘nano reactors’ for reactions involving fine chemicals and pharmaceuticals. Organometallic compounds, metal oxides, heteropolyacids, and enzymes have all been supported onto mesoporous silica, but the application of mesoporous supports in metal catalysis has only started.[65,66] Advanced zeolite-based architectures such as zeolite shells, fibers, tissues, monoliths, capsules, membranes, and coatings as well as mesoporous materials with sturdy zeolite walls have also been constructed by assembly of nanozeolite building blocks (Figures 9c and 9d).[67–69] These new materials with ordered secondary advanced structures are expected to allow for fast mass transfer during catalysis.

Physical methods such as those developed for the semiconductor industry have also started to make an inroad into metal catalysis.[38,70,71] Figures 9e and 9f show micrographs of metal particles supported on metal oxide thin films fabricated by electron beam lithography and by metal vapor deposition, respectively.[70,71] As exemplified by Figure 9e, the size, height, and spatial distribution of the metal particles may be easily adjusted with these techniques according to experimental needs. Although applications of these new materials technologies to the manufacturing of new commercial catalysts are still somewhere in the future, they already offer new opportunities for the study of reaction kinetics on supported metal particles with unique and uniform structures.

4.2 Surface Science of Catalysis

The development of new catalytic materials needs to be complemented with detailed studies of the surface chemistry of catalysis at the molecular level in order to better define the requirements for the catalytic active sites. The wide array of modern spectroscopies available to surface scientists today is ideally suited for this task (*see* ***Surfaces***). Surface science studies on catalysis typically probe reaction intermediates on model metal samples under well controlled conditions. This kind of study is traditionally carried out in ultrahigh vacuum (UHV) systems such as that shown in Figure 10. Single crystals or other well-defined metal surfaces are cleaned and characterized in situ by physical and chemical means, and then probed using a battery of surface sensitive techniques such as photoelectron (XPS and UPS), electron energy loss (ELS

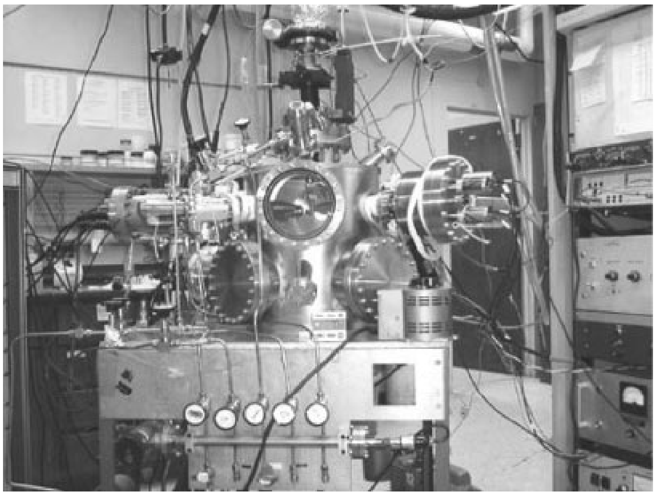

Figure 10 Typical ultrahigh vacuum system used for surface science studies of catalytic reactions on model systems.[74] The combined development of new preparation methods for realistic catalytic samples and in situ spectroscopies for the molecular level characterization of surface species during catalysis promises to advance the basic understanding of catalytic processes

and HREELS), secondary ion mass (SIMS), infrared (IR), and temperature programmed desorption (TPD) spectroscopies. By characterizing the catalytic surface before, during, and after chemical reactions using a combination of these surface science methods, a molecular picture of the reaction pathways of catalytic processes on solid surfaces can be extracted.[38,72–74]

Although traditional surface science studies have greatly helped advance our understanding of catalysis at a fundamental level, the differences between the pressure and materials employed in UHV studies and those encountered in applied catalysis have limited the extrapolation of the knowledge developed this way to real systems. Ex-situ characterization experiments can be carried out on catalytic surfaces before and after reactions, but those are also subject to limitations due to potential changes during the handling of the sample. This is why there has been a renewed interest in closing these so-called ‘materials’ and ‘pressure’ gaps between surface science and catalysis by using new spectroscopic and material preparation methods. To bridge the materials gap, novel model catalysts consisting of metal particles supported on planar metal oxide thin films have started to be developed and tested for a number of simple catalytic reactions such as ethylene hydrogenation, CO methanation, CO oxidation, ethane hydrogenolysis, NO reduction, and methanol decomposition.[38,75,76] To bridge the pressure gap, in situ spectroscopic methods such as sum frequency generation (SFG), Fourier transform infrared (FT-IR), and Raman spectroscopies as well as scanning (STM) and electron (SEM, TEM) microscopies adopted for *in situ* operation under nonvacuum conditions have been employed to study reactions on metal surfaces under realistic conditions.[77] These approaches promise to advance our fundamental chemical understanding of complex catalytic systems at the molecular level.

4.3 High Throughput Catalyst Testing

Because of the complexity of catalytic systems and the lack of understanding of their microscopic properties, the design of catalysts from first principles is still limited. Instead, the traditional way of developing successful catalysts in industry has been by trial and error. This approach is not only costly, but also time-consuming. Consequently, to expedite the development of new catalysts, intensive efforts have been recently placed on automating their production and characterization during the first stages of screening. With these high throughput (sometimes called combinatorial) techniques, small amounts of many catalysts with slightly different and systematically varied compositions are prepared in parallel, and simultaneously subjected to reaction testing by techniques such as scanning mass spectrometry, resonance-enhanced multiphoton ionization, fluorescence detection, and IR thermography. The data collected are subsequently analyzed with the aid of computers and sophisticated software to mine promising leads from the thousands of candidates. The best cases are then scaled up, optimized, and subjected to a more quantitative second screening to select even better leads for further scaling up and testing in conventional lab reactors.[78]

High throughput catalyst screening is especially useful for the development of metal catalysts with multiple components such as alloys. Figure 11 shows the results of a secondary screening of four-component catalysts for the

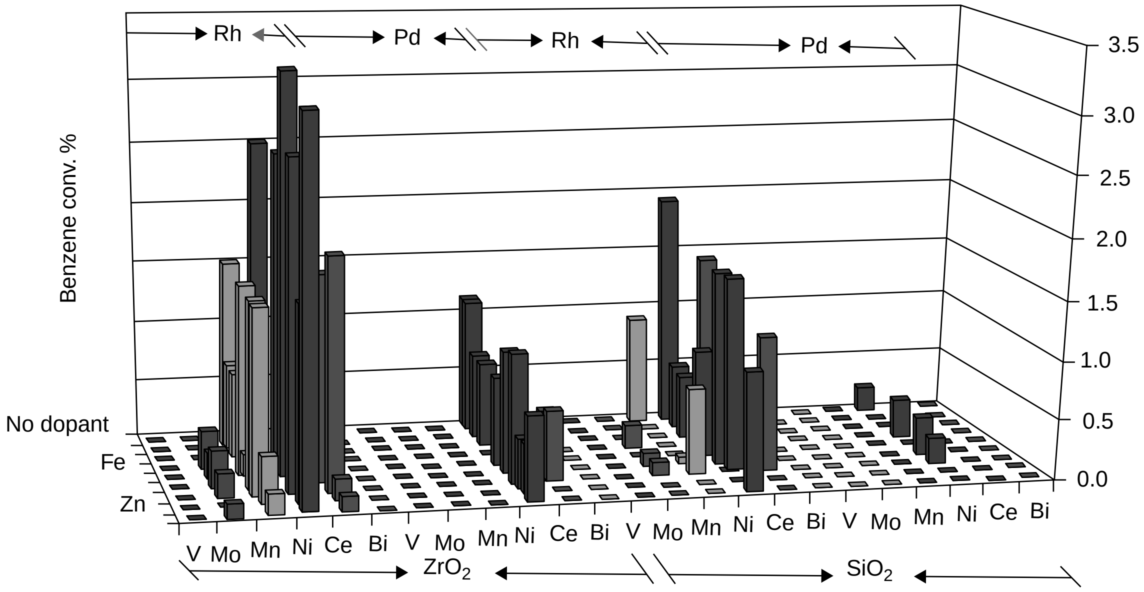

Figure 11 Results from high throughput studies on four-component catalysts for the direct ammination of benzene to aniline. A library with (Rh, Pd)–M_1–M_2–(ZrO_2, SiO_2) components was tested. New technology for the fast screening of complex materials offers an opportunity to test a wide variety of potential catalysts for specific catalytic applications. (Reprinted from Ref. 79, © 1998, with permission from Elsevier)

direct ammination of benzene to aniline. The library used there consists of combinations of an active metal (Rh or Pd), a support (ZrO_2 or SiO_2), an oxidant (V, Mo, Mn, Ni, Ce, or Bi), and a dopant (blank, V, Cr, Mn, Fe, Co, Ni, Cu, or Zn).[79] 216 samples generated by the combination of these four components were tested 24 samples at a time by using parallel high-pressure batch reactors. It became clear from these data that ZrO_2 is a better support than SiO_2, that Rh is a better metal than Pd, that NiO is the best oxidant, and that metal dopants can further modify the overall activity of the system.[79] The use of combinatorial methods for the development of a few other catalysts for processes such as the oxidation of CO by O_2 or NO with Rh–Pd–Pt alloys has been reported as well. Nevertheless, their usefulness for the design of commercial catalysts is still in question.[78,80]

4.4 Improved Selectivities, Green Chemistry

Historically, the emphasis in catalysis has been on increasing activity rather than selectivity. This is not surprising, since catalysts are generally regarded as substances that can speed up reactions. In addition, many early catalytic processes were based on relatively simple reactions with negligible sidesteps. As the field of catalysis expanded and covered more complex reactions, however, selectivity started to become crucial in designing industrial processes.[81] One example of this already mentioned above is that of the partial oxidation of alcohols to oxygenated hydrocarbons.[82]

A more subtle but important example of the need for good catalytic selectivity is that of the manufacture of chiral medicines. The market for single-enantiomer drugs has recently reached 160 billion dollars, accounting for close to half of the profits from sales of drugs worldwide.[83] If regular catalysts are used, only racemic mixtures of the products are obtained. This is at the very least quite wasteful, since those processes require at least twice the amount of reactants. Moreover, in many instances, one enantiomer may be biologically active but the other may be poisonous, so the desired product needs to be isolated by expensive separation techniques such as selective crystallization, chiral chromatography, membrane separation, or chemical methods. Clearly, the production of enantiomerically pure chemicals directly via heterogeneous catalysis would be much preferred. In this direction, tartaric acid-modified nickel and cinchona-modified platinum catalytic systems have proven successful for the enantioselective hydrogenation of β- and α-ketoesters, respectively, showing enantioselectivities of up to 98%.[44,84] The role of the chiral modifiers is still not fully understood, but in the latter case appears to involve the formation of a 1:1 complex with the reactant on the surface to force an adsorption geometry where the hydrogenation is only possible on one side of the molecule (Figure 12).[84] The use of heterogeneous catalysis in chiral

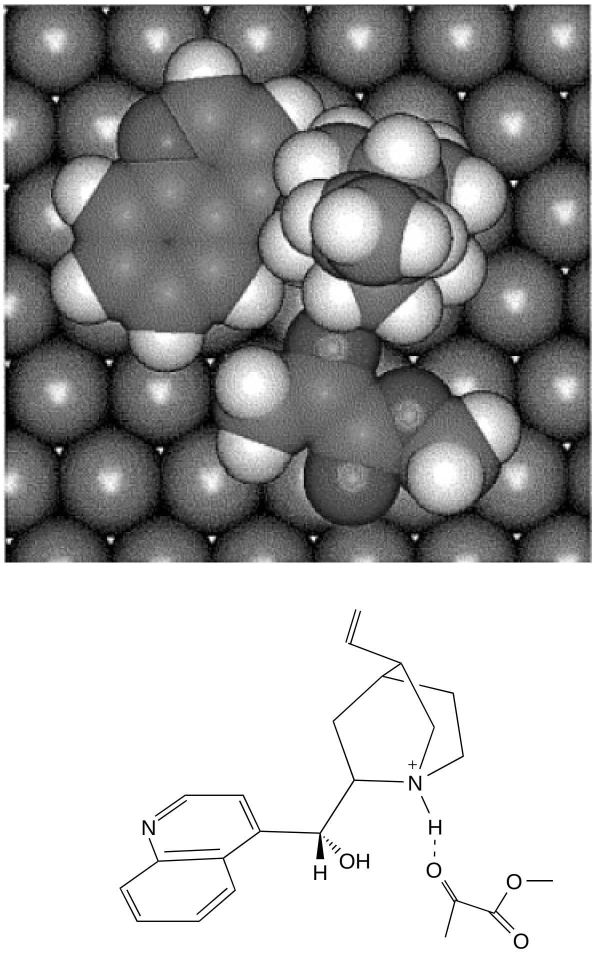

Figure 12 Schematic representation of the mechanism proposed for the enantioselective hydrogenation of α-ketoesters on cinchonidine-modified platinum catalyst. The development of general methods for imparting enantioselectivity to regular heterogeneous catalysts promises to revolutionize the pharmaceutical and agrochemical industries[84]

manufacturing is still quite limited, but ongoing work to try to understand the details of this chemistry promises to lead to the development of new catalysts for these applications.[85]

Many industrial catalytic processes in use nowadays are far from ideal in terms of cleanliness, economy, and simplicity. For one, multiple-steps processes often require the disposal of many side products, and display low compounded yields. With the introduction of the concept of green chemistry in the 1990s, whereby a new emphasis is placed on the design of chemical products and processes that reduce or eliminate the use and generation of hazardous substances, significant efforts are being placed to develop alternative more efficient routes to replace some existing processes in industry.[86,87] Heterogeneous metal catalysis is expected to play a crucial role in these new processes as well.

1 INTRODUCTION

Chemical composition, temperature, and pressure may be considered as the independent axes of the three-dimensional space in which materials exist. At high pressures, materials assuming compact structures are formed. Artificially, high pressure is generated by focusing a relatively small, manageable mechanical force upon a small area, and it is transmitted to the material to be compressed through a medium of gas, liquid, or solid. The highest static pressure attained using specially designed diamond anvils reaches ∼400 GPa, which is comparable with the Earth's core pressure.

The Earth itself is a huge high pressure and high temperature vessel.[1] The interior is so dynamic and mysterious that geochemists and geophysicists have long been driven to develop high pressure technology as a means to look into the interior. Another attractive research subject is concerned with behavior of solidified hydrogen under pressures of the order of 100 GPa.[2] In 1935, Wigner and Huntington predicted a pressure-induced transition from the insulating molecular phase to a metallic monoatomic phase.[3] Interest in the metallic monoatomic phase has increased because of the possibility of high-temperature superconductivity[4] and also for its possible existence on a massive scale in Jupiter and Saturn.

Diamond, the hardest material known, is the most representative inorganic product of natural and artificial high pressure synthesis. As illustrated later, it can be obtained from graphite at 5.4 GPa and 1667 K, typically,[5] while it is not diamond but graphite that is thermodynamically stable at ambient conditions. Though solid hydrogen cannot be 'quenched' to ambient conditions, diamond can be and remains stable, in effect, to about 600 K. From practical viewpoints, high pressure synthesis is of value if the product has a particular important property and, at the same time, if it is stable after being decompressed.

Also included in some successful cases is the application of high pressure for the purpose of crystal growth: growth of huge rock crystals (∼1 kg each) by means of a hydrothermal technique utilizing hot compressed water (650 K and 150 MPa, typically)[6] has proved to be of great technological significance. In this case, high pressure is generated internally by heating volatile water confined in a vessel (autoclave), not by application of a mechanical force from the outside. The use of high oxygen pressures generated similarly, will also be included in this article.

From an academic viewpoint, factors such as metastability and crystal size are not so important. Phase identification, chemical reaction, and physical properties such as magnetism, conductivity, elasticity, and so on can be studied for a sample of 10 mg (or even much less depending upon the research subject) in a short time. These studies can even be done in situ, that is, under high pressure at various temperatures.

In this article, both classical and modern aspects of high pressure synthesis will be outlined, taking diamond, rock crystals (α-quartz), perovskites, and some other materials as examples.

2 HYDROTHERMAL SYNTHESIS[6–8]

2.1 Outline

Hydrothermal synthesis is carried out in the presence of water heated above 373 K in a pressure vessel. Geologists and mineralogists initiated this method in the nineteenth century, since they knew that many kinds of minerals, and beautiful crystals of them, formed from magma containing compressed hot water and steam.

The system enclosed in the vessel contains water as a volatile, low-melting point component which lowers the liquidus curve. The increase in the solubility of solids, even of those insoluble at ambient pressure up to the boiling point of water, such as $BaSO_4$, SiO_2, and metals, is quite remarkable, and this makes it possible to control their reactivity and also to control their precipitation or their reaction products, so that beautiful and pure crystals may grow. Water plays multiple roles as a solvent, as a catalyst accelerating the attainment of equilibrium between different crystalline solids, and as a mineralizer that accelerates crystal growth. It is known that the appropriate choice of pH and additive is also important. Water may or may not remain in the precipitates as an ingredient. A variety of crystals obtained with this method are listed, with the temperature and pressure conditions, in Table 1.

The advantages of this method are as follows. These essentially come from the use of a low temperature homogeneous reaction in a closed system.

Table 1 Hydrothermal crystal growth

Material	Solvent	Temperature (K)		Pressure (MPa) (Degree of fill (%))
		Solution zone	Growth zone	
α-Al_2O_3	2–3.4 M Na_2CO_3 or K_2CO_3	770–810	660–760	110–160 (75–82)
$AlPO_4$	6.1 M H_2PO_4 + 3.8 M $NH_4H_2PO_4$		Slow heating: 520 → 670	(80)
$BaPb_{0.75}Bi_{0.25}O_3$	3 M NaOH	700–750	670–720	100
$CaCO_3$	0.1–0.2 M NH_4NO_3	430–480	420–470	50–150
$CaWO_4$	4% wt NaOH	700	650	(60–70)
CdS	1 M HCl or HBr		770	130
ZnO	3–6 M KOH + 0.5–2 M LiOH	650–670	630–650	60–120
Fe_3O_4	1–5 M NaOH	650–680	625–655	(75–80)
$NiFe_2O_4$	0.5 M NH_4Cl		740–750	110–130 (70–75)
α-SiO_2	0.5–1 M NaOH or 0.25–0.5 M Na_2CO_3	630–640	600–610	80–150 (75–85)
$Y_3Al_5O_{12}$	2 M K_2CO_3	870	820	100
$YfeO_3$	20–25 M KOH	680	650	(70–90)
$Y_3Fe_5O_{12}$	20 M KOH	700	660	(87)

1. Crystals that decompose or lose volatile components at elevated temperatures can be prepared.
2. Low temperature polymorphs can be obtained (*see Polymorph*).
3. Pure and high-quality crystals can be grown. Concentrations of impurities, point defects, and dislocations are generally low (*see* ***Defects in Solids***).
4. The oxidation state of transition metals can be controlled by using appropriate oxidants or reductants (*see Formal Oxidation State* and *Oxidation Number*).

2.2 Apparatus

Laboratory experiments below 800 K and 100 MPa can be conducted with sealed autoclaves developed initially by Morey *et al.*[9] Figure 1(a) shows this type of vessel, which is to be wholly put into a furnace. The liner and the seal disk are made of an inactive metal such as silver or gold. Since the pressure cannot be measured directly, one should calculate it from the degree of fill and the pressure–volume–temperature (*PVT*) data of water.[10]

At higher temperatures and pressures to 1300 K and 300 MPa, test-tube type vessels, like the one illustrated in Figure 1(b), are most generally used (first developed by Tuttle).[11] The vessel is made of superalloy, a group of alloys containing Co and Ni and some additional elements such as Cr and Mo. A small silver or gold-welded capsule containing starting solid materials and an appropriate aqueous solution is placed in the bottom of the vessel. The degree of fill and temperature determine the pressure balance with the surrounding water in the tube.

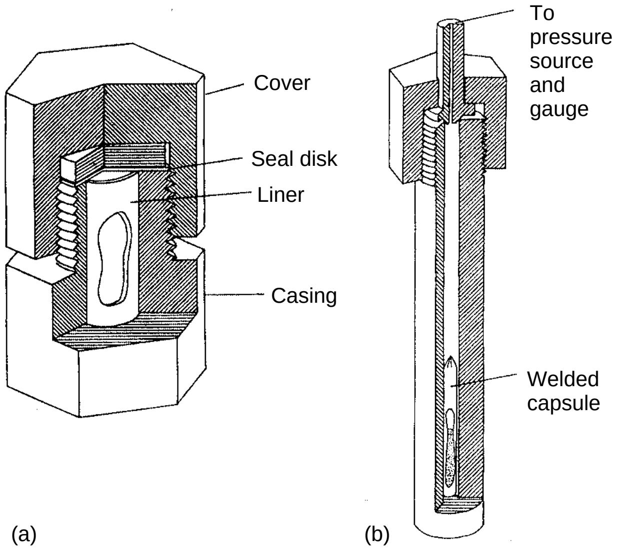

Figure 1 (a) Morey vessel and (b) test-tube type vessel

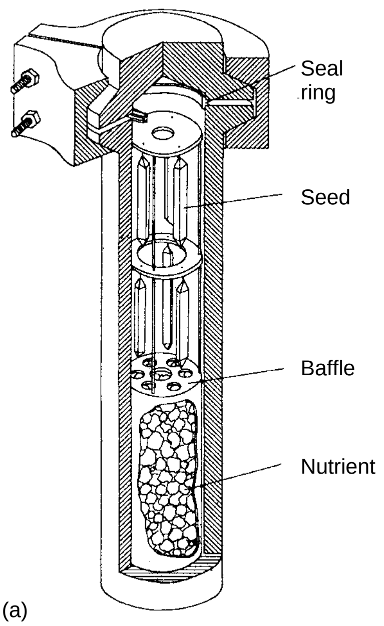
2.3 α-Quartz (Rock Crystal)[12]

α-Quartz, α-SiO_2, is an extremely important material for its piezoelectricity and also for its optical transparency over a wide range from ultraviolet to infrared. Because the piezoelectric property is anisotropic, depending upon the crystalline orientation, and because polycrystalline compacts are far less transparent, single crystals serve for commercial use. A suitable hydrothermal growth technique was basically established in the 1950s. 2.5 tons of crystals can be grown in one run in a huge autoclave of 5-m^3 capacity, working at 150 MPa.



(a)

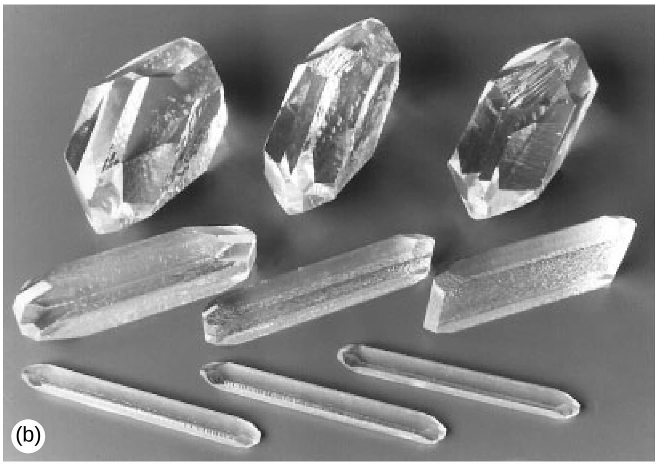


Figure 2 (a) Autoclave for the growth of rock crystals and (b) a photo of cultured crystals. (Courtesy Nihon Dempa Kogyo Co., Ltd)

In the autoclave illustrated in Figure 2(a), a baffle plate separates the reaction chamber into two parts, the upper cool zone and the lower hot zone. α-Quartz is dissolved in the lower zone and deposited on the seed crystals supported in the upper zone. This is because the solubility in water depends upon temperature at 150 MPa. The solution is made alkaline (0.5–1 M) with NaOH or Na_2CO_3 to raise the solubility by an order of magnitude.

To minimize the content of a specific impurity, the OH group, that seriously affects the piezoelectric properties, crystals are grown slowly, at a rate of 0.5–1.5 mm day^{-1}. The temperature of the hot and cool zones are kept at 630–640 K and 600–610 K, respectively, for 20–100 days. Some beautiful crystals thus obtained are shown in Figure 2(b). It should be noted that the crystal growth is carried out at such a low temperature. More common techniques allowing crystals to grow from their molten liquids cannot be applied to α-quartz, because a structural transition to the β-form occurs at 846 K.

Note finally that the solubility does not always vary monotonically with temperature and pressure. So the optimum experimental conditions need to be searched for very carefully. Mentioning an unusual example from Table 1, $AlPO_4$ dissolves at 520 K and grows at 670 K.

3 HIGH OXYGEN PRESSURE

3.1 Outline

Structural details and physical properties of transition metal oxides depend quite remarkably upon their oxygen content.[13] $SrFeO_3$ crystallizing in the cubic perovskite structure (see Figure 9(b)) retains metallic conductivity down to the lowest temperature, while $SrFeO_{2.95}$ is semiconductive at room temperature. A better known case is $YBa_2Cu_3O_{7-z}$.[14] It is a superconductor with a transition temperature (T_c) at 93 K for $z \leq 0.1$, while it is insulative at $z = 1$. On the other hand, $SrTiO_3$ is an insulator, while $SrTiO_{3-x}$ is a superconductor. Moreover, oxygen vacancies usually interact very strongly with each other, leading to a series of compounds with discrete vacancy contents and vacancy ordered superstructures. For example, a homologous series of oxygen-deficient phases $SrFeO_{3-1/n}$ with $n = \infty$, 8, 4, and 2 are known.[15] It is to be noticed that the formal oxidation state of transition metals changes with oxygen content as it varies from Fe^{IV} for the $n = \infty$ phase, $SrFeO_3$, to Fe^{III} for the $n = 2$ phase, $Sr_2Fe_2O_5$ (*see* ***Mixed Valence Compounds***; ***Oxides: Solid-state Chemistry***; ***Superconductivity***; *Metal–Insulator Transitions*; *Formal Oxidation State*; *Oxidation Number*).

Change in oxygen content also causes a change in color. TiO_2 is a colorless insulator, while reduction toward Ti_2O_3 makes it colored and conductive. Between these is a series of many phases formulated as Ti_nO_{2n-1} with $3 \leq n \leq 50$. Ti_2O_3 powder looks reddish black, while slightly oxidized Ti_3O_5 powder is bluish black. A mixed powder of these (1:1) looks completely black and is used as a harmless cosmetic pigment.[16]

Control of oxygen content is thus very important from various aspects. High oxygen pressure[17] can be used in two seemingly opposite ways, to increase oxygen content (as in equation 1) and to decrease it (as in equation 2). In either case, high pressure is used as a means to control oxygen fugacity. Representative experiments are listed in Table 2.

$$2SrFeO_{3-z} + zO_2 \longrightarrow 2SrFeO_3 \quad (1)$$

$$2CrO_3 \longrightarrow 2CrO_2 + O_2 \quad (2)$$

Table 2 Treatments at high oxygen pressure

Structure type	Product[a]	Starting material	Oxygen pressure (MPa)	Temperature (K)	Remarks (Special oxygen source)
Rutile	$Cr^{IV}O_2$	CrO_3	10	670	
	CrO_2	$Cr(OH)_3$	10	670	
	$Pt^{IV}O_2$	'Hexagonal PtO_2'	300	970	
	$Rh^{IV}O_2$	'Unidentified structure RhO_2'	300	970	
Pyrochlore	$R_2Pt_2^{IV}O_7$	R_2O_3 + 2 'PtO_2'	300	970	R = Nd to Ho, Y
	$R_2Pd_2^{IV}O_7$	$R_2O_3 + 2PdO_2$	6000	1300	R = Gd, Dy, Y ($KClO_4$)[b]
	$Y_2Cr_2^{IV}O_7$	$Y_2O_3 + Cr_2O_3$	7000	1250	($KClO_4$)[b]
Perovskite	$CaFe^{IV}O_3$	$Ca_2Fe_2O_5$	2000	1220	(CrO_3, $KClO_4$)[b]
	$SrFe^{IV}O_3$	$SrFeO_{2.8}$	100	570	
	$La_2LiFe^{V}O_6$	$2La_2O_3 + Li_2O + Fe_2O_3$	6500	1270	($KClO_3$)[b]
	$SrCo^{IV}O_3$	$SrCoO_{3-z}$	100	570	
	$RNi^{III}O_3$	R_2O_3 + NiO	20–40	1270	R = Pr, Nd
	$LaCu^{III}O_3$	La_2CuO_4 + CuO	6500	1270	($KClO_3$)[b]
	$Tl^{I}Tl^{III}OF_2$	TlF_2	450	770	
Copper oxide superconductor	$Bi_2Sr_2CuO_{6+z}$	Bi_2O_3 + 2SrO + CuO	3	1110	
	$La_{1.8}Ca_{1.2}Cu_2O_{6+z}$	$La_{1.8}Ca_{1.2}Cu_2O_{6-z}$	40	1340	
	$Y_{0.9}Ca_{0.1}Ba_2Cu_4O_8$	Y_2O_3, CaO, BaO, CuO	20	1250	
	$La_2CuO_{4.08}$	La_2CuO_4	6000	1220	($KClO_4$)[b]

[a]Superscripts indicate the oxidation numbers of transition metals. [b]See Section 4.2.

3.2 Apparatus

Hydothermal vessels of the test-tube type can be used for the generation of high oxygen pressures below 800 MPa and 1100 K. A typical experimental system is illustrated in Figure 3(a), where oxygen is introduced from a reservoir to the reactor, by the aid of a compressor if necessary. The sample is contained in an open cell, not sealed. The degree of oxygen fill, temperature, and absorption, or release of oxygen by the sample determine the operational oxygen pressure. To avoid any explosive accident, special care should be taken. Any part of the system that the oxygen touches, the pipe line, valves, and so on should not be oiled or greased.

Illustrated in Figure 3(b) is an apparatus designed for hot isostatic pressing in an oxidizing atmosphere (O_2–HIP). The inside is filled with high pressure Ar–O_2 mixed gas. The maximum oxygen ratio is limited to 20% for safety and the maximum total gas pressure to 200 MPa. A large sample of 50 cm^3 can thus be treated at an oxygen partial pressure of 40 MPa and 1900 K. The heating element is a Pt–Rh alloy. Uniformity of oxygen pressure over the large sample volume, and the use of relatively high temperatures, accelerating reaction and crystallization, are the merits of this apparatus.

3.3 Materials

3.3.1 $SrFeO_3$

$SrFeO_3$ was the first phase found containing iron in its unusual high oxidation state of IV only.[18] By heating an appropriate mixture of $SrCO_3$ and α-Fe_2O_3 at 1300 K in air, one obtains $SrFeO_{3-z}$ with $z \approx 0.2$, not a single phase but a mixture of the $n = 8$ and 4 phases mentioned above.[15] For conversion to $SrFeO_3$ this mixture is treated at about 600 K at an oxygen pressure of 100 MPa.

3.3.2 CrO_2

CrO_2 is a metallic ferromagnet which can be used as a magnetic recording medium (*see* ***Magnetic Oxides*** and *Ferromagnetism*. Thermal decomposition of CrO_3 is the most common way to obtain this interesting material. The decomposition proceeds sequentially (as shown in equation 3), while at ambient atmosphere it is almost impossible to freeze the rapid process at CrO_2 before Cr_2O_3 forms. If CrO_3 is confined in a Morey's vessel, it transforms with oxygen pressure and temperature as illustrated in Figure 4.[19] It is to be noted that the oxygen in the vessel originates from CrO_3 itself. By choosing the amount of CrO_3 and temperature one can thus obtain pure CrO_2 rather easily.

$$CrO_3 \longrightarrow Cr_3O_8 \longrightarrow Cr_2O_5 \longrightarrow CrO_2 \longrightarrow Cr_2O_3 \quad (3)$$

3.3.3 $YBa_2Cu_3O_7$, $Y_2Ba_4Cu_7O_{15}$, $YBa_2Cu_4O_8$

In 1986, Bednorz and Müller announced the high T_c superconductivity of $La_{2-x}Ba_xCuO_4$ ($x \approx 0.15$) (*see High-temperature Superconductivity*). Since then a few tens of superconducting copper oxides have been discovered, and the highest T_c reaches 135 K, far beyond liquid nitrogen temperature. Among these, $YBa_2Cu_3O_7$ is the celebrated

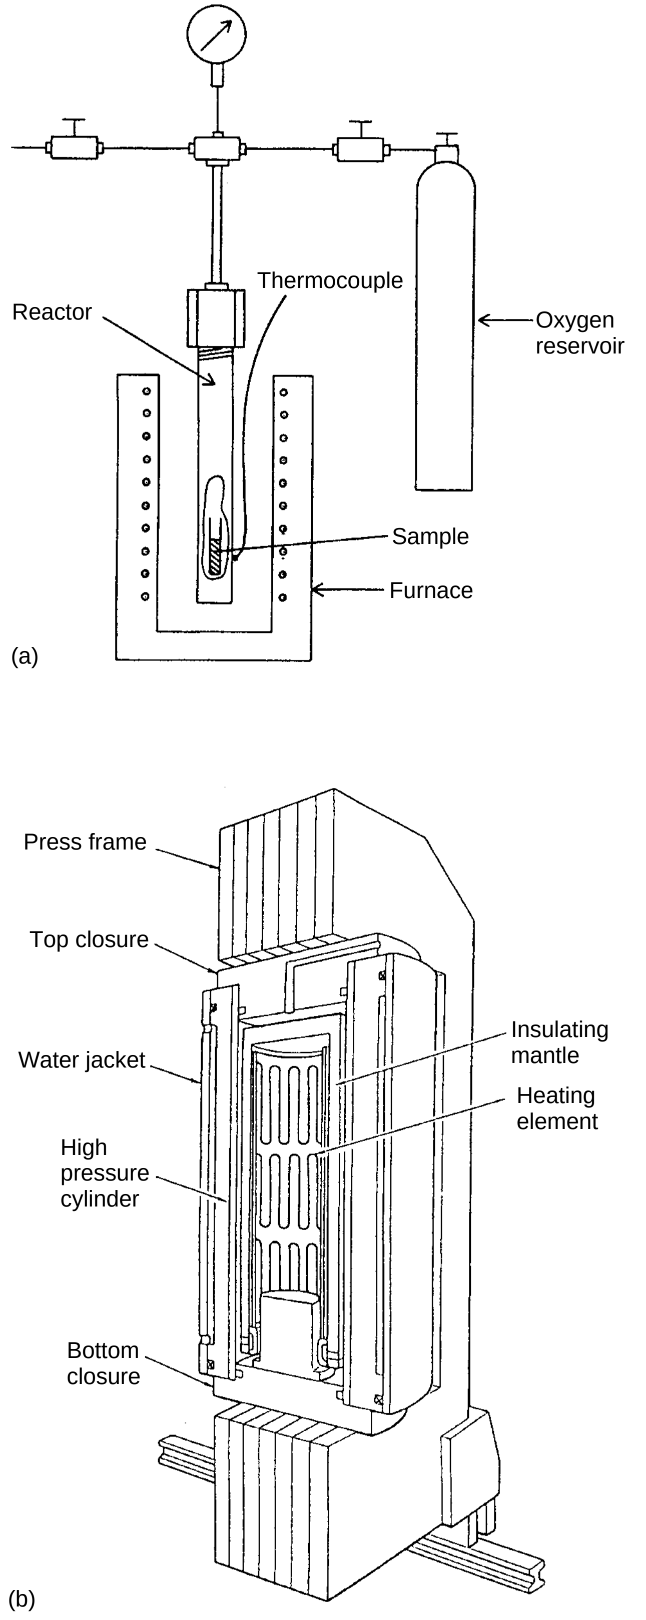

Figure 3 (a) Conventional high oxygen pressure system and (b) oxygen–hot isostatic pressing (O_2–HIP) apparatus. (Courtesy Kobe Steel, Ltd)

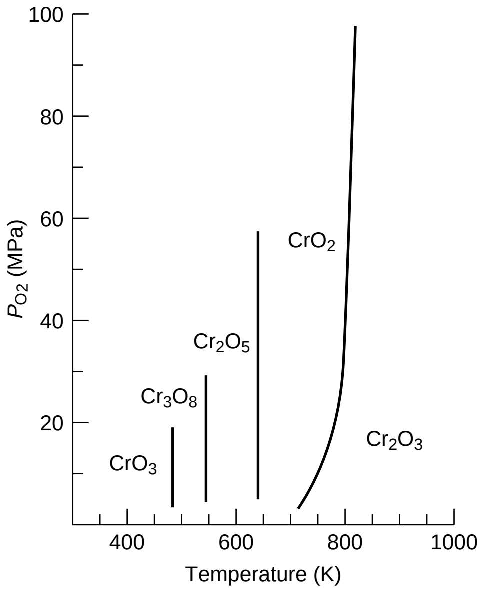

Figure 4 Formation of chromium oxides as a function of oxygen pressure and temperature. (Ref. 19. Reproduced by permission of Blackwell)

material whose T_c went beyond 77 K for the first time. In due course, two other superconductors were found in the Y–Ba–Cu–O system, $Y_2Ba_4Cu_7O_{15}$ and $YBa_2Cu_4O_8$. Their structures are compared in a schematical way in Figure 5(a). All these contain atomic sheets stacked sequentially as $/BaO/CuO_2/Y/CuO_2/BaO/$ in common, while those sandwiched between these are different. There are single CuO chains for $YBa_2Cu_3O_7$ and double CuO chains for $YBa_2Cu_4O_8 \cdot Y_2Ba_4Cu_7O_{15}$ contains both types of chains at a ratio of 1:1.

Karpinski *et al.*[20] studied the stability of these phases as a function of oxygen pressure and temperature, using a specially designed two-chamber autoclave.[21] The inner chamber contains the sample and oxygen gas, and it is placed in the outer chamber which is filled with argon. A relatively large amount of sample ($\sim$10 g) can be treated safely in oxygen pressures up to 300 MPa and 2000 K. The obtained phase relation is reproduced in Figure 5(b), where 123, 123.5, and 124 indicate the structure types in terms of the Y:Ba:Cu ratio. The 124 phase is stabilized over a wide oxygen pressure range, especially at high oxygen pressures. Discussion of the relative stability as a function of oxygen pressure and temperature is, however, difficult, because the 123 and 123.5 phases do not keep a constant oxygen content.

One important feature of $YBa_2Cu_4O_8$ is its thermal stability. $YBa_2Cu_3O_7$ begins to release oxygen at about 650 K, while $YBa_2Cu_4O_8$ loses little oxygen up to about 1050 K. Moreover, the T_c can be raised to 90 K by partially substituting Ca for Y, to give $Y_{0.9}Ca_{0.1}Ba_2Cu_4O_8$. These two points may be of importance for practical applications.

4 HIGH PRESSURE ABOVE 1 GPA

4.1 Outline

A variety of solid materials, including metals, semiconductors, molecular solids, and ionic compounds, show a remarkable deviation from the simple Hooke's law in the pressure dependence of volume at 1–10 GPa. The deviation is quite often a prelude to a pressure-induced transition to a denser structure.[22–24] For example, Fe metal changes its structure from cubic (α-phase) to hexagonal (ε-phase) at 11 GPa at room temperature, when ferromagnetism is lost. Ge and Si show a very sharp decrease in resistance by orders of magnitude at 9.2 GPa and 12 GPa, respectively. Their high pressure metallic phases assuming the β-Sn structure show superconductivity below $T_c = 5.4$ K and 6.7 K, respectively.[25] As is well-known, NaCl, KCl, and RbCl transform from the NaCl type to the CsCl type at 29.5, 1.9, and 0.53 GPa, respectively, when the coordination number increases from six to eight. After seeing these, it sounds quite reasonable to expect that pressure of the order of 10 GPa or even less would also strongly influence the phase formation: compounds stabilized at ambient pressures in a given composition system may be replaced by some others with new compositions and new structures.

As stated by Goodenough *et al.* in their review article,[26] high pressure effects from the viewpoint of inorganic synthesis can be divided into three groups.

1. High pressure transformations of compositions prepared at atmospheric pressure.
2. Composition formations requiring elevated pressures.
3. Syntheses greatly facilitated by pressure.

Some typical examples of the first two cases are listed in Tables 3 and 4, respectively. Since solid-state reactions and transformations are accelerated at elevated temperatures, high pressure synthesis almost automatically assumes treatments at elevated temperatures. Reaction times are usually short, 0.5–1 h. However, discrimination between these kinetic effects and thermodynamical stability should always be kept in mind.

The increase in density ranges widely in Table 3 from 1.3% for $CsMnCl_3$ (9L → 6L) to 46% for SiO_2 (coesite → rutile). The two successive transformations of SiO_2 provide an instructive comparison of the degrees of structural change. The density of coesite is higher than that of quartz by only 11%. In either phase, every Si atom is tetrahedrally coordinated by oxygen atoms and every O atom has two Si neighbors. The densification mainly results from a more compact packing of the oxygen arrays in coesite. On the other hand, in the rutile phase, SiO_6 octahedra form and every O atom is shared by three Si atoms. It is a general rule that transitions accompanied by relatively large increases in density involve changes in primary coordination. The coordination increase under high pressures has been thought to occur because large anions have higher compressibilities so that the radius ratio of cations and anions, r_c/r_a, increases (*see* ***Coordination Numbers & Geometries***).

Another remarkable tendency results from the electrostatic repulsion of cations of small sizes. Transition metal–anion octahedra are linked by face sharing in the 2L phases of $BaMnO_3$ and $CsNiF_3$, by corner sharing in the 3L (perovskite, see Section 4.3.2) phase of $CsMnCl_3$, and in a mixed way in $BaRuO_3$ (9L) and $CsMnCl_3$ (9L).[27,28] The sequential densification of 2L → 9L → 4L → 6L → 3L (perovskite)

Table 3 Transformations to denser structures

Low-pressure phase[a] (Structure type)	High-pressure phase[a] (Structure type)	Pressure (GPa)	Temperature (K)
^{III}C (graphite)	^{IV}C (diamond)	5.4	1667

$^{XII}Cs^{VI}MnCl_3$ (6L)	$^{XII}Cs^{VI}MnCl_3$ (3L, perovskite)	2.7	970

[a]Superscripts indicate the coordination numbers. [b]Nonhydrostatic pressure.

results from a successive increase in the proportion of corner sharing. Because the distance between cations in a pair of corner-sharing octahedra is greater than the distance between those in face-sharing octahedra, the above transitions have been thought to imply that small cations are redistributed under pressure in order to reduce the electrostatic repulsion. No doubt this tendency is enhanced if the cations have high oxidation numbers.

Roth and De Vries treated the 1:1 mixture of PbO and CrO_2 at various pressures and temperatures.[29] If the pressure is fixed at 5.5 GPa, the product varies as a function of temperature as $PbO + Cr^{IV}O_2$ (below about 1020 K), $PbCr^{IV}O_3$ (between 1020 K and 1370 K), and $Pb_2Cr^{VI}O_5 + Cr_2^{III}O_3 + PbO$ (above 1370 K). The temperature range for $PbCrO_3$ (cubic perovskite) becomes narrower as pressure is lowered, and one cannot obtain this compound below about 5 GPa. It is not straightforward to explain this kind of change in phase formation as a function of pressure, temperature, and composition: Goodenough *et al.*[26] have mentioned the specificity of the electronic state of Cr^{IV} ions in addition to the size effects in relation to the necessity of high pressure to stabilize these ions in the perovskite structure. Cr ions can assume a variety of oxidation states of I–VI, while octahedral site Cr^{III} and tetrahedral Cr^{VI} ions are by far the most common (*see* ***Chromium: Inorganic & Coordination Chemistry***). The Cr^{IV} ($3d^2$) state is special also in a sense that it is a transitional state between two normal states, the localized electron state and the itinerant electronic state (*see* ***Electronic Structure of Solids***). Application of high pressure at relatively low temperatures seems to be required to stabilize the relatively unstable Cr^{IV} ions in oxygen octahedra.

The materials described below include diamond, cubic BN (the hardest material next to diamond), $SrCuO_2$ (from which two types of superconductors have been derived by compositional modification), $MgSiO_3$ (a geologically interesting perovskite), and GeO_2 (amorphized under pressure at room temperature).

4.2 Apparatus[30]

Static and shock wave compressions are the two remarkably different ways for generating pressures above 1 GPa. Here, only apparatus generating static pressures of more general use will be considered. These are classified into several types, piston-cylinder, Bridgman anvil, belt, multi-anvil, and cascaded multi-anvil types. The available pressure range depends on the type and also on the volume of the sample chamber used. It is 2–4 GPa with the piston-cylinder type, 5–8 GPa with the belt type, 10–20 GPa with

Table 4 Syntheses requiring high pressures

Product			Preparation		
Structure type	Composition[a]	Starting material	Pressure (GPa)	Temperature (K)	Remarks
Rock salt	$Fe_{0.980}O$	$10Fe_{0.952}O + Fe$	18	1270

the Bridgman anvil type, 5–10 GPa with the multi-anvil type, and 10–30 GPa with the cascaded multi-anvil type. Anvils are made of sintered tungsten carbide (WC) superhard alloys. Recent attempts to use sintered diamond instead of WC are expected to extend these pressure ranges. While a sample of tens of cm^3 can be treated at 2 GPa with a conventional piston-cylinder type apparatus, it is limited to several mm^3 for compression at 30 GPa with a cascaded multi-anvil type apparatus.

The pressure generated in a sample chamber is first calibrated against the supplied load in reference to the pressure fixed points listed in Table 5. This pressure calibration is carried out at room temperature by detecting changes in the electric resistance of these standard materials as they transform to their denser phases. For accuracy of temperature and pressure at elevated temperatures, an additional calibration is done utilizing melting of gold, silver, copper, and various solid-state transitions.

The practical pressure strongly depends on details of the sample chamber assembly and also on the change in sample volume during treatment. In addition, a pressure gradient and a sheer stress are, more or less, inevitable. This kind of pressure quality largely depends on the type of apparatus and often affects the results of high pressure synthesis. The piston-cylinder, Bridgman anvil, and belt types generate rather a uniaxial pressure, while more isostatic compression can be generated with the multi-anvil types.

Table 5 Pressure fixed points

Material (Transition)	Pressure (GPa)	Temperature (K)
Bi (1–2)	2.55	273
Tl (2–3)	3.77 ± 0.03	298
Cs (2–3)	4.25 ± 0.1	298
Cs (3–4)	4.30 ± 0.1	298
Ba (1–2)	5.5 ± 0.2	298
Bi (5–6)	7.7 ± 0.3	298
Fe ($\alpha - \varepsilon$)	11.0–11.3	298
Ba (2–3)	11.8–12.2	298
ZnS	15.0 ± 0.5	298
GaP	22.0 ± 1.0	298
NaCl[a]	29–30	298

[a]Change in resistivity is not remarkable.

Sample heating up to about 2300 K is performed by applying an electric current through a cylindrical or sheet heater around the sample. The heater may be made of graphite, platinum, or lanthanum chromite. Thermal quenching is possible by turning off the current. The sample temperature decreases below 600 K in a few seconds and to ambient temperature in a minute, since the anvils and blocks act as massive heat sinks. Whether the high-pressure phase can be recovered after

decompression or not depends upon the kinetics. A flash heating technique has been introduced for further heating up to 10^4 K. In this case, however, the temperature is estimated indirectly from the electric power supply.

If the fugacity of a volatile component such as oxygen or water needs to be controlled, the sample is sealed with an appropriate buffer material in platinum, gold, molybdenum, or tantalum. If metal powder of Ti or Zr is used as the buffer material, it would work as a strong oxygen remover, while oxygen released at elevated temperatures from $KClO_4$ and CaO_2, and so on will fill the capsule. To prevent mixing and reaction of the sample with the buffer material, these are separated by a disk or layered powder of an appropriate inactive substance such as gold, platinum, ZrO_2, BN, and so on. $R_2Pd_2O_7$ and others prepared using 'special oxygen sources' listed in Table 2 were treated in this way.

The Bridgman anvil[31] is illustrated in Figure 6(a). Tapered anvils made of WC are supported by steel rings. The sample (or sample cell) is surrounded by a gasket made of pyrophyllite.

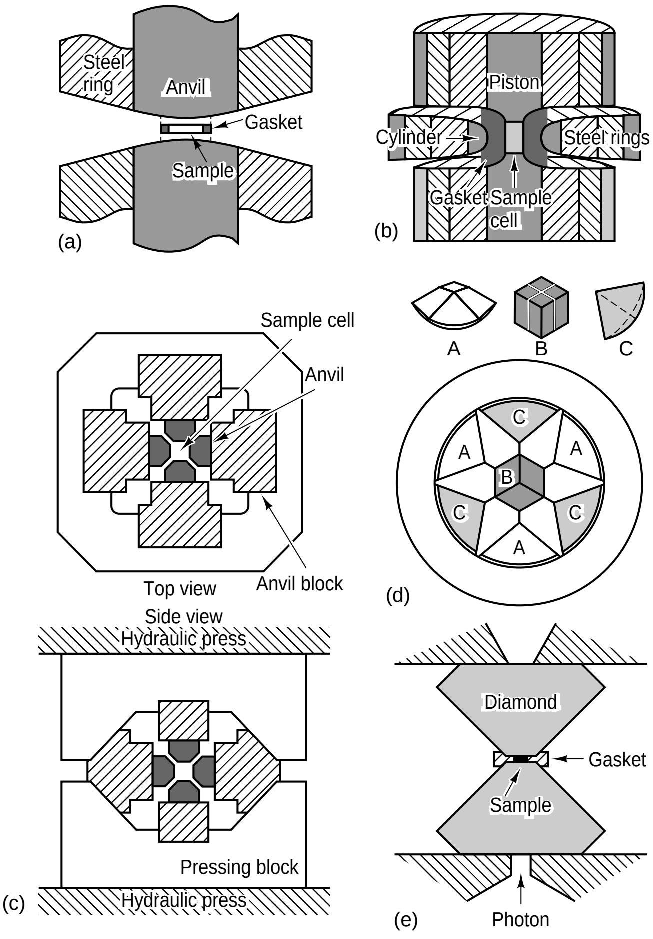

Figure 6 Essential parts of high pressure apparatus of (a) the Bridgman type, (b) the belt type, (c) the cubic anvil type, (d) the 6–8 split sphere anvil type, and (e) the diamond anvil type

By placing the assembly into a large conventional hydraulic press, pressures up to 20 GPa can be generated.

Figure 6(b) shows the essential part of a belt apparatus schematically. It consists of two tapered pistons and a cylinder. By using strongly tapered pistons, a large piston motion becomes possible without thinning out the pyrophyllite gasket. The pistons and the cylinder are made of WC, and these are supported by special steel rings. The first synthetic diamond was produced with this type of apparatus. This type is most widely used in both laboratories and industry, since the preparation of the sample cell assembly and the compressing operation are relatively easy.

Diagrams illustrating the core of a cubic anvil type apparatus are shown in Figure 6(c). The apparatus consists of six anvils, four of which are fixed horizontally to the anvil blocks. These blocks contact with the upper and lower pressing blocks, at the centers of which the other two anvils are fixed vertically. When a hydraulic press works, the lower pressing block advances upwards. Through the contact at an angle of 45° the pressing blocks move the horizontal anvil blocks centripetally. In this way, the six anvils synchronously compress the sample three dimensionally.

The '6–8' split-sphere device[32] is one of the cascaded multi-anvil type apparatus, the essential parts of which are illustrated in Figure 6(d). Six equal wedge-shaped anvils, A, each having a square surface in front and one corner cut off into a fan shape, are placed together with faceted blocks, C, in two hemispherical cylinders, as illustrated. When these hemispheres are put together face to face, a cubic space remains open at the center of the sphere. The space is to be filled with eight, equal small cubes, B. If the inmost corner of each small cube is cut into a regular triangle, a small octahedral void forms. By placing a sample covered with a pressure medium in the void, compression along the four axes perpendicular to the triangular faces of the octahedron can be done. The more axes along which compression is carried out, the more isotropic is the generated pressure. MgO and pyrophyllite are the medium materials generally used. This sophisticated type of high pressure apparatus has mainly been used by scientists studying the Earth's interior.

To be referred to next is the most modern diamond anvil type, generating pressures of order of 10–100 GPa.[33] The cell illustrated in Figure 6(e) consists of two gem diamonds with optically flat surfaces, between which a sample confined in a drilled hole of a thin metal gasket is sandwiched. To attain isostatic compression an inert gas or an organic liquid, like a 4:1 volume mixture of methanol and ethanol, is contained with the sample. The generated pressure is measured directly from the pressure shift of the fluorescence line of ruby powder mixed with the sample. Temperatures to 5000 K can be obtained by laser heating. The quantity of sample confined in a typically 0.1-mm-wide hole is extremely small, just a few microcrystals. At present, research has focused on in situ observations using X-ray and other optical methods, rather

than synthesis. Diamond acts not only as the anvils but also as an optical window.

4.3 Materials

4.3.1 Diamond[5]

Diamond, the hardest substance known to man, is the only material that is produced using high pressure on a commercial scale. The most probable pressure–temperature phase diagram of carbon is shown in Figure 7(a) (*see* ***Carbon: Inorganic Chemistry***).[34] Laborious studies over years by many investigators were required to establish the diagram, though some details still remain uncertain. Diamond is actually a high pressure form of carbon and exists metastably at ambient pressure. It is a considerable kinetic barrier that prevents the conversion of hard and sparkling gem diamonds to flaky and darkish graphite. On the other hand, because of this kinetic barrier, early investigators were unfortunately unable to synthesize diamond, even though they managed to achieve the pressure–temperature conditions for thermodynamic stabilization of diamond. A series of technological innovations were required before controlled diamond crystallization became possible.[35] It is also true that the demand for 'diamond made by men' accelerated the development of high pressure technology.

It is evident from the phase diagram that diamond may be obtained in a very wide pressure–temperature range, thus allowing several synthesizing methods to work in various regions. Those mainly applied are conversion of graphite to diamond by a flux method, direct conversion by shock wave compression, and direct conversion by static compression. Synthetic diamond is mostly produced by the flux method, which will be outlined below.

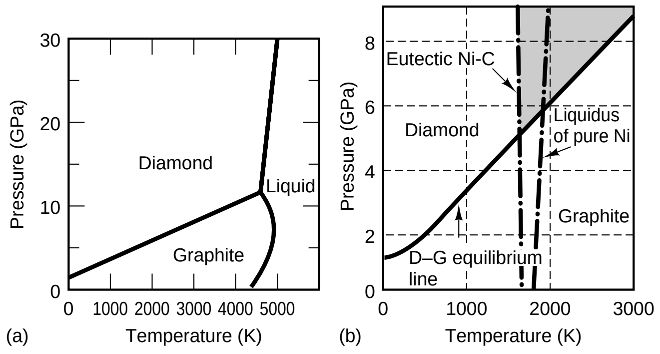

Figure 7 (a) Phase diagram of carbon. (Reproduced by permission of Elsevier from F.P. Bundy, *Physica*, 1989, **A156**, 169) (b) A portion of the phase diagram including the melting line of pure Ni, the Ni–graphite eutectic, and the diamond synthesis zone. (Reproduced by permission of Decker from F.P. Bundy.[5])

Flux Method. Certain kinds of metals and alloys, when molten in a high-pressure cell, dissolve graphite and precipitate diamond. This conversion process proceeds under much milder temperature–pressure conditions than required for the direct conversion. The group 8–10 metals Fe, Ni, and Co, and also Fe–Ni, Fe–Ni–Co, Ni–Mn, and some other alloys, have been used traditionally for this purpose. Figure 7(b) contains the melting line of pure Ni and the Ni–graphite eutectic superimposed on the phase diagram of carbon. In the shaded region, the Ni-mediated graphite–diamond conversion proceeds as a result of the difference in solubility between graphite and diamond in Ni. For example, at 9 GPa and 1800 K, molten nickel can dissolve about 4% wt of carbon from metastable graphite, while the solubility of carbon from diamond is limited to 3.6% wt. Thus carbon corresponding in amount to the solubility difference of 0.4% wt crystallizes out as diamond, because diamond is the stable form under the given conditions. Diamond thus formed contains a small amount of Ni impurity, of about 10^{-4} at%. The metals and alloys that mediate the transformation as above are often referred to as catalyst/solvent. Interestingly, elemental phosphorus and also certain inorganic compounds such as $CaCO_3$, $Ca(OH)_2$, $MgSO_4$, and so on have recently been found to catalyze the transformation, probably in their molten state.[36]

A typical arrangement of the reactants in a pyrophyllite cell is illustrated in Figure 8(a). The reaction zone consists of alternately stacked cylinders of graphite and nickel. After compression to 5.4 GPa, the temperature is raised to 1667 K to melt the nickel plates and to stabilize diamond coming out. Molten nickel dissolves graphite and precipitates diamond at the interface initially. In a few minutes, graphite wholly transforms to diamond as the molten nickel moves through the graphite disks from both ends toward the center. Crystals thus obtained measure from a few dozen μm to 0.5–1.0 mm. The crystal habit largely depends on temperature. At relatively low temperatures the (100) faces tend to develop preferentially, while the (111) faces develop at high temperatures.

For the growth of large and clear diamond crystals of desired morphologies, such as shown in Figure 8(b), it is necessary to control both the nucleation and the growth carefully.[37] A reaction chamber suitable for this is illustrated in Figure 8(c). A vertical temperature gradient of the order of $10\,K\,mm^{-1}$ is given to the chamber to take advantage of the fact that the solubility of carbon in the flux increases with temperature. From the upper hot zone, carbon is transported through the molten flux metal toward the seed crystal fixed at the bottom of the lower cool zone. The carbon source in the hot zone may either be graphite or diamond. Large single crystals of about 1 cm in size can be grown. This process is essentially the same as the hydrothermal growth of α-SiO_2 crystals described in Section 2.3: molten flux here corresponds to hot water.

Sintered Diamond. A natural polycrystalline form of diamond called *carbonado* is known. It is much tougher

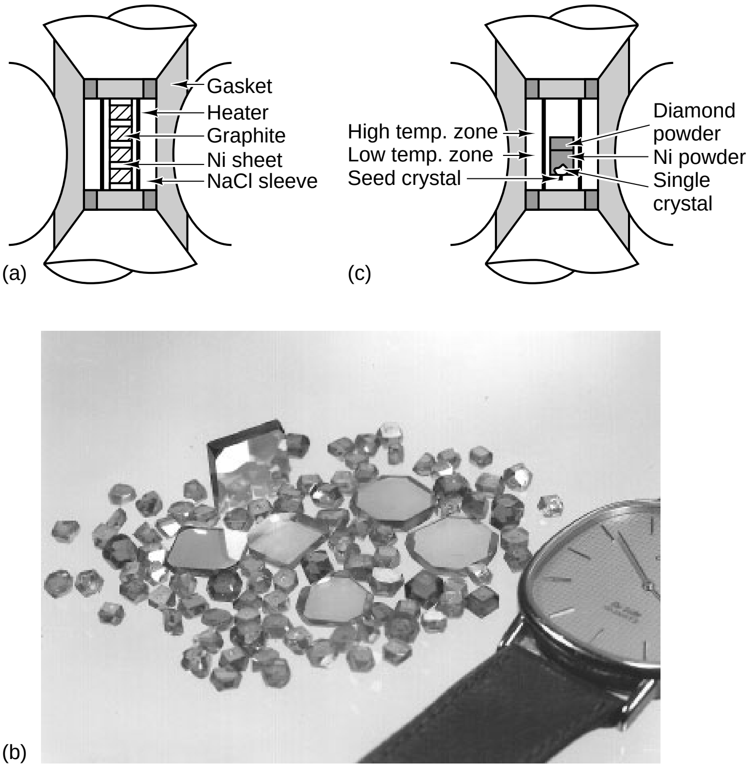

Figure 8 (a) Belt type apparatus containing a sample cell for graphite to diamond conversion. (b) Single crystals of diamond. (Courtesy of Sumitomo Electric Industry, Ltd). (c) A typical arrangement of reactants for the crystal growth

than single crystals. Small, randomly oriented microcrystals are tightly compacted, so that the cleavage brittleness of single crystals is overcome. However, carbonado that looks black is not pure diamond.

A close approach to carbonado is an as-grown compact of synthetic grains cemented with a solvent metal. To increase direct intergrain diamond–diamond bonding, fairly high pressures and temperatures and/or a special additive that promotes carbon diffusion and then remains as a binder are used. Although several kinds of thus sintered diamond have been produced on a commercial scale, their performance is not so high as that of natural carbonado. Demand for man-made superhard and highly tough materials like carbonado is keen.

4.3.2 *Cubic Boron Nitride*[38,39]

Boron nitride shows polymorphism which is parallel to that of carbon (*see* ***Boron–Nitrogen Compounds***). The hexagonal low-pressure phase, *h*-BN, crystallizes in a graphite-like structure where boron and nitrogen are arranged in an ordered way so that these are threefold coordinated with each other. Under high pressures and temperatures it transforms into the cubic phase assuming the zinc blende structure, *c*-BN, where boron and nitrogen are tetrahedrally coordinated with each other. This is the same type of structure as diamond. Both *h*- and *c*-BN are synthetic materials; graphite and diamond can be found in nature.

c-BN is the hardest material following diamond, and its thermal conductivity is very high, as it is for diamond. The merits of *c*-BN in comparison with diamond from the viewpoint of applications as a grinding medium and use in cutting tools are the low reactivity with the iron group metals and the strong thermal resistance in oxidizing atmosphere.

c-BN is prepared from *h*-BN mainly by a flux method, as diamond is from graphite. Direct conversion is also possible. A wide variety of materials can be used as the flux, including alkaline and alkaline-earth metals, their nitrides and fluoronitrides, ammonium borate, and so on. If reactive metals like Li and Mg are to be used, these are heat-treated beforehand with *h*-BN in a stream of dry nitrogen. Disks of the flux material and *h*-BN are stacked alternately, as illustrated in Figure 8(a) for the case of diamond, and the assemblage is treated at 6 GPa and 1750 K, typically. The presence of oxygen should be carefully avoided. The flux is removed chemically by using hydrochloric acid or other appropriate solvents. Transparent yellowish single crystals faceted mainly with the (111) planes can be grown up to about 2 mm.

4.3.3 *SrCuO*$_2$

All the copper oxide superconductors ever known contain a common structural unit: the two-dimensional CuO_2 sheet

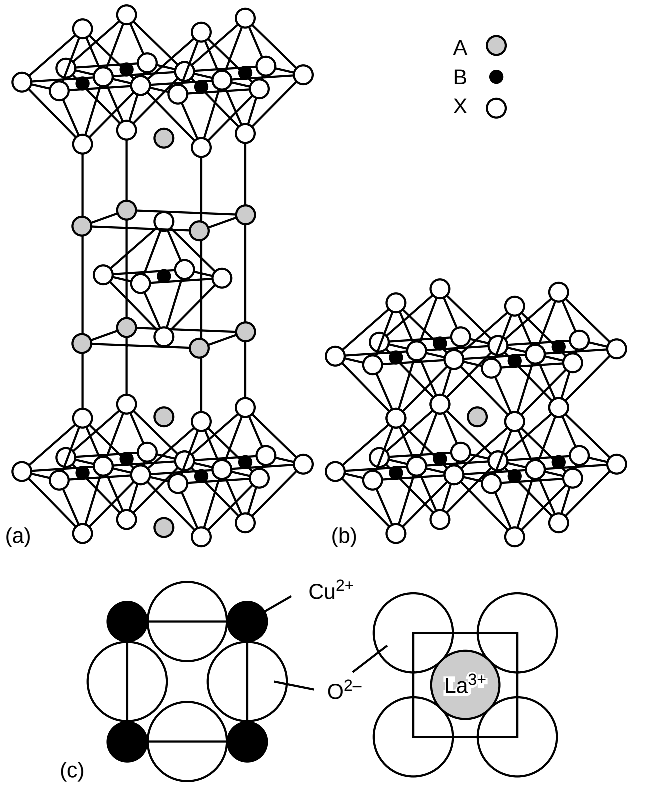

Figure 9 (a) K_2NiF_4 structure, (b) perovskite structure, and (c) comparison of the specific area of the free $(CuO_2)^{2-}$ and $(LaO)^+$ sheets

(see Figure 5(a)). $La_{2-x}Ba_xCuO_4$ ($x \approx 0.15$), the first high T_c superconductor, crystallizes in the K_2NiF_4 structure.[26–28] In the ideal tetragonal structure illustrated in Figure 9(a), regular NiF_6 octahedra share corners with each other along the *a* and *b* axes, a two-dimensional Ni–F–Ni bond network thus being formed. However, La_2CuO_4 and the Ba-substituted superconductor are subject to an orthorhombic distortion, making the CuO_2 sheet puckered. Moreover, the CuO_6 octahedra are considerably elongated along the *c* axis as a result of the Jahn–Teller effect of the Cu^{II} ions (*see* ***Structure & Property Maps for Inorganic Solids*** and *Jahn–Teller Effect*).

A regular three-dimensional cation–anion–cation network is developed in the ideal perovskite structure (illustrated in Figure 9(b)).[26–28] Perovskite compounds are often formulated as ABX_3, where A stands for a relatively large cation like Sr^{2+}, B a small cation like Ti^{4+}, and X an anion like O^{2-}. $SrTiO_3$ is the representative perovskite oxide. Along this line, K_2NiF_4 type compounds may be formulated as A_2BX_4. These two structures can be easily interconverted. To derive the latter structure from the former requires the replacement of the single AX sheets by the double $(AX)_2$ sheets and a shift of the alternate BX_2 sheets along the direction.

In Figure 9(c) the ideal specific areas for flat LaO and CuO_2 sheets, calculated from Shannon's ionic radii, are compared.[40] If the regular K_2NiF_4 structure is to be assumed for La_2CuO_4, these sheets should be stacked along the *c* axis without any distortion. In reality, however, these sheets match each other very poorly. The puckering of the CuO_2 sheet may thus be considered to be a strategy to improve the matching by making the Cu–Cu distance shorter. Generally speaking, it is quite interesting to learn from complex compounds containing two or more different kinds of cations (or anions) how they manage to minimize the free energy by modifying bond angles, bond distances, and oxidation states from the ideal, unstrained ones.

For the perovskite and related structures, including K_2NiF_4, the 'tolerance factor', t, measures the degree of bond length mismatch. Denoting the radius of the ith ion as r_i, the tolerance factor is given by equation (4). If the matching is perfect, the value is equal to unity. For K_2NiF_4 and $SrTiO_3$, $t = 1.00$ and 1.05, respectively, and their structures are not distorted at room temperature. On the other hand, a small value of $t = 0.87$ for La_2CuO_4 leads to an orthorhombic distortion.

$$t = \frac{r_A + r_X}{2^{1/2}(r_B + r_X)} \qquad (4)$$

One important thing to be kept in mind here is that the ionic radii are derived from the cation–anion bond distances measured experimentally at room temperature, not at the temperatures where the formation reactions take place. At present, there is no way to estimate exactly the tolerance factor at high (or low) temperatures. So, whether one can obtain a perovskite or related material from a given A–B–X combination or not depends mostly upon experimental tests.

Generally, cation–anion bonding is soft for large cations and anions. In other words, the coefficients of thermal expansion and compressibility are both larger for the A–X bond than for the B–X bond. Thus, not only temperature but also pressure should be considered to affect the bond length matching to be estimated in terms of tolerance factor.

$SrCuO_2$ compressed at 6 GPa and 1200 K crystallizes in an oxygen-deficient perovskite structure in which all the oxide ions on the vertical axes of the unit cell illustrated in Figure 9(b) are lost.[41] This is the simplest structure containing the two-dimensional CuO_2 sheet, the superconducting structural unit. $LaNiO_2$ was the first compound found to crystallize in this structure, and $Ca_{0.84}Sr_{0.16}CuO_2$ followed.[42] This structure is often called an 'infinite layer' structure. If the alkaline earth–copper–oxygen system is studied at atmospheric pressure, this structure is stabilized only for a narrow composition range of $Ca_{1-x}Sr_xCuO_2$ with $x \approx 0.1$ and only in a narrow temperature range near the melting point. However, at 6 GPa and 1200 K the composition range can be extended in the large alkaline-earth ion side up to $Sr_{2/3}Ba_{1/3}CuO_2$, passing $SrCuO_2$. It should be noted here that $SrCuO_2$ prepared at atmospheric pressure crystallizes in a quite different type of structure. The high-pressure phase is denser by 8%, as estimated from the lattice constants measured at room temperature.

As the average counter cation size increases, the unit cell volume increases as a matter of course. However, the

expansion is quite anisotropic. The c axis length, which is equal to the inter-CuO_2 sheet distance, increases three times as fast as the a axis length, the Cu–O–Cu distance. The oxygen polyhedron trapping the counter cations should preferably be cubic, because alkaline-earth ions have spherical electronic configurations. However, in reality they become more and more stretched along the c axis. This is because the Cu–O bond is so stiff that its length is almost saturated for $SrCuO_2$.

One way to relax the stress caused by the substitution of large alkaline-earth ions is to inject excess electrons into the CuO_2 sheets. The Cu–O bond accepting the excess electron into its lowest incompletely filled antibonding orbital becomes weak and long. The injection can be done by substituting trivalent rare earth ions at the counter cation site so that $A_{1-x}R_xCuO_2$ (R = rare-earth elements, La to Gd) may form. Another way is to partially remove the too large counter cations so that $A_{1-x}CuO_2$ may form. In this case, the CuO_2 sheet is oxidized, in contrast to the reduction in $A_{1-x}R_xCuO_2$.

It is known that high T_c superconductivity occurs if the CuO_2 sheets are properly oxidized or reduced, as first recognized from $La_{2-x}Ba_xCuO_4$ ($x \approx 0.15$) and $Nd_{2-x}Ce_xCuO_4$ ($x \approx 0.15$), respectively. It is clear that the Ba^{II}-for-La^{III} substitution and the Ce^{IV}-for-Nd^{III} substitution work differently on the CuO_2 sheets, and from the sign of the carriers created in the CuO_2 sheets these superconductors are classified into p-type and n-type, respectively. $(Ca_{0.7}Sr_{0.3})_{1-x}CuO_2$ ($x \leq 0.1$) is a p-type superconductor with a T_c of 110 K,[43] while $Sr_{1-x}R_xCuO_2$ (R = La to Gd, $x \approx 0.1$) is an n-type superconductor with a T_c of 43 K.[44]

All the efforts to make $Ca_{0.84}Sr_{0.16}CuO_2$ superconducting have failed. Injection of carriers into the CuO_2 sheets seems to go well when these are subject to an instability caused by the counter part. Extension of the composition range of a given structure using high pressure sounds quite meaningful in this sense.

4.3.4 *(Mg,Fe)SiO$_3$ (Perovskite)*[1,45]

A silicate perovskite, $Mg_{1-x}Fe_xSiO_3$ ($x \geq 0.8$), is likely to be the most abundant single phase of the Earth. It is confined, however, to the lower mantle, extending from about 670 km to 2900 km in depth, where pressure and temperature both increase from 26 GPa and 2000 K to 140 GPa and 3000 K with increasing depth. Numerous phase equilibrium studies of the MgO–FeO–SiO_2 system and others have revealed that all the major minerals of the upper mantle transform to dense phase assemblages dominated by the silicate perovskite in the pressure–temperature range appropriate to the lower mantle.

From seismic evidence, the density and elastic properties of the Earth are known to change markedly at the boundary between the mid-mantle (the transition zone) and the lower mantle. The ‘670-km discontinuity’ has been attributed to a pressure-induced transformation of $(Mg,Fe)_2SiO_4$ to a fine mixture of the above silicate perovskite and magnesio-wüstite, (Mg,Fe)O (equation 5). Iron is likely to be preferentially condensed in the wüstite phase. It is not difficult to prepare magnesio-wüstite at atmospheric pressure. The above transformation includes coordination changes. The spinel structure of $(Mg,Fe)_2SiO_4$ provides Mg and Fe with sixfold octahedral coordination and Si with fourfold tetrahedral coordination, while after the transformation the coordinations are sixfold or more.

$$(\mathrm{Mg, Fe})_2\mathrm{SiO}_4 \longrightarrow (\mathrm{Mg, Fe})\mathrm{SiO}_3 + (\mathrm{Mg, Fe})\mathrm{O} \qquad (5)$$

It is well-established that pure and iron-substituted $MgSiO_3$, quenched to ambient pressure and temperature, exhibit a distortion to the so-called $GdFeO_3$ type structure in which the Mg and Fe ions are only eightfold coordinated, not twelvefold coordinated as in the ideal perovskite structure. However, their structures under the lower-mantle conditions still remain uncertain, though some experimental evidence suggesting transitions toward the ideal structure at elevated pressures and temperatures has been reported.

The perovskite phase of $MgSiO_3$ does not form at atmospheric pressure, because both Mg^{II} and Si^{IV} ions are far too small to meet the qualifications for the perfect perovskite of r_A:r_B:r_X = 1:0.41:1. It is an accelerated contraction of the oxide ions that makes the Mg–Si–O combination tolerated under high pressures. The $GdFeO_3$ type structure is the most frequently encountered type of distortion for compositions having relatively small t values of about 0.9. This structure can be derived from the ideal one by rotating BX_6 octahedra around the three crystal axes appropriately.[46] Rotate one octahedron around the a, b, and c axes by angles $+\alpha$, $+\alpha$, $+\gamma$, respectively. Next, rotate its edge-sharing neighbor on the a axis by $-\alpha$, $-\alpha$, $-\gamma$, the neighbor on the b axis also by the same degree, $-\alpha$, $-\alpha$, $-\gamma$, and finally the third neighbor on the c axis by $-\alpha$, $-\alpha$, $+\gamma$. By repeating the same process, one eventually obtains the $GdFeO_3$ structure. The addition of slight atomic shifts is quite common. The lattice constants of the resulting orthorhombic structure (space group *Pbnm*) are related to the cubic lattice constant, a_c, as $a_0 \approx b_0 \approx 2^{1/2}a_c$ and $c_0 \approx 2a_c$. The degree of distortion depends on the t value. Generally, the BX_6 octahedra remain relatively regular, while the oxygen polyhedra around the A ions are remarkably distorted so that the coordination number is reduced to eight, as in $GdFeO_3$ and quenched $MgSiO_3$, and nine, as in $LaFeO_3$.

Exactly as for $MgSiO_3$, high pressure stabilizes a variety of compositions in the compact perovskite structure. Competition with other structures, such as ilmenite, defect pyrochlore, and various polytypes of perovskite, as a function of ionic radius, pressure, and temperature has been reviewed.[26,28]

4.3.5 *Pressure-Induced Amorphization: Amorphous GeO$_2$*

Glass obtained by quenching a molten liquid to room temperature is an amorphous metastable state,

and the loose atomic packing leads to a low density (*see* ***Noncrystalline Solids***). Since we have learned that high pressure stabilizes high density forms of materials, pressure-induced amorphization might sound strange. GeO_2, SiO_2, $Ca(OH)_2$, Fe_2SiO_4, and some other materials have, in fact, been found to vitrify if they are compressed at low temperatures, low enough to kinetically suppress the formation of the crystalline phase that is thermodynamically stable under the pressure. Pressure-induced amorphization is a transition to a metastable, highly dense amorphous phase. If it were possible to quench it to ambient pressure, one would obtain another kind of glass.

Pressure-induced amorphization was reported for the first time in 1984 for hexagonal ice.[47] Since then, a number of fundamental questions have been raised and are still now under investigation. Here, typical experimental data for GeO_2 will be outlined in brief.[48]

At ambient pressure, GeO_2 is stabilized in the rutile form below about 1300 K, while at higher temperatures it transforms to the α-quartz type. It is to be noted that the coordination polyhedron is octahedral in the former and tetrahedral in the latter. The specific density at ambient pressure and temperature is very different, 6.27 g cm^{-3} for rutile but only 4.28 g cm^{-3} for α-quartz. Because conversion from α-quartz to rutile is kinetically very slow even at 1273 K, it is quite easy to quench α-quartz GeO_2 to room temperature.

Effects of pressure upon the α-quartz form are strongly temperature dependent. As can be seen in Figure 10, conversion to rutile is accelerated if both pressure and temperature are elevated slightly: the (110) peak from rutile appears even at 0.1 GPa at 358 K. In contrast, at 335 K it is absent up to 20 GPa. Amorphization occurs at 7 GPa, as confirmed by complementary methods including in situ

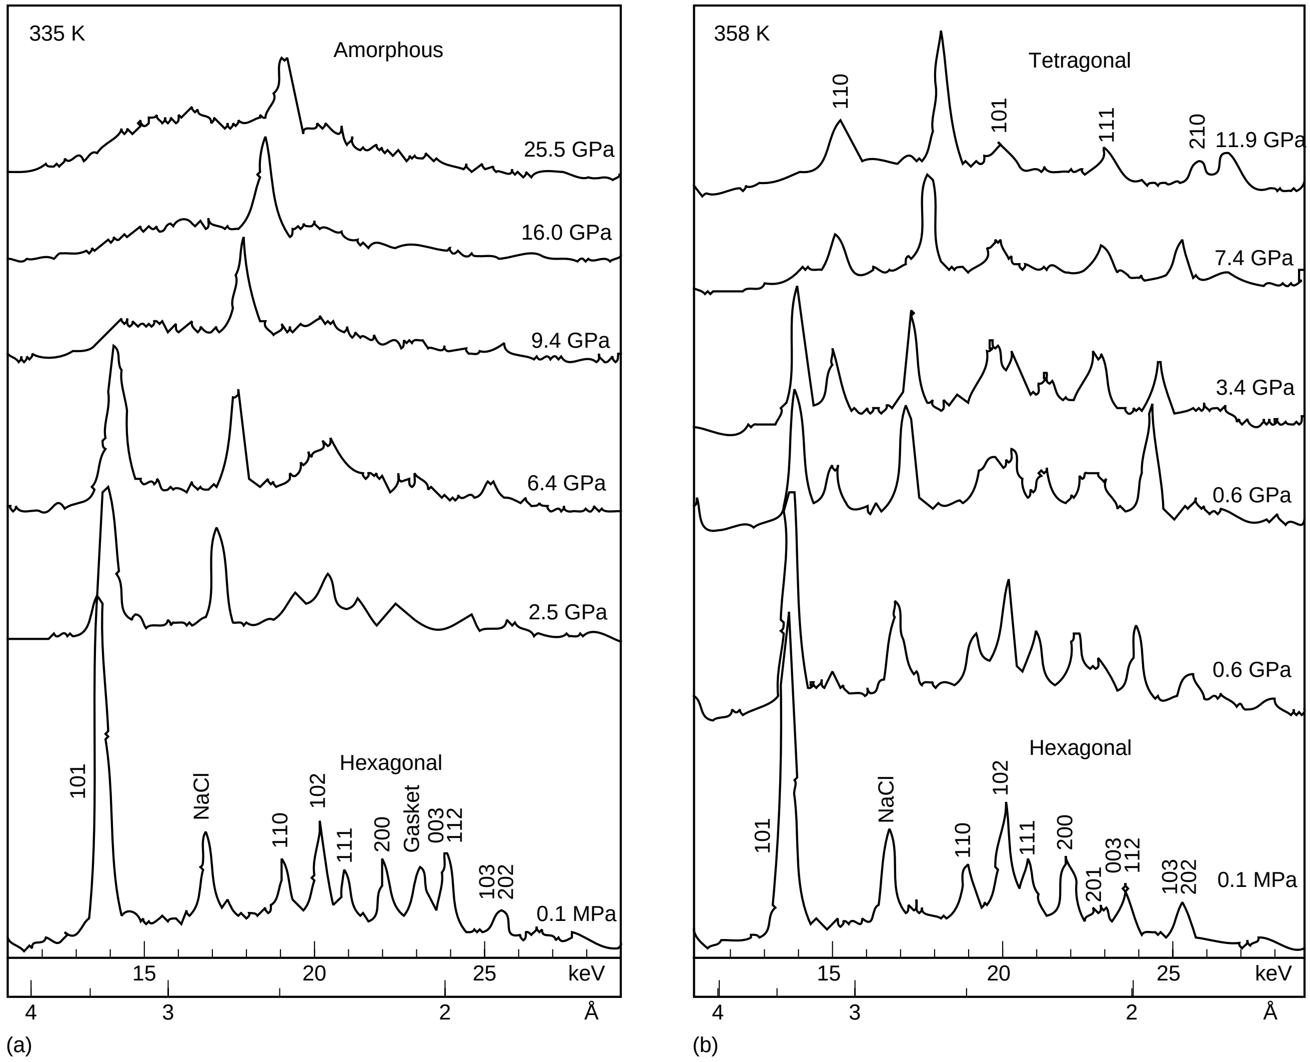

Figure 10 X-ray diffraction patterns of α-SiO_2 under pressure at (a) 335 K and (b) 358 K. (Ref. 48. Reproduced by permission of American Geophysical Union)

Raman scattering and high-resolution electron microscopy on a decompressed specimen.

The amorphization is preceded by some disruption of the α-quartz lattice at about 6 GPa. A gradual fourfold to sixfold coordination change occurs as the pressure increases, and in a specimen decompressed from 20 GPa nucleation of the rutile form was found in the amorphous matrix. An amorphous sample decompressed from 13 GPa has a specific density of 4.5 g cm^{-3}, which is considerably higher than that of α-quartz mentioned above.

The pressure-induced amorphous phase should be discriminated from thermally vitrified glass by the difference in density and also by different behavior under pressure: compression of the glass up to 60 GPa does not yield rutile, and germanium completely reverts to tetrahedral coordination on decompression.

The physical and chemical properties of these new pressure-induced amorphous phases may be quite interesting.

Dihydrogen complex: complex of H_2 that retains the H–H bond

Abbreviations

tacn = 1,4,7-tetraazacyclononane.

1 INTRODUCTION

As the simplest ligand, H or hydride has a special place in coordination chemistry. In spite of its simplicity, it shows a remarkable variation in structure and reactivity. With $H_2Fe(CO)_4$[1] and $HCo(CO)_4$,[2] Hieber was the first to describe transition metal hydrides in the 1930s, but his formulations were not always regarded as correct; for example, his iron hydride was wrongly reformulated as $Fe(COH)_2(CO)_2$ by Sidgwick (1950). In the absence of further examples, they remained chemical curiosities for many decades. Only with the discovery of several series of hydride complexes in the mid-1950s did the existence of the M–H bond as a normal covalent bond become widely accepted. The neutron diffraction (*see* ***Diffraction Methods in Inorganic Chemistry***) study of $[ReH_9]^{2-}$ by Ginsberg[3] (1960), the first on a hydride complex, was very influential. By the mid-1960s, it had become clear that metal hydrides were key intermediates in important metal-catalyzed reactions, such as alkene hydrogenation (*see* ***Hydrogenation & Isomerization of Alkenes***).

In the first description of a dihydrogen complex (1984), $[W(H_2)(CO)_3(PCy_3)_2]$, Kubas[4] showed by neutron diffraction that H_2 is coordinated to the metal as an intact molecule. This opened a new phase in hydride chemistry, and hundreds of examples of this phenomenon are now recognized, including some pre-1984 examples that lay unrecognized in the literature (*see* ***Dihydrogen Complexes & Related Sigma Complexes***). The existence of [Ni,Fe] and [Fe] *Hydrogenase*,[5] in which H_2 is believed to bind Ni and Fe respectively, suggests that hydride chemistry also has biological relevance. Useful reviews have appeared on the chemistry of polyhydrides,[6] and dihydrogen complexes.[7,8] In addition, two recent monographs are largely devoted to the subject.[9] Some hydrides, such as MnH_2 and CoH, are only known in the gas phase; others, such as $FeTiH_2$, occur only in the solid phase. Solid-state hydrides are discussed elsewhere (*see* ***Hydrides: Solid State Transition Metal Complexes***).

2 STRUCTURE[6–9] AND BONDING

2.1 Terminal Hydrides

The terminal hydride (**1**) is the most common type. In these species, the M–H distance is close to the sum of the *Covalent Radii*. Neutron diffraction gives this distance reliably, but X-ray methods, because they detect electron density and not the nuclear positions, underestimate the M–H distance by about 0.1 Å. It is not uncommon for the H to escape detection entirely by X-ray methods as a result of the proximity of the metal, always a strong diffractor of X rays. Typical M–H distances are 1.45 to 1.6 Å for first-row elements, 1.6 to 1.7 Å for the second row, and 1.65 to 1.75 Å for the third row; actinides have M–H distances near 2 Å. Early transition metals have M–H distances about 0.1 Å longer than do late metals. Electron diffraction methods have been used for volatile carbonyl hydrides such as $HMn(CO)_5$, $HCo(CO)_4$, and $H_2Fe(CO)_4$; for the Mn compound, the e-diffraction and n-diffraction Mn–H bond lengths are in good agreement.

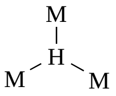
Because of the small size of the hydride ligand and its tendency to give weak attractive interactions with neighboring hydrides, it is often found in high coordination compounds such as $[ReH_9]^{2-}$, ReH_7L_2, $CpReH_5$, WH_6L_3, and MoH_4L_4 (L = tertiary phosphine), in which the typical coordination geometries (*see* ***Coordination Numbers & Geometries***) are nine coordinate, *Tricapped Trigonal Prism* (TTP); eight coordinate, *Dodecahedral*; seven coordinate, *Pentagonal Bipyramid*.

2.2 Bridging Hydrides

The bridging hydride (**2**) is also very common. Normally, the M–H distances are 0.15 to 0.2 Å longer in this situation,

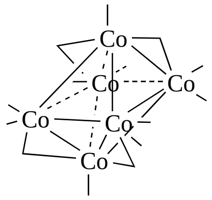
(**1**)

(**2**)



(**3**)

(**5**)



(**4**)

(M— = M—CO)

but the M–H–M system is usually bent, not linear. One, two, and three bridges are common, and there are a few examples of the M(μ^4-H)M system. Triple (**3**) and higher-order bridging hydrides are found in cluster compounds, the highest coordination number recorded to date being six in $[Co_6(\mu^6\text{-H})(CO)_{15}]^-$ (**4**).

Dihydrogen complexes (**5**)[10,11] such as $[Cr(H_2)(CO)_5]$ are covered in a separate article. Dihydrogen bonding, the tendency of an MH bond to act as proton acceptor in an unconventional hydrogen bond with an OH or NH group, is also covered in a separate article. (*see Hydrogen Bonding*).[6d]

2.3 Stereochemical Activity

Hydrides can be more or less stereochemically active. For example, in $HPtCl(PR_3)_2$, the T-shaped geometry of the heavy ligands around Pt shows that the H is fully stereochemically active. On the other hand, in $HCo(CO)_4$, the CO groups are close to tetrahedral and the H occupies a face-capping position. The difference seems to be controlled by the charge on the H. For example, in the first case the hydride is truly hydride-like and the metal has the T-shaped geometry appropriate for a $[PtCl(PR_3)_2]^+$ group, while in $HCo(CO)_4$, the hydride is very protonic and the metal has the tetrahedral geometry appropriate to a $[Co(CO)_4]^-$ group.[12]

2.4 Ligand Field Strength

The hydride ligand is one of the highest-field ligands in terms of *Crystal Field Theory* and this, together with its small size, very often makes hydrides 18e and diamagnetic. Formulations that do not conform to the 18e rule (*see Effective Atomic Number Rule*) have frequently been proposed, but they often turn out to be erroneous. As a soft ligand (*see* ***Hard & Soft Acids and Bases***), H is often found with CO, Cp, or PR_3 as a co-ligand, but a few examples are known where such hard ligands as oxo, amine, and fluoride coexist with hydride in the same complex. Polyhydrides without Cp or PR_3 as co-ligands, such as $ReH_5\{HB(pz)_3\}$, are still very rare. Hydride chemistry provides something of a bridge between coordination and organometallic chemistry in that it is a noncarbon ligand that imparts properties to the complex similar to those found for organometallic species.

Hydride is also one of the highest *Trans Effect* and *Trans Influence* ligands. Structures of hydride complexes often show rather long M–L bond lengths trans to H. H_2 is a low trans effect ligand, however, and a trans H–M–(H_2) arrangement is found in many nonclassical hydrides.

3 SPECTROSCOPY

3.1 NMR

The NMR method is extremely useful for hydride complexes because the corresponding resonance usually appears from 0 to 40 ppm to high field of TMS, a region otherwise free of signals. Exceptions can be found, especially among d^0 and d^{10} species, such as $Cp_2ZrH(BH_4)$ at +4.3 ppm. Coupling to any phosphines present can help determine the stereochemistry, because ^2J(P,H) is ca. 15 to 30 Hz for a cis arrangement and 90 to 200 Hz for a trans arrangement. Integration of the signal to determine the number of hydrides may need special care because the T_1 for M–H and ligand signals is often quite different. $IrH_5(PPh_3)_2$ was originally assigned as $IrH_3(PPh_3)_2$ for this reason.

Even in cases where several different hydride ligands are present, a single proton NMR resonance is often observed at room temperature and even below. For example, ReH_7L_2 species have at least three distinct types of hydrogen, yet only a single hydride resonance is normally seen down to −100 °C. This is because hydrides have a high tendency to be fluxional (i.e. undergo rapid positional permutation, *see Fluxional Molecule*). Possible reasons are the small size of hydride ligands and their facility in forming H_2 complexes, which then undergo rotation about the M–(H_2) axis, leading to permutation of the H nuclei. Bridging hydrides resonate to high field of TMS, except in rare cases such as the μ^6-H of the cluster $[Co_6(\mu^6\text{-H})(CO)_{15}]^-$, which resonates at +23.2 ppm. Coupling constants are lower for bridging hydrides than for terminal ones, in line with the reduction in M–H bond order implied by the presence of a 2e, n-center bond. Coupling to spin-1/2 metals, such as ^{187}Os (1.3% abundance), ^{195}Pt (33.7%), ^{103}Rh (100%), and ^{183}W (14.3%) can give information about the number of metals directly bonded.[13] If an (H_2) ligand is present in a complex, special techniques are available for NMR studies.[7–9,14]

Isotopic Perturbation of Resonance is a method for detecting X–H–M bridges (X = C, Si, ...) or $HM(H_2)$ species in highly fluxional systems and relies on temperature-dependent shifts in the averaged resonances between the different isotopomers in partially deuterated samples.[15] This is caused by zero-point energy differences, which make H prefer the weaker (usually bridging) bond over D. If the system is nonfluxional, deuteration is not needed and reduced Si–C or C–H coupling constants in the bridged X–H bonds is usually sufficient to diagnose the structure.

Tunneling effects are apparent in some polyhydrides, particularly trihydrides.[6] This leads to an apparent J(H,H′) that is highly temperature dependent and can be extremely large (up to 45 000 Hz). The best-known examples are Chaudret's [Cp*Ru(PR_3)H_3] and Heinekey's [CpIr(PR_3)H_3]$^+$. The H···H distances are not short (1.6 Å), so these are not ground-state H_2 or H_3 complexes. These exchange couplings are a quantum tunneling effect, as shown by D and T substitution,[6b,6c] and are relatively rare – most trihydrides behave normally. There is still some discussion as to exactly how the tunneling occurs.[6a]

3.2 IR Spectroscopy

M–H bands often appear in the IR (*see Infrared Spectroscopy*) in the range 1500 to 2300 cm^{-1}, although their intensity can be low or very low for late metal cations. Lower frequencies tend to be observed for the early transition metals. In certain systems, for example, Ir^{III}, enough examples are known to be able to define the ranges of ν(M–H) that tend to be found depending on the nature of the trans ligand.[16] Bridging hydrides appear in the range 1200 to 1700 cm^{-1} (ν_{as}). M–H bending modes have been seen in the range 700 to 900 cm^{-1}. An M–H stretching vibration can be identified by isotopic substitution, in which case the M–D band appears at ca. 1.414[ν(M–H)].

3.3 Other Spectroscopic Methods

Binary hydrides such as MH and M′H$^-$ (M = Ti, Cr, Mn, Fe, Co, Ni, Pd, Pt, Cu; M′ = Ti, Cr, Mn, Co, Ni) exist in the gas phase and can be detected in ion beam *Mass Spectrometry* experiments. More generally useful is electrospray MS in which large complexes such as Fe(dmpe)$_2$$H_2$ can be detected in solution.[17]

Few paramagnetic hydrides are known and even fewer have been studied by *Electron Paramagnetic Resonance*. For example, [TiH_2Cp_2]$^-$ and TaH_2(dmpe)$_2$$Cl_2$ have been examined in this way.

3.4 Matrix Studies

Matrix studies (*see Matrix Isolation*) of hydrides have been useful for determining the electronic and vibrational spectra of unstable hydride species, sometimes ones produced by photolysis.[18] For example, HCo(CO)$_3$ has been detected from irradiation of the tetracarbonyl.

4 ENERGETICS

The M–H dissociation energies (*see Bond Dissociation Energy*) estimated from ion beam experiments are quite large (see Table 1). The strength of the bond has been correlated with the promotion energy from the ground-state electronic configuration of the atom or ion to the lowest-energy $ns(n-1)d^{n-1}$ spin-decoupled state: the lower the promotion energy, the stronger the bond. Eighteen-electron hydride complexes have been studied in solution and their M–H bond strengths estimated; some are given in Table 1.

Table 1 M–H dissociation energies[a] of some M–H cations, neutrals, and anions in the gas phase and of some hydride complexes in solution

M–H	Cation	Neutral	Anion
Fe–H	208 (6)	157 (8)	235 (17)
Co–H	195 (6)	194 (13)	195 (13)
Ni–H	166 (8)	252 (8)	187 (8)
HMn(CO)$_5$	–	245 (15)	–
H_2Fe(CO)$_4$	–	272 (4)[b]	–
HCo(CO)$_4$	–	227 (18)	–

[a]In kJ mol^{-1}; uncertainties in parentheses. [b]Average of the two Fe–H bonds.

5 SYNTHESIS

5.1 Hydride Reagents

The commonest route is treatment of a metal halo complex with a hydride donor such as $NaBH_4$ (equation 1), $LiAlH_4$, or $LiBHEt_3$ (equation 2). The last reagent is useful in that it tends to be more selective and partial substitution can be achieved if desired; in addition, there is less risk of forming bridging borohydride or aluminohydride complexes of the type $L_nM(\eta^3\text{-}QH_4)_m$ (Q = B or Al). Sometimes, these can revert to normal hydrides on hydrolysis.[19] HCO_2H and HCO_2Na are particularly mild hydride forming reagents.

$$\mathrm{FeCl_2(triphos)} + \mathrm{NaBH_4} \longrightarrow \mathrm{(triphos)Fe(\mu\text{-}H)_3Fe(triphos)} \quad (1)$$

$$\mathrm{WCl_6} + \mathrm{LiBHEt_3} + \mathrm{PR_3} \longrightarrow \mathrm{WH_6(PR_3)_3} \quad (2)$$

5.2 Oxidative Addition

A wide variety of hydrides are formed by *Oxidative Addition* of H_2 to metal complexes (equation 3). There has been some interest in the direction of H_2 addition to square-planar Ir^I. Of the two possible outcomes, one is usually favored kinetically.[20]

$$\mathrm{Ir^ICl(CO)(PR_3)_2} + \mathrm{H_2} \longrightarrow \mathrm{Ir^{III}H_2Cl(CO)(PR_3)_2} \quad (3)$$

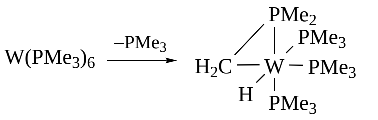
Hydrogenolysis of metal alkyls is another route involving H_2 (equation 4). This probably involves initial formation of an H_2 complex that leads to protonolysis of the W–Me bond.

For non-d^0 cases, oxidative addition/*Reductive Elimination* is also a possibility (equation 5).

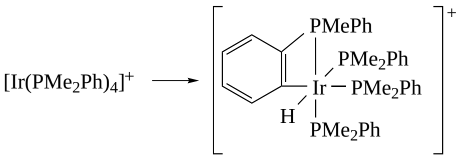
$$\mathrm{WMe_6 + H_2 + PR_3 \longrightarrow WH_6(PR_3)_3} \quad (4)$$

$$\mathrm{M{-}R \xrightarrow{H_2} H_2M{-}R \xrightarrow{-RH} M{-}H} \quad (5)$$

Oxidative addition of other X–H compounds other than H_2 can also lead to the formation of hydrides. For example, silanes H–SiR_3 give silyl hydrides, hydrohalic acids give halohydrides, and *Orthometalation* of aryl C–H gives an orthometalated aryl hydride (equations 6 and 7).



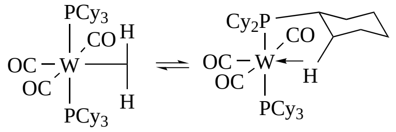
(6)



(7)

Dihydrogen complexes are sometimes formed by H_2 addition to N_2 complexes or to agostic species (equations 8 and 9) (*see Agostic Bonding*). Complexes that prefer oxidation by 1e rather than 2e can undergo a dinuclear oxidative addition of the type shown in equation (10). Catalytic processes involving hydride intermediates, often formed by oxidative addition, include isomerization, hydrogenation, hydroformylation, hydrocyanation, and hydrosilation of unsaturated species (*see* ***Hydrocyanation by Homogeneous Catalysis***; ***Hydrogenation & Isomerization of Alkenes***; ***Hydrosilation Catalysis***).

$$\mathrm{FeH_2(N_2)(PEt_2Ph)_3 + H_2 \xrightarrow{-N_2} FeH_2(H_2)(PEt_2Ph)_3} \quad (8)$$



(9)

$$\mathrm{2[Co^{II}(CN)_5]^{3-} + H_2 \longrightarrow 2[HCo^{III}(CN)_5]^{3-}} \quad (10)$$

5.3 β-elimination

β-Elimination from any of a variety of alkyls or alkoxides is a source of hydrides, although when formed in this way, they are often intermediates in a larger reaction scheme rather than being simple preparative reactions. Some purely preparative examples have been reported, however (equation 11).

$$\mathrm{RuCl_2(PR_3)_4 + 2KOCHMe_2 \xrightarrow[-Me_2CO]{-KCl} RuH_2(PR_3)_4} \quad (11)$$

5.4 Protonation

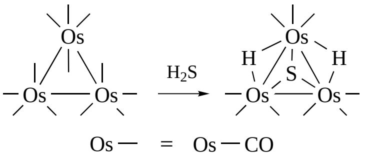
Addition of protons often occurs readily to a variety of neutral and anionic complexes and is a rich source of hydrides (equation 12). Protonation can also take place on a ligand in certain cases. Protonation of metal hydrides is a common source of H_2 complexes (equation 13).

$$\mathrm{[Co(CO)_4]^- + H^+ \longrightarrow HCo(CO)_4} \quad (12)$$

$$\mathrm{IrH_5(PCy_3)_2 + H^+ \longrightarrow [Ir(H)_2(H_2)_2(PCy_3)_2]^+} \quad (13)$$

5.5 Clusters and Bridging Hydrides

Compounds with M–H–M bridges can often be formed by oxidative addition to preformed *Cluster* compounds (equation 14). A general strategy for synthesizing hydride clusters from mononuclear precursors is to generate a coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*) fragment L_nM in the presence of a metal hydride, say L_nM'–H. The metal hydride tends to bind to the second metal, as might any classical 2e ligand like PPh_3, to give the bridged system L_nM'–H–ML_n (equation 15).



(14)

$$\mathrm{[IrH_2(solv)_2(PPh_3)_2]^+ + ReH_7(PPh_3)_2 \longrightarrow [H(PPh_3)_2Ir(\mu\text{-}H)_3ReH_3(PPh_3)_2]^+} \quad (15)$$

6 REACTIONS

Even before any real understanding of hydride chemistry had been obtained, alkene *Hydroformylation* (also *see Oxo Process*), a catalytic reaction involving hydride intermediates, was being practiced on an industrial scale (Otto Roelen, Ruhrchemie, 1938) (equation 16).

$$\mathrm{RCH{=}CH_2 + 2H_2 + CO \xrightarrow{HCo(CO)_4} RCH_2CH_2CHO} \quad (16)$$

6.1 Stability of Hydrides

The first reactivity issue is stability, that is, the complex must be stable enough to isolate or at least to exist as a kinetically significant intermediate. A coordination inert metal (*see Coordinatively Inert & Labile Complexes* and ***Coordination & Organometallic Chemistry: Principles***) is useful, and third-row metals tend to bind H and other ligands more strongly. More hydrides are known for Ir and Re than for any other elements. Hydrides often decompose by loss

of H_2, or by loss of HX, where X is a co-ligand such as a Me group. High-field co-ligands and a strongly backbonding metal site can minimize these reactions, but loss of CH_4 is so favorable that very few methyl or alkyl hydrides are known. Early metal hydrides can be hydridic and therefore unstable to water, and hydrides with strong donor ligands can be unstable to air. Finally, they can be light sensitive.

6.2 Reaction Types

In spite of the fact that the term ‘hydride’ is used for all M–H groups, their reactivity patterns suggest that most hydrides have little net charge on H. Hydrides L_nM–H can act as H^-, $H^{\bullet}$, or H^+ donors according to the nature of the attacking group and the stability of L_nM^+, $L_nM^{\bullet}$, or L_nM^-, respectively. A di- or polyhydride can also lose H_2. The polarization of the M–H bond in the ground-state structure (M^+–H^- or M^-–H^+) may not be the key factor; Sweany has IR evidence on $HM(CO)_n$ and $M(CO)_n$ that suggests that the charge on H in $HMn(CO)_5$, $H_2Fe(CO)_4$, and $HCo(CO)_4$ is always negative to about the same extent through the series,[21] yet these hydrides differ markedly in their propensity to donate hydride or protons: the cobalt compound is a strong acid in water, but the Mn compound tends to donate H^- or $H^{\bullet}$ in its reactions. This implies that the stability of the product, L_nM^+, $L_nM^{\bullet}$, or L_nM^-, may be more important, including such factors as solvation of these species.

6.3 Hydridic Reactivity

True hydride-like reactivity is often seen for the early metals, for anionic complexes, and for some polyhydrides. These metals are closer in behavior to the main group hydrides, which are often hydridic in character. One problem pointed out by Labinger[22] is that if L_nMH is an 18e compound, hydride loss will give a 16e L_nM^+ species that is rarely, if ever, stable. Coordinative unsaturation encourages the reduced substrate to bind to the metal (equation 17). This makes it difficult to define a scale of H^- donor power independent of the nature of the substrate. Another ambiguity is whether the reaction is a true H^- transfer or whether electron transfer is followed by H atom transfer (equation 18).

$$L_nMH + RCHO \longrightarrow L_nMOCH_2R \tag{17}$$

$$L_nMH^- + S \longrightarrow L_nMH^{\bullet} + HS^{\bullet -} \longrightarrow L_nM + SH^- \tag{18}$$

An early example of a hydride with pronounced H^- donor character is $[Cp_2ZrHCl]_n$, which attacks ketones, aldehydes, esters, epoxides, and even CO_2, as shown in Scheme 1. $Cp^*{}_2ScH$ is so active that it even attacks nitriles to give $Cp^*Sc(N{=}CHR)$; the resulting imine complexes react with H_2 to give amines, and the Sc complex is a nitrile hydrogenation catalyst.[23]

Berke and coworkers have shown how hydrides can be activated by a trans nitrosyl so that CO_2 inserts into the MoH bond of *mer*-$Mo(CO)H(NO)(PMe_3)_3$ to give a formato-complex.[24]

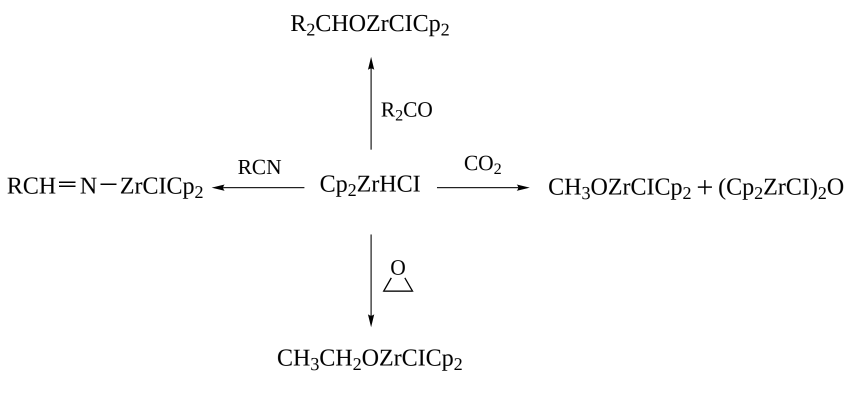
6.4 Homolytic Reactivity

A wide variety of hydrides act as H atom donors; for example, the key step in the hydrogenation of alkenes by $[HCo^{III}(CN)_5]^{3-}$ is known to go in this way (equation 19). A number of metal hydrides react with CCl_4 to give $CHCl_3$ and the metal halo complex. The mechanism may involve electron transfer, followed by H atom abstraction from the metal by $\bullet CCl_3$.

$$2[HCo^{III}(CN)_5]^{3-} + PhCH{=}CH_2 \longrightarrow 2[Co^{II}(CN)_5]^{3-} + PhCH_2CH_3 \tag{19}$$

6.5 Proton Donor Reactions

Carbonyl hydrides tend to be acids because of the stabilization of the resulting anions by the strong π-acceptor power of the CO ligand (equation 20). H_2 complexes can also be relatively acidic, because they are only formed when



Scheme 1 Some reactions of Cp_2ZrHCl

back donation from the metal is weak, and hence, the H_2 tends to accumulate a net positive charge. pK_a values of -2 to 15 have been reported for H_2 complexes, which implies a high degree of acidification of H_2 [pK_a(H_2, free) $\sim$ 35] on binding. Proton loss is possible if the L_nM fragment that remains can stabilize the negative charge. This is particularly the case for carbonyl hydrides and for cationic dihydrogen complexes. For example, pK_a values have been determined for several hydrides (Table 2). The cation radicals derived from oxidizing typical 18e metal hydrides are about 20 pK_a units more acidic.[25]

$$HCo(CO)_4 \longrightarrow H^+ + [Co(CO)_4]^- \quad (20)$$

The rate of proton transfer has been measured for a number of metal hydride/organic amine combinations. The rates appear to follow Marcus behavior (*see Marcus Treatment*), in which the rate goes up with driving force (equation 21, where k_{AB} is the rate of proton transfer between AH and B^-, and K_{AB} is the equilibrium constant for the proton transfer). Proton transfer appears to be the slow step in the process, rather than slow electron transfer followed by fast H atom transfer, because the rates show an isotope effect. For example, in the self-exchange of $[CpM(H,D)(CO)_3]/[CpM(CO)_3]^-$, k_H/k_D is 3.6, 3.7, and 3.7 for Cr, Mo, and W. There seems to be a good relation between thermodynamic acidity and kinetic acidity for a variety of terminal hydrides, although bridging hydrides are often kinetically weaker acids than would be expected from their pK_a. For example, Table 3 shows rates of proton transfer for some hydride complexes. The fact that deprotonation from bridging hydride positions is slower than for terminal positions implies that a protonation that eventually gives a bridging hydride may well go via a terminal hydride intermediate. An excellent example is shown in equation (22), where the second step takes two weeks at 25 °C.

Table 2 Thermodynamic acidities[a] for some hydride complexes

Complex	Acidity
$VH(CO)_5(PPh_3)$	6.8 (H_2O)
$[MoH(CO)_3(tacn)]^+$	2.4 (H_2O)
$H_2Fe(CO)_4$	4.0, 12.7 (H_2O)
$[NiH\{P(Ome)_3\}_4]^+$	1.7 (MeOH), 13.4 (MeCN)
$HCo(CO)_4$	Strong (H_2O), ca. 1 (MeOH), 8.4 (MeCN)
$CpCrH(CO)_3$	13.3 (MeCN)
$[CpCrH(CO)_3]^{+\bullet}$	−9.5(MeCN)
$CpMoH(CO)_3$	13.9 (MeCN)
$[CpMoH(CO)_3]^{+\bullet}$	−6.0(MeCN)
$CpWH(CO)_3$	16.1 (MeCN)
$[CpWH(CO)_3]^{+\bullet}$	−3.0(MeCN)

[a]Water scale; solvent in brackets.

Table 3 Rates of proton transfer to aniline in acetonitrile[a]

Compound	Rate ($M^{-1}\,s^{-1}$)	pK_a
$HCo(CO)_4$	1.7×10^7	8.4
$H_2Fe(CO)_4$	5.4×10^4	11.4
$CpCrH(CO)_3$	1.7×10^4	13.3
$CpMoH(CO)_3$	3.9×10^3	17.1
$CpWH(CO)_3$	250	16.1
$HMn(CO)_5$	210	14.2
$CpFeH(CO)_2$	0.4	19.4
$CpWH(CO)_2(PMe_3)$	$<10^{-3}$	26.6

[a]At 25 °C.

$$k_{AB} = [k_{AA}k_{BB}K_{AB}]^{1/2} \quad (21)$$

$$Cp(CO)_2M(\mu\text{-}PPh_2)Pt(CO)PPh_3(M{-}Pt) + HBF_4 \longrightarrow [Cp(CO)_2HM(\mu\text{-}PPh_2)Pt(CO)PPh_3(M{-}Pt)]BF_4 \longrightarrow [Cp(CO)_2M(\mu\text{-}PPh_2)(\mu\text{-}H)Pt(CO)PPh_3(M{-}Pt)]BF_4 \quad (22)$$

In some cases, the second step is too slow to observe without a catalyst being present. For example, Cp(NO)Re(μ-PCy_2)$Pt(PPh_3)_2$(*Re–Pt*) protonates at Re to give a terminal hydride. Only on treatment with Cl^- does the rearrangement to Cp(NO)Re(μ-PCy_2)(μ-H)$Pt(PPh_3)_2$(*Re–Pt*) occur. This is not simply base catalysis because F^- is ineffective, and it has been proposed that Cl^- attacks the complex and breaks the M–M bond, allowing the H to reach the terminal position in the product.[26] The finding that the rate of a reaction for differing hydrides parallels the known rates for proton transfer, for the same hydrides, helps establish proton transfer as the slow step in that reaction.[27]

Protonation can take place on a ligand in preference to the metal; proton transfer to a hydride occurs in $CpFe(Ph_2CH_2CH_2PPh_2)H$ to give an H_2 complex as the kinetic product that only slowly rearranges to the final thermodynamic product, a cationic Fe(IV) dihydride.[28]

6.6 Insertion Reactions

Unsaturated ligands such as alkenes often undergo insertion into M–H bonds to give alkyls or vinyls (equation 23). This is an important step in catalytic alkene isomerization, hydrogenation, hydroformylation, hydrocyanation, and perhaps also hydrosilation, although in this last case, insertion into the M–Si bond may be preferred. This is simply the reverse of the β-elimination reaction discussed above.

$$Cl(PR_3)_2Pt{-}H + C_2H_4 \longrightarrow Cl(PR_3)_2Pt{-}C_2H_5 \quad (23)$$

Insertion of an M–H bond into a multiple bond of an unsaturated ligand is a very important reaction, because it is a key step in catalytic processes such as hydrogenation. Osborn has observed a rare reversible example (equation 24).[29]

$$Mo(C_2H_4)_2(dppe)_2 \xrightarrow{H^+} [HMo(C_2H_4)_2(dppe)_2]^+ \rightleftharpoons [C_2H_5Mo(C_2H_4)(dppe)_2]^+ \quad (24)$$

The selectivity of hydride insertion into an unsymmetrical unsaturated species plays a role in determining the selectivity of catalytic reactions; the outcome is a complex function of electronic and steric effects and cannot readily be predicted other than by analogy with similar systems. In hydrogenation, the direction of insertion is usually not an important issue because an H is added to each end of the multiple bond, but in hydroformylation and hydrocyanation, where HX (X = CHO or CN) adds to the unsaturate, the direction of the initial insertion can be inferred. In hydrosilation, an Si–H bond is added, but there is some doubt as to whether the first insertion occurs into the M–H or M–Si bonds. Among non-H ligands, the M–Si bond is the closest analog to M–H in polarity and reactivity.

6.7 Photochemical Reactions

Hydride complexes have a rich photochemistry. Often, nonhydride ligands are lost, but a common reaction of polyhydrides is loss of H_2. Photoextrusion of H_2 from Cp_2WH_2 in benzene gives Cp_2W, which inserts into a C–H bond of the solvent (equation 25). $CpIrH_2(PMe_3)$ gives a species that even attacks alkanes (equation 26).[30] For linear and branched alkanes, preferential attack takes place at primary and relatively unhindered secondary C–H bonds, presumably for steric reasons. Time-resolved infrared experiments probing the initial femtosecond dynamics through the nano- and microsecond kinetics to the final stable products have been used to generate a detailed picture of the C–H activation reaction.[30a]

$$Cp_2WH_2 \xrightarrow{h\nu} Cp_2W \xrightarrow{PhH} Cp_2WH(Ph) \quad (25)$$

$$CpIrH_2(PMe_3) \xrightarrow{h\nu} CpIr(PMe_3) \xrightarrow{CyH} CpIrH(Cy)(PMe_3) \quad (26)$$

6.8 Other Reactions

Hydride complexes have been important precursors in the study of *Alkane Activation*. For example, alkanes can be catalytically dehydrogenated by $ReH_7(PR_3)_2$ or $[IrH_2(OH_2)_2(PR_3)_2]^+$ or (PCP)IrH_2 thermally or photochemically.[30c–30d] Cyclooctane is the best substrate, presumably because it has the least unfavorable heat of dehydrogenation of all common alkanes (equation 27).

$$C_8H_{16} + t\text{-BuCH=CH}_2 \xrightarrow{\text{catalyst}} C_8H_{14} + t\text{-BuCH}_2\text{CH}_3 \quad (27)$$

7 INDIVIDUAL HYDRIDES OF INTEREST

7.1 $[ReH_9]^-$

This remarkable species is one of the very few homoleptic transition metal hydrides (*see Homoleptic Compound*). The neutron diffraction structure dating from 1964[3] put the M–H bond on a secure footing. The molecule has a TTP geometry. It was originally formulated as $K[Re(H_2O)_4]$, then $K[ReH_4]\cdot 2-4H_2O$ or $K_6[Re_2H_{14}]\cdot 6H_2O$, then $KReH_8$, illustrating the difficulty of characterizing the complex.

7.2 $ReH_7(PR_3)_2$

These species can be classical with a TTP geometry or nonclassical with a dodecahedral geometry. For example, the dppe compound is TTP but the P(*o*-tolyl)$_3$ complex is dodecahedral with one coordination site occupied by an H_2 ligand with a long (1.357 Å) H–H distance. These species more or less easily lose H_2, and the resulting 16e intermediate can react with a number of 2e ligands, such as pyridine, or with a silane $HSiR'_3$. In the latter case, an interesting silyl hydride $ReH_6(SiR'_3)(PR_3)_2$ is obtained.[31] In the case of the $SiHEt_2$ complex, a neutron diffraction study[32] has revealed several short Si···H distances, suggesting that attractive Si···H interactions replace the H···H interactions present in the original molecule. In such a high coordination compound, attractive interactions between ligands are probably important in stabilizing the structure.

7.3 $[(OC)_5Cr–H–Cr(CO)_5]^-$

Early work on this compound suggested the M–H–M bridge might be linear, but careful analysis[33] of the neutron diffraction data showed that the H is disordered over four positions so that although the averaged H position leads to an apparently linear M–H–M group each of the disordered structures has a bent M–H–M group. This implies that the system is trying to maximize the bonding between all three atoms, as appropriate for a 2e, three-center bond.

7.4 $[IrH_2(8\text{-methylbenzoquinoline})(PPh_3)_2]^+$

This complex is agostic and contains a short C–H···M interaction; comparison with related structures led to the definition of a reaction trajectory for the M + C–H reaction.[34]

7.5 $CpMn(CO)_2(H\cdots SiR_3)$

These interesting molecules were discovered and briefly studied by Graham,[35] but Schubert[36] put them on a firm basis with his systematic neutron diffraction studies. The H···Si distances can be short or long, bonding or nonbonding, depending on the nature of R. Replacing the CO groups by other ligands also affects the H···Si distance. This system shows a series of σ-bond complexes, which more closely resemble the full oxidative addition products than the silane precursor. Sabo-Etienne, Chaudret, and collaborators have produced some of the most remarkable such structures, including one, $(PR_3)_2H_2Ru(SiH_4)RuH_2(PR_3)_2$, with an SiH_4 ligand bridging between the two metals.[37]

Glossary

Complex metal hydride: solid-state compound containing homoleptic, anionic metal–hydrogen complexes
d^1, d^2, d^3 etc: electron configuration of transition element
ΔH: enthalpy of hydride formation as determined from pressure–composition isotherms during desorption by using van't Hoff's method
Homoleptic hydride complexes: complexes having hydrogen ligands only
Hydrido complexes: structural units formed by central metal atoms and terminal hydrogen ligands

Abbreviations

APW = Augmented plane wave; HT = High temperature; INS = Inelastic neutron scattering, IR = Infrared; lif = Limiting ionic formula; lin = Linear; LCAO-MO = Linear combination of atomic orbitals-molecular orbitals; LT = Low temperature; M = Alkali (Li, Na, K, Rb, Cs), alkaline earth (Mg, Ca, Sr, Ba), divalent (Yb, Eu) or trivalent (La, Nd) lanthanide; NMR = Nuclear magnetic resonance; μ_{eff} = Magnetic moment in units of Bohr magneton, μ_B; npd = Neutron powder diffraction; oct = Octahedral; pbp = Pentagonal bipyramidal; sad = Saddle-like; spl = Square planar; spy = Square pyramidal; SQUID = Superconducting quantum interference device; T-metal = Transition metal (Mn, Fe, Co, Ni, Cu, Zn, Tc, Ru, Rh, Pd, Cd, Re, Os, Ir, Pt); T_C = Curie temperature; dis = Disordered; tet = Tetrahedral; tri = Triangular; ts = T-shaped; ttp = Tricapped trigonal prismatic; Z = Number of formula units per crystallographic unit cell.

1 INTRODUCTION

This article is an update of a review written[1] some 10 years ago. It covers the currently known solid-state complex homoleptic transition (T) metal hydrido complexes and some of their properties of interest for science and technology. The complexes occur in a wide variety of solid-state compounds. Historically, the first fully characterized example is K_2ReH_9. Its structure was reported in 1964 by Abrahams, Ginsberg, and Knox,[2] and found to contain tricapped trigonal prismatic $[ReH_9]^{2-}$ complex anions. The second member is Sr_2RuH_6, which was reported in the 1970s by Moyer and collaborators,[3] was found to contain octahedral $[RuH_6]^{4-}$ complexes. Wider interest in this type of hydride started only in the 1980s after the discovery of ternary transition metal hydrides such as $LaNi_5H_6$ and $FeTiH_2$, which were suitable media for reversible hydrogen storage (for useful reviews see books and journal issues edited by Schlapbach).[4] The compounds showed metallic properties and had a large homogeneity range with respect to hydrogen. One of them, however, Mg_2NiH_4, was nonmetallic and had a fixed hydrogen content. Originally reported in 1968 by Reilly and Wiswall,[5] it was classified as a hydride containing a T-metal hydrido complex only 18 years later, after its structure was fully characterized by Zolliker *et al.*[6] and found to contain tetrahedral $[NiH_4]^{4-}$ units called 'complexes'. In the meantime, other homoleptic hydrido complexes were discovered, such as square-pyramidal $[CoH_5]^{4-}$, square-planar $[PtH_4]^{2-}$, and linear $[PdH_2]^{2-}$, and also hydrides that contained both complex bonded hydrogen and ionic hydrogen not bonded to the transition metal. In 1991, some 13 ternary hydride structure types were known. Some of them were reviewed and named 'complex transition metal hydrides' by Bronger,[7] a term now widely accepted. The first comprehensive review as written in 1993 by Yvon[1] covered 25 different transition metal hydride complexes in some 69 compounds, including quaternary hydrides. Over the years, the number of complex metal hydrides increased continuously and reviews appeared on various of their aspects such as synthetics,[8,9] diffraction methodology,[10,11] bonding,[12–14] crystal chemistry,[15,16] complex formation in hydrogenated intermetallic compounds,[17] and materials science.[18,19] The hydrides were also incorporated into a public online database.[20] At present, over 127 complex T-metal hydrides covering 47 structure types are known, that is, since the 1993 review their number has almost doubled. In this update, both mononuclear (terminal hydrogen ligands only) and polynuclear (terminal and bridging hydrogen ligands)

complexes are covered. Only those hydrides are treated whose structures are fully characterized. Most contain well-defined T-metal hydride complexes and show nonmetallic behavior. Some, however, do not, and their classification as 'complex' hydrides is debatable. They are, nevertheless, included here because they illustrate the continuous transition that exists between complex and interstitial (metallic) hydrides. Among the aspects discussed are factors that govern the formation of complex hydrides, hydrogen contents, and thermal stability. These factors are not only of fundamental interest but also of practical relevance, because they determine the potential of metal hydrides for hydrogen storage applications.

2 EXPERIMENTAL DETAILS

2.1 Compositions and Structures

The presently known complex transition metal hydrides are based on late 3d, 4d, and 5d transition elements of groups 7–10, and on monovalent, divalent, and trivalent metals (M) belonging to the alkali, alkaline earth, and/or lanthanide series, respectively. For completeness, complexes based on closed-shell elements of group 11 (Cu, etc.) and 12 (Zn, etc.) are also included. Most hydrides are true ternary (or quaternary) compounds in the sense that they do not derive from stable intermetallic compounds, but form only in the presence of hydrogen. Some hydrides, however, do and show interesting physical phenomena. The metal ratios are usually situated in the range M/T = 1–4, and the hydrogen contents in the range $H/(M + T) = 1–4.5$. The compounds crystallize with 47 different, mostly new, structure types and represent over 127 hydrides. The first representative of each hydride structure type and the isostructural compounds known are listed in chronological order in Table 1 (year of publication in parentheses).

There exist two broad families of complex transition metal hydrides. The first contains hydrogen bonded to transition elements only and has the general composition

$$M_m{}^{\delta+}[TH_n]^{\delta-} \quad (m, n, \delta = 1, 2, 3\ldots) \tag{1}$$

where $[TH_n]^{\delta-}$ are complexes that are stabilized by charge transfer from the surrounding metal cations $M^{\delta+}$. The second family contains hydrogen bonded to T elements and hydride anions H^- bonded to metal cations $M^{\delta+}$ only, corresponding to the general composition

$$M_m{}^{\delta+}[TH_n]^{\delta-}M_o{}^{\delta+}H^-{}_p \quad (m, n, o, p, \delta = 1, 2, 3\ldots) \tag{2}$$

These 'composite' hydrides are of particular interest because they combine different types of metal–hydrogen bonding in the same structure.

Table 1 Complex transition metal hydride structure types and representatives

Structure types	Representatives	Complex transition metal hydrides
I	K_2ReH_9 (1964)	K_2TH_9 (T = Tc, Re)
II	Sr_2RuH_6 (1971)	M_2FeH_6 (M = Mg, Ca, Sr, Eu, Yb) M_2RuH_6 (M = Mg, Ca, Sr, Ba, Eu, Yb) M_2OsH_6 (M = Mg, Ca, Sr, Ba) M_2PtH_6 (M = Na, K, Rb, Cs)
III	Sr_2IrH_5 (1971)	Mg_2CoH_5 M_2RhH_{5+x} (M = Ca, Sr, Eu) M_2IrH_{5+x} (M = Mg, Ca, Sr, Eu)

2.2 Synthesis

The most common route of synthesis is by solid-state reaction, such as sintering powder mixtures of the elements, binary alloys, and/or binary metal hydrides at relatively high pressures (up to 160 bar) and moderate temperatures (<1000 K). Synthesis from binary metal compounds is rarely possible because such compounds either do not exist, such as in the Mg–Fe and Mg–Os systems, or form at metal ratios that differ significantly from those of the ternary (or quaternary) complex metal hydrides, such as Mg_2CoH_5 (MgCo, $MgCo_2$) or Mg_2RuH_6 (Mg_3Ru_2). Some hydrides derive from two-phase mixtures such as $Ba_7Cu_3H_{17}$ (Ba–Cu alloy with compositional ratio Ba/Cu$\sim$7/3) while others can be prepared by inexpensive ball milling (Mg_2FeH_6) and combustion synthesis (Mg_2NiH_4). Solution methods, such as those employed to synthesize K_2ReH_9 and related hydrides, are not yet fully explored. The only other soluble T-metal hydride complex known is $[FeH_6]^{4-}$.[21] The solid-state reaction products are mostly polycrystalline and often colored. They usually contain impurity phases (nonreacted T and/or binary M metal hydrides), but rarely contain single crystals of sufficient size and quality for diffraction measurements or measurements of physical properties. Those based on alkali and heavy alkaline earth metals are often sensitive to air and moisture.

A decisive parameter for hydride formation is pressure. The synthesis of hydrides based on light transition elements usually requires higher hydrogen pressures than those based on heavier congeners. Examples are the palladium compounds M_2PdH_4 and M_3PdH_5, which form at 20 and 70 bar, respectively, in contrast to their platinum congeners, that form already at 1 bar. For a given transition metal, an increase of hydrogen pressure usually allows the stabilization of higher formal oxidation states. Examples are found for palladium in $M_3Pd^0H_3$ and $M_2Pd^{II}H_4$, which form at 1 and 20 bar, respectively, for platinum in $K_2Pt^{II}H_4$ and $K_2Pt^{IV}H_6$, which form at 1 and 1800 bar respectively, and for ruthenium in $Mg_2Ru^0H_4$ and $Mg_2Ru^{II}H_6$, which form at 20 and 90 bar, respectively. However, the inverse situation prevails for manganese based $Mg_3Mn^IH_7$, which forms under a mechanical pressure of 20 kbar, while $K_3Mn^{II}H_5$ forms under a hydrogen gas pressure of only 3 kbar.

2.3 Structure Analysis

Owing to the low X-ray scattering power of hydrogen, neutron diffraction experiments on deuterides are necessary. Most atomic arrangements are determined on powders, and this may cause difficulties owing to poor crystallinity, the presence of impurity phases (often not detected by X rays), structural complexity ($Mg_6Ir_2D_{11}$, e.g., has 126 free positional parameters), heavy absorption (Eu, Cd), microtwinning owing to temperature induced phase transitions, and disorder in the hydrogen complex ligand spheres. High-resolution measurements (e.g. with synchrotron radiation) are rare. The data are usually analyzed by the Rietveld method. For better convergence, the number of refined parameters, in particular, those of the atomic displacement amplitudes, are reduced by constraints. For all these reasons, hydride structures are generally less well characterized than other solid-state structures.

2.4 Properties

Most compounds are nonmetallic. Only few other properties are known. The main reason for this is the lack of single crystals, the presence of impurity phases in the samples, and the sensitivity of many compounds to air and moisture. Data on magnetic, electric, and spectroscopic (NMR, Mössbauer, IR) properties are scarce. Enthalpies of hydride formation as measured from pressure–composition isotherms are known for hydrides based on 3d elements only. Theoretical band structure calculations are available only on relatively simple crystal structures. Structural dynamics are investigated by spectroscopic methods (INS, Raman, IR, NMR) and magnetic properties on SQUID magnetometers. Owing to the absence of single crystals of suitable size, reliable measurements of the electric conductivity are rare. Enthalpies of hydride formation, ΔH, are usually determined from pressure-composition isotherms as measured on Sievert's apparatus or on a thermobalance, by using the relation

$$\ln(p_{\mathrm{eq}}) = \frac{-\Delta H}{R.T} + \frac{\Delta S}{R} \quad \text{Van't Hoff equation} \qquad (3)$$

where p_{eq} is the hydrogen equilibrium pressure and T the absolute temperature. Given that the entropy term, ΔS, does not much change from one system to another ($\Delta S \sim 130\ \mathrm{J\,K^{-1}\,mol^{-1}}\ H_2$) the hydrogen decomposition temperatures at a given pressure scale roughly with enthalpy (293 K: $\Delta H \sim 30$ kJ/H_2 for $p_{\mathrm{eq}} = 1$ bar). Finally, the reaction products ought to be handled with care because many are air sensitive and some are extremely pyrophoric. For these reasons, quite a few complex metal hydrides are known to exist but have not yet been fully characterized.

3 HYDRIDE STRUCTURE TYPES AND PROPERTIES

Complex transition metal hydrides combine structural features typical for coordination compounds and ionic solids. They display covalently bonded hydrogen such as in molecular transition metal complexes[22] (*see* ***Hydride Complexes of the Transition Metals***), and hydride anions (H^-) bonded to electropositive metals (M^+, M^{2+}, M^{3+}) only, such as in saline hydrides. In metal-rich systems, hydrogen has interstitial character, as in typically metallic transition metal hydrides.[23] The structural and physical properties of the 47 known hydride structure types and of their representatives (stated in parentheses) are summarized below. Limiting ionic formulas (lif) and the corresponding formal oxidation states and electron configurations of the transition elements are indicated whenever possible. Such formulas do not provide an adequate description of the bonding but allow one to rationalize the H content (see below). For each structure, T–D bond distances and shortest M–D (complex D), M–D^- (anionic D^-) and D–D distances are stated. For all structure types, illustrations are given (see Figures 1–47; TH_n complexes are drawn by heavy lines, disordered ligands by double lines, M–M contacts surrounding TH_n complexes by single lines, M atoms as large circles, and H^- ions as small isolated circles).

3.1 K_2ReH_9 (K_2TcH_9)

From reaction of $KReO_4$ with K metal in ethylenediamine–water solution;[2] colorless crystals, unstable in moist air; NMR and IR data, optical absorption spectra and LCAO-MO calculations; ordered structure (Figure 1) from single-crystal neutron diffraction on hydride and later on deuteride:[24] $P\bar{6}2m$, $Z = 3$; two different Re sites, occurring at the ratio Re1:Re2 = 1:2, both forming ttp-$[ReH_9]^{2-}$ 18-electron complexes with T site symmetries $\bar{6}2m$ and $\bar{6}$, respectively; surrounded by two types of K cations; four H sites; lif: $2K^+\cdot[ReH_9]^{2-}$; Re^{VII}, d^0; no structure data on Tc compound.

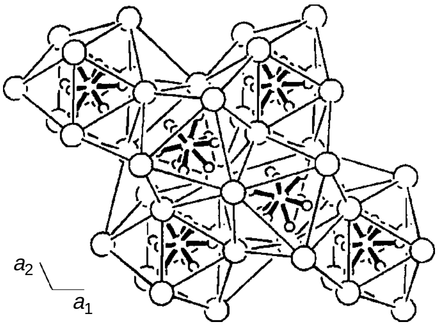

Figure 1 Structure of K_2ReH_9

Distances (Å):[24] Re–H (3×) = 1.68 (Re1); 1.67 (Re2); Re–H (6×) = 1.69 (Re1); 1.70 (Re2); K–H = 2.69; H–H = 1.90.

3.2 Sr_2RuH_6 (M_2FeH_6, M = Mg, Ca, Sr, Yb, Eu; M_2RuH_6, M = any; M_2OsH_6, M = Mg, Ca, Sr, Ba; M_2PtH_6, M = Na, K, Rb, Cs)

Sr_2RuH_6 and isostructural hydrides M_2TH_6 from elemental T (Fe, Ru, Os) and binary hydrides MH_2 or Mg by sintering at various temperatures and hydrogen pressures;[3,25–30] or by mechanical alloying followed by sintering (T = Fe);[31,32] powders either colored (Mg_2FeH_6, green; Eu_2RuH_6, red), or white-gray (Ca_2RuH_6, Mg_2OsH_6), or black (Yb_2RuH_6); moisture sensitive and partly pyrophoric (Mg_2OsH_6); M_2FeH_6 (M = Ca, Sr, Eu), M_2OsH_6 (M = Mg, Ca), Mg_2RuH_6 and various solid solutions;[29] M_2PtH_6 (M = Na, K, Rb, Cs)[33–35] by reaction of alkaline hydride with platinum sponge at 770 K under high hydrogen pressure (between 2 and 4 kbar); M_2PtH_6 are colorless and very sensitive to moisture and air; IR stretching frequencies of T–H (T = Fe, Ru, Os) bonds range between 1450 and 1850 cm^{-1}, and increase in the sequence Fe, Ru, Os, and decrease as the ionic size of M^{2+} increases;[28] Eu_2RuH_6 and solid solution series $(Ca,Eu)_2RuH_6$ and $(Sr,Eu)_2RuH_6$ are paramagnetic with $\mu_{eff} = 7.7\mu_B$, and magnetic order below $T_C = 29$ K;[25] low-temperature magnetic properties of Eu–Ru, (Ca,Eu)–Ru, and (Sr,Eu)–Ru hydrides[36] show ferromagnetic behavior; electric resistivities of Mg_2FeH_6, Ca_2RuH_6, Sr_2RuH_6, Yb_2RuH_6, and Eu_2RuH_6 indicate nonmetallic behavior; band structure calculations[37] predict band gaps that range from 1.3 eV (Sr_2FeH_6) to 4.0 eV (Mg_2OsH_6) and increase in the sequence Mg_2TH_6 (T = Fe, Ru, Os) and decrease in the sequence M_2FeH_6 (M = Mg, Ca, Sr); Mg_2FeH_6, Ca_2RuH_6, Sr_2RuH_6 are diamagnetic, or weakly paramagnetic; other properties of Mg_2FeH_6: Mössbauer spectra[26] consistent with low-spin Fe^{II}; hydrogen density 5.4 wt%; 9.0×10^{22} H atoms cm^{-3}; desorption enthalpy[26] $\Delta H = 98$ kJ mol^{-1} H_2; INS, infrared, and Raman spectroscopies;[38] has potential for thermochemical thermal energy storage;[39] IR of Ru based hydrides;[40] ordered structures (Figure 2) by npd on deuterides;[3,26–29] $Fm\bar{3}m$, $Z = 4$; K_2PtCl_6 type structure; octahedral $[TH_6]^{4-}$ 18-electron complexes having T site symmetry $m\bar{3}m$; surrounded by M in eightfold cubic configuration corresponding to a CaF_2 type metal substructure; lif: $2M^{2+}\cdot[TH_6]^{4-}$; T = Fe^{II}, Ru^{II}, Os^{II}; d^6. Interatomic distances are given in Table 2.

3.3 Sr_2IrH_5 (Mg_2CoH_5, Mg_2IrH_5, Ca_2IrH_5, $Ca_2RhH_{5.4}$, $Sr_2RhH_{5.3}$, Eu_2IrH_5)

Sr_2IrH_5 from Ir and SrH_2 powder at 1033 K under hydrogen;[41] Eu_2IrD_5 from ^{153}Eu isotope enriched intermetallic $EuIr_2$ at 673 K under deuterium,[42] or by reaction of binary europium hydride (natural isotope mixture) with iridium metal

[a]Disordered.

Ca_2IrD_5, and solid solutions $(Ca,Eu)_2IrD_5$, $(Sr,Eu)_2IrD_5$: disordered structure by npd at room temperature:[42] $Fm\bar{3}m$, $Z = 4$; Ir surrounded by five D atoms in a disordered average octahedral configuration similar to II; transition occurs between 200 and 275 K to partially ordered tetragonal modification $I4/mmm$ similar to Sr_2IrD_5;[43] paramagnetic with $\mu_{eff} = 7.3\mu_B$; ferromagnetic below $T_C = 20$ K; rhodium-based 'Mg_2RhH_5' analog not obtained, presumably because of the formation of competing hydride $Mg_2RhH_{1.1}$ (filled Ti_2Ni type structure) and binary Mg_2Rh (Ti_2Pd type structure).[48] Other Rh compounds known:[49] Eu_2RhH_5 and solid solutions $(Sr,Eu)_2RhH_5$. Interatomic distances are given in Table 3.

3.4 Na_2PtH_4 (K_2PdH_4, Na_2PdH_4)

Na_2PtH_4 by sintering NaH and Pt at about 573 K under hydrogen;[50] red-violet powder; diamagnetic from susceptibility measurements; K_2PdH_4 by heating KH with Pd at 610 K under 16 bar hydrogen pressure;[51] yellow-green powder, nonmetallic; band gap of 1.2 eV predicted from theoretical band structure calculations;[52] decomposes before melting; Na_2PdH_4 from NaH and Pd at up to 2500 bar and 770 K;[53] ordered structures (Figure 4) from npd on deuterides: $I4/mmm$, $Z = 2$; square-planar $[PtH_4]^{2-}$ (or $[PdH_4]^{2-}$) 16-electron complexes with T site symmetry $4/mmm$; surrounded by Na (K) in eightfold cubic configuration; one D site; Na_2PtH_4 transforms at about 573 K into disordered cubic HT modification similar to II; Na_2PdH_4 does not transform up to 600 K and decomposes into Na_2PdH_2;[53] lif: $2M^+ \cdot [TH_4]^{2-}$; T = Pd^{II}, Pt^{II}, d^8. Interatomic distances are given in Table 4.

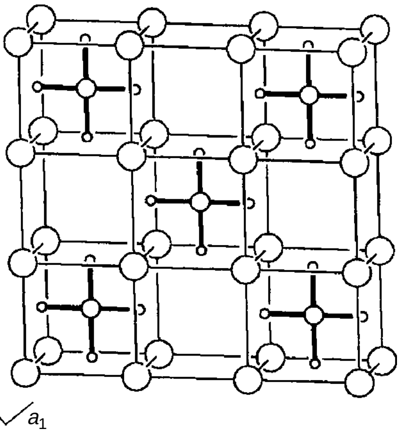

Figure 4 Structure of Na_2PtD_4

3.5 Mg_2NiH_4

From binary alloy Mg_2Ni by hydrogenation at temperatures above 623 K,[5] or by sintering powder mixtures of the elements at 723–773 K under 90 bar hydrogen pressure;[30] fine powder

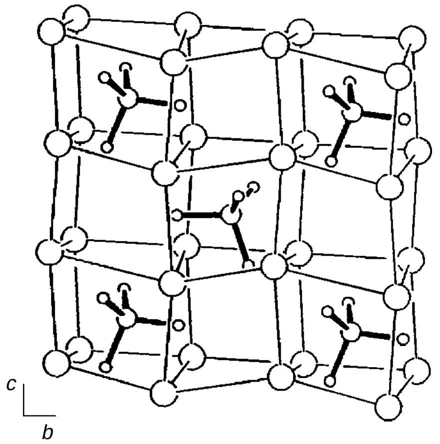

Figure 5 Structure of Mg_2NiD_4

of dark-red (fully hydrided) or brownish (partially hydrided) color; stable in air; diamagnetic, nonmetallic; theoretical band structure calculations[37] on disordered structure model predict band gap of 1.8 eV; vibrational spectroscopy;[54] bonding and stability investigated by ab initio density functional calculations;[14,55] H density: 3.6 wt%, 5.8×10^{22} H atoms cm^{-3}; desorption enthalpy $\Delta H = 64\,kJ\,mol^{-1}$ H_2; ordered structure (Figure 5) by high-resolution npd on deuteride:[6] $C2/c$, $Z = 8$; tetrahedral $[NiH_4]^{4-}$ 18-electron complex having symmetry 1; surrounded by three Mg sites in eightfold, strongly distorted cubic configuration; four D sites; X-ray and electron microscopy evidence for microtwinning[56] parallel to *bc* plane; transforms between 483 and 513 K into disordered cubic HT modification similar to II;[57] influenced by mechanical grinding;[58] lif: $2Mg^{2+}\cdot[NiH_4]^{4-}$; Ni^0, d^{10}.

Distances (Å) and angles: Ni–D = 1.52–1.57; D–Ni–D = 104–119°; Mg–Ni = 2.65; Ni–Ni = 4.30; Mg–Mg = 3.10; Mg–D = 1.97; D–D = 2.42.

3.6 K_2PtH_4 (Rb_2PtH_4, Cs_2PtH_4, Rb_2PdH_4, Cs_2PdH_4)

From binary hydrides and Pt(Pd) sponge at 593–693 K under 0.8 bar (Pd compounds 20 bar) hydrogen pressure;[59]

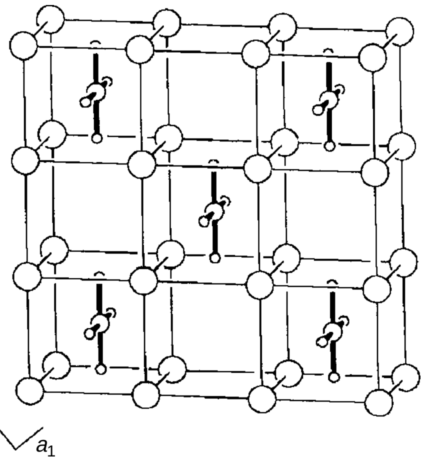

Figure 6 Structure of K_2PtD_4

pyrophoric, colorless powders; sensitive to moisture and air; K_2PtH_4: diamagnetic; NMR data at room temperature consistent with rotational disorder of PtH_4 groups; structures from npd on deuterides at 295 and 15 K (K_2PtD_4, Rb_2PdD_4, Cs_2PdD_4), 16 K (Rb_2PtD_4), and 12 K (Cs_2PtD_4); disordered room temperature structure: cubic, $Fm\bar{3}m$, $Z = 4$, CaF_2 type metal substructure similar to II; transforms at 250 K (Rb_2PdD_4), 225 K (Cs_2PdD_4), 195 K (K_2PtD_4), 170 K (Rb_2PtD_4), and 150 K (Cs_2PtD_4), into ordered tetragonal low-temperature (LT) structure (Figure 6): $P4_2/mnm$, $Z = 2$; planar $[PtH_4]^{2-}$ (or $[PdH_4]^{2-}$) 16-electron complexes with T site symmetry *m.mm*; unlike Na_2PtH_4, these complexes are oriented perpendicular to the tetragonal base; surrounded by M^+ in eightfold, nearly cubic configuration; two D sites; lif: $2M^+\cdot$ $[TH_4]^{2-}$; T = Pd^{II}, Pt^{II}, d^8. Interatomic distances are given in Table 5.

3.7 Na_2PdH_2 (Li_2PdH_2)

Na_2PdH_2 from NaH with Pd at 643 K under 50 bar hydrogen pressure;[60] brittle solid; single crystals show metallic luster; melts at 681 K without decomposing; metallic conductivity measured on single crystals and semiconducting behavior on powder; Li_2PdH_2[51] from LiH and Pd at 680 K; melts at 773 K; electronic band structure calculations[52,61] predict filled d bands and metallic properties in two dimensions (*ab* plane), originating from overlap between Pd d-block bands and alkali metal s- and p-block bands; Na_2PdH_2 found to be metallic;[61] ordered structure of Na_2PdH_2 (Figure 7) from X-ray single-crystal diffraction on hydride and npd on deuteride: $I4/mmm$, $Z = 2$; Na_2HgO_2 type structure; linear $[PdH_2]^{2-}$ 14-electron complexes centered on site having $4/mmm$ symmetry; surrounded by Na in 10-fold bicapped cubic configuration; one D site; lif: $2Na^+\cdot[PdH_2]^{2-}$; Pd^0, d^{10}; structure of Li_2PdH_2 from npd;[51] evidence for linear $[PtH_2]^{2-}$ complexes in quaternary Na_2PdH_2–Na_2PtH_4 system.[62]

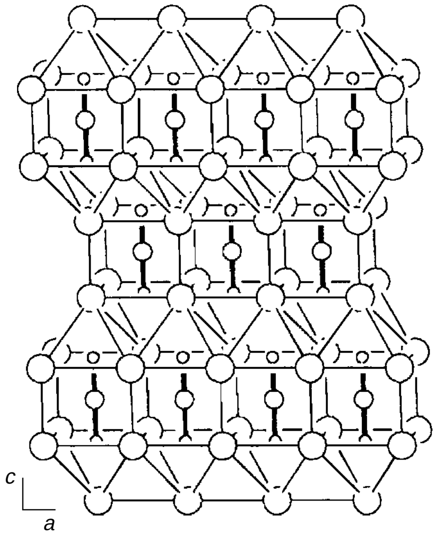

Figure 7 Structure of Na_2PdD_2

Distances (Å): Pd–D = (2×) 1.68 (Na), (2×) 1.67 (Li); Pd–Na(Li) = 3.13 (2.64); Pd–Pd = 3.60 (Na), 3.11 (Li); Na(Li)–D = 2.42 (2.03); D–D = 3.35 (Na), 2.85 (Li).

3.8 K_3PtH_5 (Rb_3PtH_5, Cs_3PtH_5, K_3PdH_5, Rb_3PdH_5, Cs_3PdH_5)

From binary alkali hydrides and platinum (palladium) sponge at 573–623 K under 0.8 bar (Pd compounds 70 bar) hydrogen;[63] colorless powders, sensitive to air and moisture; ordered structures (Figure 8) by npd on deuterides: $P4/mbm$, $Z = 2$; isostructural to Rb_3PdF_5; planar $[PtH_4]^{2-}$ (or $[PdH_4]^{2-}$) 16-electron complexes with T site symmetry *m.mm*; surrounded by two M sites in irregular ninefold configuration; two D sites, of which the twofold is octahedral surrounded by M^+ only; lif: $3M^+\cdot[TH_4]^{2-}\cdot H^-$; T = Pd^{II}, Pt^{II}, d^8; K_3PtH_5 decomposes at 673 K into K_2PtH_4 and KH; Rb_3PtH_5 and Cs_3PtH_5 transform reversibly above 615 and 465 K, respectively, into disordered cubic HT modifications with Cu_3Au type metal substructure ($Pm\bar{3}m$, $Z = 1$; H positions not refined); no evidence for such transitions in Pd compounds; ordered substitution on M sites leads to quaternary hydrides K_2RbPtH_5 and K_2CsPtH_5 (H positions not refined). Interatomic distances are given in Table 6.

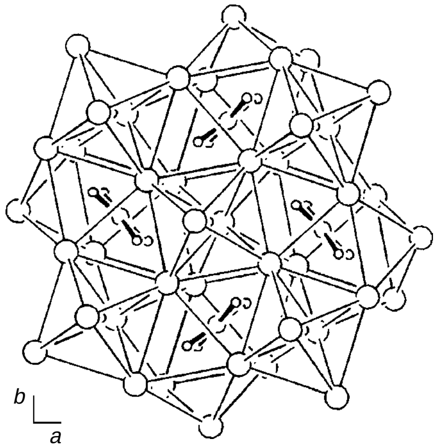

Figure 8 Structure of K_3PtD_5

3.9 K_3PdH_3 (Rb_3PdH_3, Cs_3PdH_3)

From KH and Pd sponge at 623 K under hydrogen; yellow powder at room temperature, orange-red at high temperature,[64] ordered structure (Figure 9) from npd on deuteride: $P4_2/mnm$, $Z = 8$; three Pd sites with ratios Pd1:Pd2:Pd3 = 1:1:2, each forming a linear $[PdH_2]^{2-}$ 14-electron complex having

3.11 Li_4RuH_6 (Na_4RuH_6, Li_4OsH_6)

From reactions of binary hydrides MH with T at 753 K and 10 bar hydrogen pressure;[72] no compound formation with KH and Fe up to 1073 K and 100 bar; Ru does not react with KH, and Os not with NaH and KH under experimental conditions; powders either white (Li) or green (Na); all air sensitive; ordered structures (Figure 11) from npd at room temperature on deuterides: $R\bar{3}c$, $Z = 6$ (hex setting), K_4CdCl_6 type structure; octahedral $[TH_6]^{4-}$ 18-electron complex with T site symmetry $\bar{3}$; surrounded by two M sites in nearly cubic configuration; one D site; lif: $4M^+ \cdot [TH_6]^{4-}$; T = Ru^{II}, Os^{II}, d^6. Interatomic distances are given in Table 8.

3.12 Na_3RhH_6 (Li_3RhH_6, Na_3IrH_6, Li_3IrH_6)

From powder mixtures of binary MH and Ir(Rh) at 630–770 K under hydrogen;[73] colorless powders, sensitive to air and humidity; Li_3RhH_6 forms either during decomposition of Li_3RhH_4[74] in hydrogen atmosphere or by sintering powder mixtures of LiH and Rh under 80 bar hydrogen pressure at 823 K;[75] ordered structures (Figure 12) from npd on deuterides[73,75] at 295 K (Na–Rh, Na–Ir, Li–Rh, Li–Ir) and 11 K (Na–Rh, Na–Ir); *Pnma*, $Z = 4$; isolated octahedral $[TH_6]^{3-}$ 18-electron complex with T site symmetry *m*; surrounded by three M sites in irregular 11-fold coordination; four D sites; no evidence for structural phase transition in Na_3RhH_6 and

Na_3IrH_6 down to 11 K and up to 670 K; lif: $3M^+ \cdot [TH_6]^{3-}$; T = Ir^{III}, Rh^{III}; d^6. Interatomic distances are given in Table 9.

3.13 Li_3RhH_4

From LiH and Rh powder at 870 K under hydrogen;[74] powder of metallic appearance; oxygen and moisture sensitive; corresponds to previously reported 'Li_4RhH_5' as characterized by X-ray diffraction on single crystals;[76] decomposes at high temperature under 80 bar hydrogen pressure into Li_3RhH_6 (XII); ordered structure (Figure 13) by npd on deuteride: *Cmcm*; $Z = 4$; planar $[RhH_4]^{3-}$ 16-electron complexes with T site symmetry $m2m$; surrounded by two Li sites in irregular 11-fold coordination; two D sites; lif: $3Li^+ \cdot [RhH_4]^{3-}$; Rh^I, d^8.

Table 9 Interatomic distances (Å) in Na_3RhD_6 and analogs

		T = Rh	T = Ir

	D–D	2.28	2.26

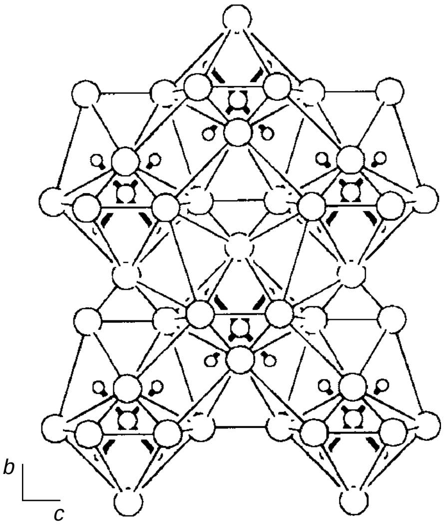

Figure 13 Structure of Li_3RhD_4

Distances (Å): Rh–D = 1.79(2×), 1.75(2×); Rh–Li = 2.31; Rh–Rh = 3.87(2×); Li–Li = 2.35; Li–D = 2.15; D–D = 2.21.

3.14 $MgRhH_{1-x}$

From binary alloy MgRh (CsCl-type structure) at 748 K and 130 bar hydrogen pressure;[77] powder of gray color and metallic appearance; partially disordered structure (Figure 14) by in situ npd at 39 bar, 2.5 bar and 10^{-2} mbar deuterium pressure: $P4/mmm$, $Z = 4$; one Rh and two Mg sites forming a tetragonal distorted CsCl-type structure with doubled a parameter ($2c/a = 1.012$ at 39 bar); one D site connecting

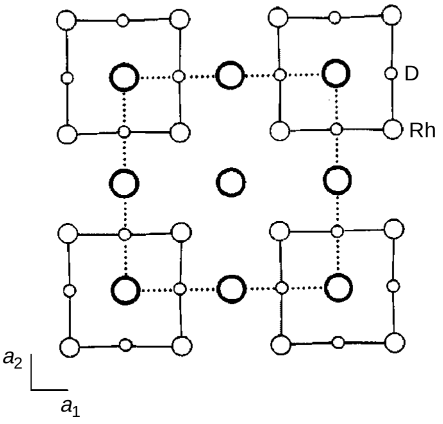

Figure 14 Structure of $MgRhD_{1-x}$

Rh into cyclic tetramer Rh_4D_4 having $4/mmm$ symmetry with nearly linear Rh–D–Rh and rectangular D–Rh–D bonds; occupancy of D site increasing as a function of D pressure (94% at 39 bar, 86% at 2.5 bar, 61% at 10^{-2} mbar), metal substructure resembles $CaPdH_2$ (X); likely phase limit near stoichiometric composition MgRhH; lif (border case) at that composition: $4Mg^{2+}\cdot[Rh_4H_4]^{8-}$; X-ray evidence for cubic $MgIrH_x$ phase ($a = 3.23$ Å) at high pressure with CsCl-type metal substructure.

Distances (Å) at 39 bar ($MgRhD_{0.94}$): Rh–D (2×) = 1.71; Mg–Rh = 2.66; Mg–D = 2.23; Rh–Rh = 2.98; Mg–Mg = 3.20; D–D = 2.36.

3.15 Mg_3RuH_3

From elements by sintering at 883 K under 9 bar hydrogen pressure;[78] dark gray powder, stable in air; partially disordered structure (Figure 15) by npd on deuteride: $P4_2/mnm$, $Z = 4$; Ru at center of orientationally disordered ts-RuH_3 units ($m.2m$ site symmetry) containing two D sites, one ordered and the other disordered (split atom position with D–D = 0.87 Å); surrounded by two Mg sites forming an eightfold bicapped prismatic coordination; joined to dimers of $m.mm$ site symmetry by possible Ru–Ru bond; lif: $3Mg^{2+}\cdot[RuH_3]^{6-}$ (monomer without Ru–Ru bond, 17 electrons/Ru); $6Mg^{2+}\cdot[Ru_2H_6]^{12-}$ (dimer with Ru–Ru bond, 18 electrons/Ru); Ru–Ru bond formation not supported by extended Hückel calculations.[12]

Distances (Å): Ru–D = 1.71 (split atom), 1.71 (2×); Mg–Ru = 2.73; Ru–Ru = 3.31; Mg–D = 2.01; Mg–Mg = 3.03; D–D = 0.87 (split atom), 2.52.

3.16 $SrMg_2FeH_8$ ($BaMg_2FeH_8$, $EuMg_2FeH_8$)

From binary alloys $SrMg_{2.2}$ ($BaMg_2$, $EuMg_2$) and Fe powder at 763–783 K under 140 bar hydrogen pressure;[66,79] green (Sr) or brownish (Ba) powder; sensitive to air; ordered structure (Figure 16) by npd on deuterides of Sr and Ba

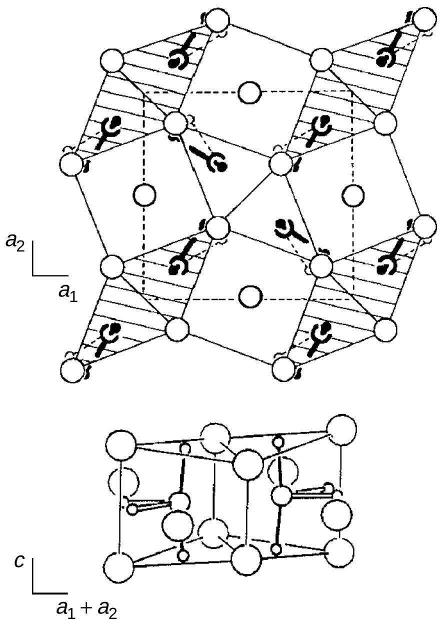

Figure 15 Structure of Mg_3RuD_3

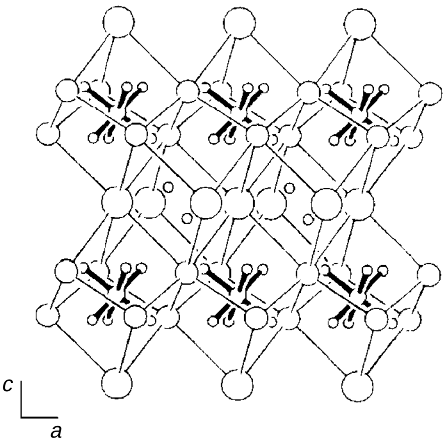

Figure 16 Structure of $SrMg_2FeD_8$

compounds: $P\bar{3}m1$, $Z = 1$; octahedral $[FeH_6]^{4-}$ 18-electron units having T site symmetry $\bar{3}m$, surrounded by eight M^{2+} in nearly cubic configuration; one Mg and one Sr(Ba) site; two D sites, of which the twofold is tetrahedrally coordinated by M^{2+} with one short Mg–D and three long Sr(Ba)–D bonds; lif: $M^{2+}\cdot 2Mg^{2+}\cdot[FeH_6]^{4-}\cdot 2H^-$; Fe^{II}, d^6. Ru analog $BaMg_2RuD_8$ (XXXVIII) crystallizes with tetragonal symmetry. Interatomic distances are given in Table 10.

3.17 $Mg_6Co_2H_{11}$

From elements by sintering at 753–773 K under 40–50 bar hydrogen pressure;[80] black powder, stable in air; nonmetallic; pressure–composition isotherms show two plateaus of

Table 10 Interatomic distances (Å) in $SrMg_2FeD_8$ and barium analog

	M = Sr	M = Ba
Fe–D	1.58	1.58
Fe–Mg	2.72	2.75
Fe–M	3.28	3.46

M–D	2.65	2.81
M–D^-	2.66	2.74
Mg–Mg	3.06	3.08
Mg–M	3.60	3.75
D–D	2.19	2.18

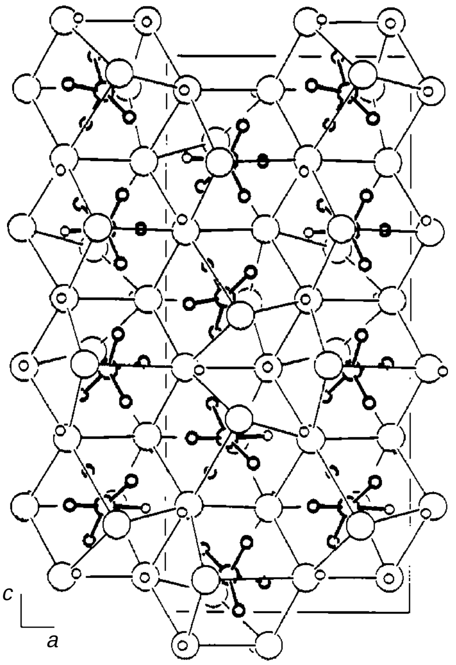

Figure 17 Structure of $Mg_6Co_2D_{11}$

which that at low pressure is attributed to decomposition of $Mg_6Co_2H_{11}$ ($\Delta H = 79\,kJ\,mol^{-1}$ H_2) and that at high pressure to decomposition of tetragonal Mg_2CoH_5 ($\Delta H = 79\,kJ\,mol^{-1}$ H_2);[81] partially disordered structure (Figure 17) from joint synchrotron X-ray and high-resolution npd:[80] *Pnma*, $Z = 8$, 63 positional parameters; two eightfold Co sites, one (Co1) forming an ordered sad-$[CoH_4]^{5-}$ 18-electron complex of symmetry 1, and the other (Co2) a partially disordered spy configuration with one half-occupied ligand; interpreted as a 1:1 mixture of spy-$[CoH_5]^{4-}$ and sad-$[CoH_4]^{5-}$ 18-electron complexes; surrounded by eight Mg sites in distorted cubic configurations; 14 D sites, of which five are surrounded by Mg in tri and sad configurations; metal substructure derives from trigonal $SrMg_2FeH_8$ (XVI) by orthorhombic distortion; short Mg–Mg bonds; lif: $2Mg_6Co_2H_{11} = 12Mg^{2+}\cdot[CoH_5]_{av}{}^{4-}\cdot2[CoH_4]^{5-}\cdot[CoH_4]_{av}{}^{5-}\cdot5H^-$; monoclinic distorted Ir analog $Mg_6Ir_2H_{11}$ (XLV) has different T–H complex ordering; other hydrides with similar metal substructure: Mg_3RuH_6 (XXV), Mg_3ReH_7 (XXIII), and $LiMg_2RuH_7$ (XXVII).

Distances (Å): Co1–D = 1.52–1.57, Co2–D = 1.51–1.62; Co–Co = 4.58; Co–Mg = 2.52; Mg–Mg = 2.78; Mg–D = 1.94; Mg–D^- = 1.82; D–D = 2.09.

3.18 Mg_2RuH_4

From the elements, by sintering at 723 K under 20 bar, or at 1050 K under 160 bar hydrogen pressure;[82] powder of reddish-brown to dark-red color, sensitive to moisture and air; ordered structure (Figure 18) from npd on deuteride: *Cmcm*, $Z = 4$; sad-$[RuH_4]^{4-}$ 16-electron complex with T site symmetry $m2m$, derives from the oct-$[RuH_6]^{4-}$ complex in Mg_2RuH_6 by removal of two cis D ligands; two D sites; surrounded by Mg in eightfold distorted cubic configuration, neighboring cubes share faces; possible Ru–Ru interactions across these faces (Ru–Ru = 3.24 Å) could lead to polyanionic $[RuH_4]_n{}^{4n-}$ zig-zag chains running along *c*; magnetic measurements consistent with d^8 low-spin configuration; lif: $2Mg^{2+}\cdot[RuH_4]^{4-}$ (monomer); Ru^0, d^8; $2nMg^{2+}\cdot[Ru_nH_{4n}]^{4n-}$ (polymer); Ru–Ru bonds not supported by extended Hückel calculations.[12]

Distances (Å) and angles: Ru–D = 1.67(2×), 1.68 (2×); D–Ru–D = 84.2°, 93.6° (cis), 170.3° (trans); Ru–Mg = 2.69; Ru–Ru = 3.24(2×); Mg–D = 2.10; Mg–Mg = 2.93; D–D = 2.23.

3.19 $CaMgNiH_4$ ($SrMgNiH_4$, $YbMgNiH_4$, $EuMgNiH_4$)

From mixtures of arc-melted binary alloys ($CaNi_2$, $CaMg_2$, SrNi, YbNi, EuNi) or Mg sintered at 723–763 K under

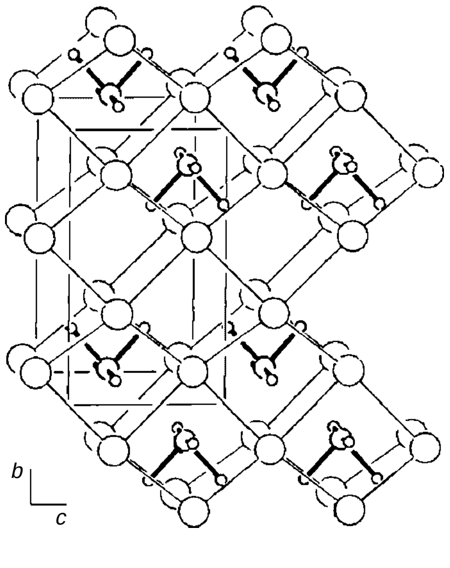

Figure 18 Structure of Mg_2RuD_4

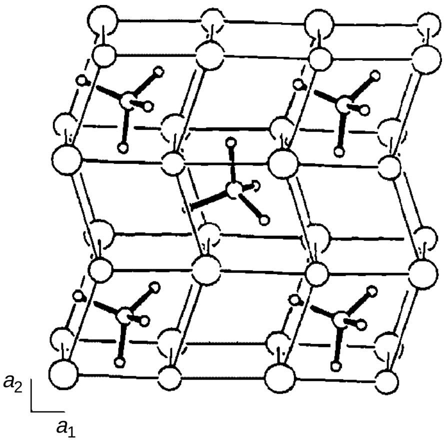

Figure 19 Structure of $CaMgNiD_4$

$M–D^-$	2.39	2.41
Mg–Mg	4.08	3.98
Mg–M	3.39	3.40
D–D	2.22	2.22

130–140 bar hydrogen pressure;[83] greenish (Ca, Sr) or black (Yb) powders; translucent single crystals of $CaMgNiH_4$ having yellow–brownish color obtained by sintering binary hydrides with LiH flux in Ni crucible at 737 K under 95 bar hydrogen pressure;[84] desorption enthalpy $\Delta H = 129(3)$ (Ca), 111(3) (Yb) $kJ\,mol^{-1}$ H_2; ordered structures (Figure 19) from npd on deuterides (Ca, Sr, and Yb[83]): $P2_13$, $Z = 4$; tetrahedral $[NiH_4]^{4-}$ 18-electron complex having T site symmetry 3, surrounded by one Ca (Sr, Yb) site, and one Mg site in ordered distorted cubic configuration; two D sites; derived from Mg_2NiD_4 (V) by partial substitution of Mg; lif: $M^{2+}{\cdot}Mg^{2+}{\cdot}[NiH_4]^{4-}$; Ni^0, d^{10}; X-ray evidence for isostructural $EuMgNiH_4$.[83] Interatomic distances are given in Table 11.

3.20 $Ca_4Mg_4Fe_3H_{22}$ ($Yb_4Mg_4Fe_3H_{22}$)

From mixtures of arc-melted binary alloys (CaMg, YbMg) and Fe powder, by adding LiH as a flux, at about 773–793 K under 100–150 bar hydrogen pressure;[85] $Ca_4Mg_4Fe_3H_{22}$: brownish powder containing brownish translucent single crystals; $Yb_4Mg_4Fe_3H_{22}$: black powder; both stable in air for several weeks; desorption enthalpies $\Delta H = 122(4)$ (Ca), 137(3) (Yb) $kJ\,mol^{-1}$ H_2; decomposition of Ca compound shows two plateaus: formation of Ca_2FeH_6, Mg, Fe, and H_2 (upper plateau), and of CaH_2, Fe, and H_2 (lower plateau); decomposition of Yb compound shows one plateau: formation of YbH_2, Mg, Fe, and H_2; ordered structures (Figure 20) from single-crystal X-ray ($Ca_4Mg_4Fe_3H_{22}$) and npd on deuterides; $P\bar{4}3m$, $Z = 1$; octahedral $[FeH_6]^{4-}$ 18-electron complexes with T site symmetry $\bar{4}2.m$, surrounded by one M and one Mg site in deformed cubic configuration; three D sites, of which the fourfold is tetrahedrally surrounded by one Mg^{2+} and three M^{2+}; derived from Mg_2FeH_6 (II) by partial substitution of Mg by Ca, and of every fourth $[FeH_6]^{4-}$ by $4\,H^-$; lif: $4M^{2+}{\cdot}4Mg^{2+}{\cdot}3[FeH_6]^{4-}{\cdot}4H^-$; Fe^{II}, d^6. Interatomic distances are given in Table 12.

3.21 Ba_2PtH_6 (Sr_2PtH_6)

From BaH_2 (SrH_2) and Pt powder in hydrogen;[86] ordered Ba_2CuF_6 type structure (Figure 21) from npd on deuteride: *Cmca*, $Z = 4$; planar $[PtD_4]^{2-}$ 16-electron complexes with T site symmetry $2/m$, surrounded by M in 10-fold bicapped cubic configuration; three D sites, of which one eightfold is tetrahedrally surrounded by M^{2+}; lif: $2M^{2+}{\cdot}[PtH_4]^{2-}{\cdot}2H^-$; Pt^{II}, d^8.

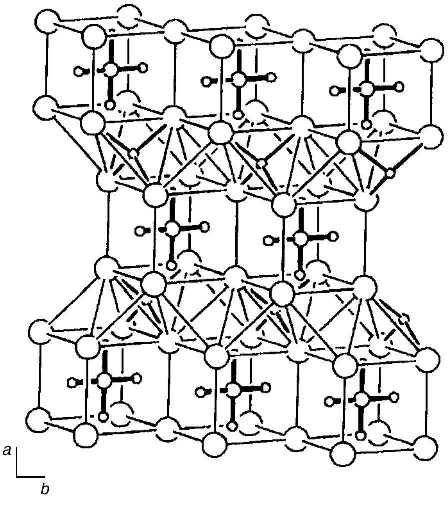

Figure 21 Structure of Ba_2PtD_6

Distances (Å): Pt–D = 1.66(2×) and 1.67 (2×); Pt–Ba = 3.63; Pt–Pt = 4.24; Ba–Ba = 4.09; Ba–D = 2.97; Ba–D^- = 2.62; D–D = 2.36.

3.22 $LiSr_2PdH_5$

From reaction of arc-melted ternary alloy $Li_{1.5}Sr_2Pd$ at 793–803 K under 155 bar hydrogen pressure;[87] dark-green powder, sensitive to air; partially disordered structure (Figure 22) from npd on deuteride at 14 K: $P4/mmm$, $Z = 1$; metals form ordered superstructure of CsCl; contains ordered $SrLiD_3$ type slabs having inverse perovskite-type structure; Pd surrounded by three D, on average, in partially disordered octahedral configuration with four half occupied equatorial D sites forming linear Pd–D–Pd bridges similar to those in $CaPdH_2$ (X), and two fully occupied axial sites belonging to the $SrLiD_3$ type slabs; both have large displacement amplitudes; three D sites, of which a twofold is octahedral surrounded by four Sr and two Li; lif: $Li^+ \cdot 2Sr^{2+} \cdot [PdH_3]_{av}{}^{3-} \cdot 2H^-$; Pd^0, d^{10} (average).

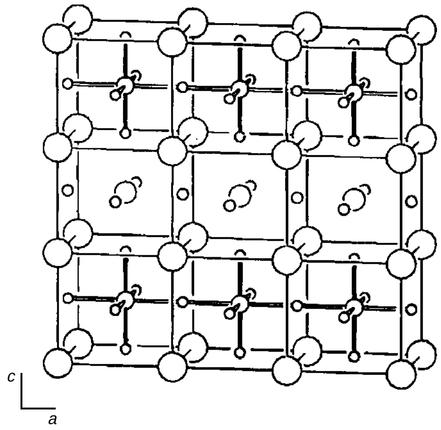

Figure 22 Structure of $LiSr_2PdD_5$

Distances (Å): Pd–D = 1.69(2×), 1.95 (4×, disordered); Pd–Sr = 3.34; Pd–Li = 3.70; Pd–Pd = 3.90; Li–D = 2.01; Li–D^- = 1.95; Li–Sr = 3.30; Sr–D = 2.71; Sr–D^- = 2.66; D–D = 2.58.

3.23 Mg_3ReH_7 (Mg_3MnH_7)

From elements by sintering powder mixtures at 783–793 K under 120 bar hydrogen pressure;[88] gray powder; sensitive to air; orange-red Mn analog Mg_3MnH_7 from powder mixtures of MgH_2 and Mn at 20 kbar pressure and 1073 K in multianvil device;[89] ordered structures (Figure 23) by npd on deuterides: $P6_3/mmc$, $Z = 2$; octahedral $[TH_6]^{5-}$ 18-electron complexes with T site symmetry $\bar{3}m$, surrounded by two Mg sites in eightfold distorted cubic configuration similar to that of $SrMg_2FeH_8$ (XVI); two D sites, of which the twofold is surrounded by Mg in trigonal bipyramidal configuration with two short collinear and three long triangular Mg–D bonds; lif: $3Mg^{2+} \cdot [TH_6]^{5-} \cdot H^-$; T^I, d^6; electronic band structure calculation on Mn compound.[90] Interatomic distances are given in Table 13.

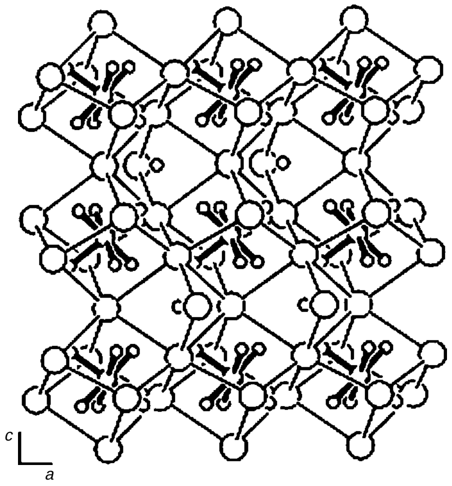

Figure 23 Structure of Mg_3ReD_7

Table 13 Interatomic distances (Å) in Mg_3ReD_7 and manganese analog

	T = Mn	T = Re
T–D	1.63	1.72

Mg–D^-	1.87	1.90
Mg–Mg	3.05	3.17
D–D	2.29	2.41

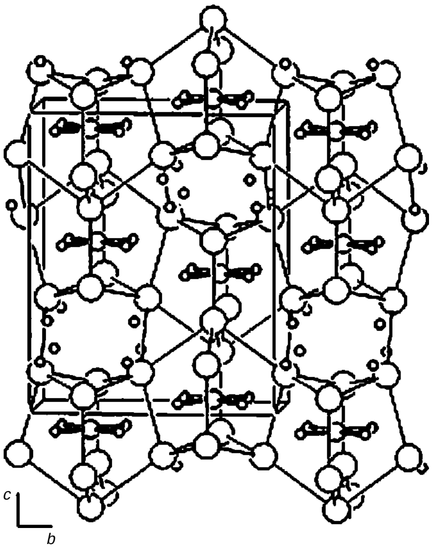

Figure 24 Structure of Mg_4IrD_5

3.24 Mg_4IrH_5

From elements by sintering powder mixtures at 783 K and 41 bar hydrogen pressure;[91] dark gray powder, stable in air; presumably metallic; partially disordered structure (Figure 24) from npd on deuteride at room temperature and 9 K: *Imma*, $Z = 4$; Ir surrounded by three D atoms, on the average, in disordered planar configuration with 75% occupancy (average T site symmetry *mm*2); surrounded by three Mg sites in irregular ninefold coordination; two D sites, of which the eightfold is coordinated by Mg in saddle-like configuration; short Mg–Mg bonds along backbone of $[Mg_9IrD_3]$ units; no apparent homogeneity range; lif (border case): $4Mg^{2+}\cdot[IrH_3]_{av}{}^{6-}\cdot 2H^-$.

Distances (Å): Ir–D = 1.70(4×, dis); Ir–Mg = 2.75; Ir–Ir = 4.62; Mg–Mg = 2.76; Mg–D = 2.15; Mg–D$^-$ = 1.88; D–D = 2.34.

3.25 Mg_3RuH_6

From elements by sintering powder mixtures at 1053 K under 90 bar hydrogen pressure;[92] powder of rusty-brown color, sensitive to moisture and air; partially disordered structure (Figure 25) from npd on deuteride at room temperature and 15 K: *Cmcm*, $Z = 4$; Ru surrounded by five D, on average, in disordered octahedral configuration (average T site symmetry $2/m$); equatorial sites have 75% and axial sites full occupancy; surrounded by two Mg sites in eightfold cubic configuration similar to Mg_3ReH_7 (XXIII); three D sites, of which the fourfold is coordinated by two Mg in linear configuration; no indication for D ordering down to 15 K; lif: $3Mg^{2+}\cdot[RuH_5]_{av}{}^{5-}\cdot H^-$; Ru^0, d^8 (average).

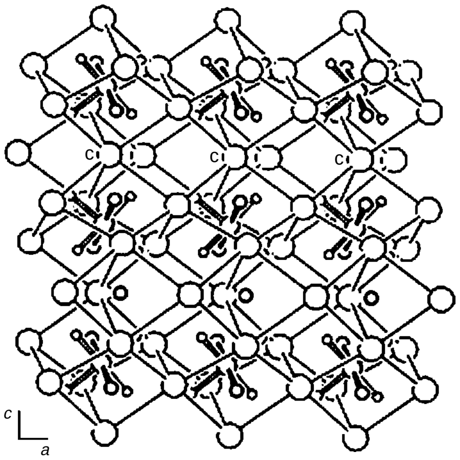

Figure 25 Structure of Mg_3RuD_6

Distances (Å): Ru–D = 1.66 (4×, dis), 1.73 (2×); Ru–Mg = 2.67; Ru–Ru = 4.79; Mg–Mg = 3.04; Mg–D = 1.91; Mg–D$^-$ = 1.87; D–D = 2.29.

3.26 $Sr_8Rh_5H_{23}$ ($Ca_8Rh_5H_{23}$)

From alkaline earth hydrides and rhodium metal by sintering powder mixtures at 1073 K under 5 bar hydrogen pressure;[46,47,93] powder of black-red (Sr) and black (Ca) color, sensitive to moisture and air; partially disordered, structure intermediate to anion deficient K_2PtCl_6 type (II) and perovskite type (Figure 26); from npd on deuterides (Sr, Ca)[46,93] at room temperature and 10 K: $Pm\bar{3}m$, $Z = 1$; three D sites of which two are terminal to Rh with full occupancies and one sixfold is bridging two Rh with partial occupancy (5/6); 3 Rh sites surrounded in octahedral configurations (site symmetries $m\bar{3}m$ and $4/mm.m$) by six ordered terminal (Rh1), six disordered (5/6 occupancy) bridging (Rh3), and four ordered terminal plus two disordered bridging (Rh2) deuterium sites, the two latter forming a quasi-infinite polynuclear $[Rh_4H_{17}]_n{}^{13n-}$ complex; one Sr (Ca) site surrounds Rh in eightfold cubic configuration; no indication for D ordering down to 10 K; lif: $8nM^{2+}\cdot n[RhH_6]^{3-}\cdot[Rh_4H_{17}]_n{}^{13n-}$ mixed valence Rh^I (d^8) and Rh^{III} (d^6). Interatomic distances are given in Table 14.

3.27 $LiMg_2RuH_7$ ($LiMg_2OsH_7$)

From LiH, Mg, and Ru (Os) powders at up to 823 K under hydrogen pressure of up to 155 bar;[94,95] light yellow powder; sensitive to air; ordered derivative of Mg_3ReH_7 type (XXIII) structure (Figure 27) by npd on deuteride of Ru compound: $P6_3/mmc$, $Z = 2$; octahedral $[RuH_6]^{4-}$ 18-electron units having T site symmetry $\bar{3}m$, surrounded by six Mg^{2+} and two Li^+ in nearly cubic configuration; one Mg and one Li site; two D sites, of which the twofold is trigonal

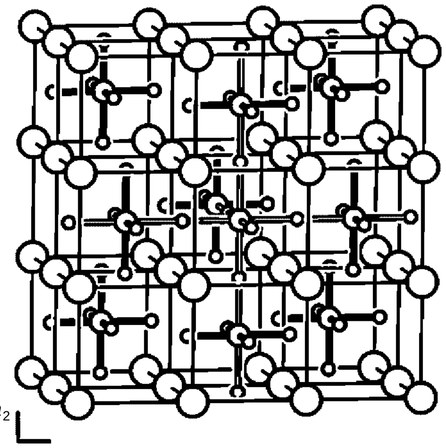

Figure 26 Structure of $Sr_8Rh_5D_{23}$

bipyramidal coordinated with two short linear Mg–D and three long triangular Li–D bonds; lif: $Li^+ \cdot 2Mg^{2+} \cdot [RuH_6]^{4-} \cdot H^-$; Ru^{II}, d^6.

Distances (Å): Ru–D = 1.69(6×); Ru–Mg = 2.83; Ru–Li = 2.67; Ru–Ru = 4.70; Mg–Li = 3.29; Mg–Mg = 3.17; Li–D = 2.14; Li–D^- = 2.71; Mg–D = 2.27; Mg–D^- = 1.85; D–D = 2.34.

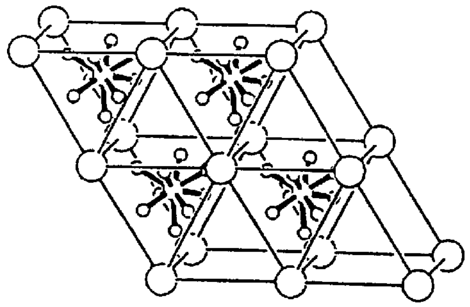

Figure 28 Structure of $BaReH_9$

3.28 $BaReH_9$

From di-sodium salt Na_2ReH_9 (obtained from reaction of $KReO_4$ with K metal in ethylene diamine–water solution) converted to the di-potassium salt by way of the Ba salt;[96] white powder, transparent crystals, unstable in moist air; ordered structure (Figure 28) from single-crystal X-ray diffraction, and IR and NMR data on hydride:[97] $P6_3/mmc$, $Z = 2$; Re site forming ttp-$[ReH_9]^{2-}$ 18-electron complexes with site symmetry $\bar{6}m2$; surrounded by Ba cations in NiAs type configuration; two H sites (not refined); lif: $Ba^{2+} \cdot [ReH_9]^{2-}$; Re^{VII}, d^0; electronic band structure by APW calculations.[98]

Interatomic distances (Å): Re–H ~ 1.69[a] (3× and 6×); Re–Ba = 3.84; Re–Re = 5.29; Ba–Ba = 4.66; Ba–H = 2.71[a], 2.86; H–H ~ 1.97[a] (distances not refined).

3.29 K_2ZnH_4 (Rb_2ZnH_4, Cs_2ZnH_4, Sr_2PdH_4, Ba_2PdH_4, Eu_2PdH_4)

M_2ZnH_4 (M = K, Rb, Cs) from elements by sintering powder mixtures at 783–793 K under 120 bar hydrogen pressure;[99,100] M_2PdH_4 (M = Sr, Ba,[101] Eu[102]), from elements gray powder; sensitive to air; ordered structure (Figure 29) by npd on deuteride: *Pnma*, $Z = 2$; β-K_2SO_4 type structure, tetrahedral $[ZnH_4]^{2-}$ 18-electron complexes with T site symmetry *m* surrounded by two M sites in eightfold distorted square antiprismatic configuration; three D sites; evidence for nonconducting behavior of Sr_2PdH_4 and Ba_2PdH_4 (measurement on powdered hydrides);[101] electronic band structure on Eu_2PdH_4;[103] lif: $2K^+ \cdot [ZnH_4]^{2-}$; Zn^{II}, d^{10}; $2M^{2+} \cdot [TH_4]^{4-}$, Pd^0, d^{10}. Interatomic distances are given in Table 15.

3.30 K_3ZnH_5 (Rb_3ZnH_5, Cs_3ZnH_5, Cs_3CdH_5, K_3MnH_5, Rb_3MnH_5, Cs_3MnH_5)

M_3ZnH_5 (M = K, Rb, Cs) from elements by sintering powder mixtures at 783–793 K under 120 bar hydrogen pressure;[104,105] M_3MnH_5 (M = Sr, Ba) from alkali metal hydrides and Mn powder at 875 K and 3 kbar H_2 gas pressure,[106,107] Cs_3CdH_5[108] from elements, gray (Zn, Cd) and rose colored (Mn) powders; sensitive to air; ordered structure (Figure 30) by npd on deuteride: *I4/mcm*, $Z = 4$; Cs_3CoCl_5 type structure, tetrahedral $[TH_4]^{2-}$ 18-electron complexes with T site symmetry $\bar{4}2m$ surrounded by two M sites in an eightfold configuration; two D sites, of which the fourfold is surrounded by M in octahedral configuration; arrangement of H^- and $[TH_4]^{2-}$ complexes similar to that in K_3PtH_5 (VIII); vibrational spectroscopy of Rb_3ZnH_5;[54] lif: $3M^+{\cdot}[TH_4]^{2-}.H^-$; Zn^{II}, d^{10}; Cd^{II}, d^{10}; Mn^{II}, d^5; Mn compounds order magnetically below 50 K.[9] Interatomic distances are given in Table 16.

3.31 $Ba_3Ir_2H_{12}$

From powder mixtures of BaH_2 and Ir at 837 K and 80 bar hydrogen pressure;[109] white powder, sensitive to air; ordered structure (Figure 31) from npd on deuteride at room temperature; $P\bar{3}m1$, $Z = 1$; octahedral $[IrH_6]^{3-}$ 18-electron complex with Ir site symmetry $3m$; surrounded by two Ba sites in irregular sevenfold coordination; two D sites; lif: $3Ba^{2+}{\cdot}2[IrH_6]^{3-}$, Ir^{III}, d^6.

Distances (Å): Ir–D = 1.60(3×) and 1.76 (3×); Ir–Ba = 3.30; Ir–Ir = 5.43; Ba–D = 2.72; D–D = 2.25.

disordered structures (Figure 32) from npd on deuterides and single-crystal X ray on $Ca_4Mg_4Co_3H_{19}$; $P\bar{4}3m$, $Z = 1$; derives from Fe analog $Ca_4Mg_4Fe_3H_{22}$ (XX) by substitution of oct $[FeH_6]^{4-}$ by spy $[CoH_5]^{4-}$ 18-electron complexes; apical Co ligands disordered (half occupancy), Co site symmetry $\bar{4}2.m$, surrounded by Mg and Ca (Yb) sites in deformed cubic configuration; three D sites, of which one anionic D^- tetrahedral surrounded by one Mg^{2+} and three M^{2+}; derives from Mg_2CoH_5 (III) by partial substitution of Mg by Ca, and of every fourth $[CoH_5]^{4-}$ by 4 H^-; lif: $4M^{2+}\cdot 4Mg^{2+}\cdot 3[CoH_5]_{av}^{4-}\cdot 4H^-$; Co^I, d^8. Interatomic distances are given in Table 17.

3.33 $KNaReH_9$

Translucent crystals obtained from di-sodium salt Na_2ReH_9[96] by slow evaporation of a solution in KOH; unstable in moist air; ordered structure (Figure 33) from single-crystal X-ray diffraction at 193 K, and IR data:[111] *Pnma*, $Z = 4$; Re site forming ttp-$[ReH_9]^{2-}$ 18-electron complexes with site symmetry *m*; surrounded by K and Na cations in

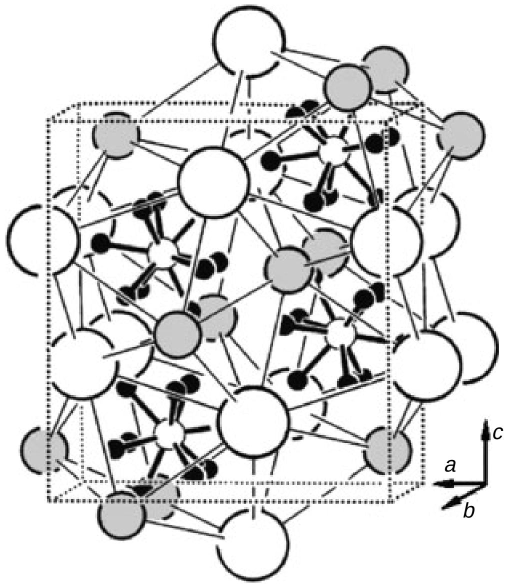

Figure 33 Structure of $KNaReH_9$

TiNiSi type metal configuration; six H sites (not refined); lif: $K^+.Na^+\cdot[ReH_9]^{2-}$; Re^{VII}, d^0.

Interatomic distances (Å): Re–H = 1.69–1.71[a]; Re–Na = 3.35; Re–K = 3.69; Re–Re = 5.33; Na–Na = 4.00; Na–K = 4.01; K–K = 4.49; Na–H = 2.33[a]; K–H = 2.61[a]; H–H = 1.73[a] (not refined).

3.34 $Li_5Pt_2H_9$

From reaction of LiH and Pt at 1250 bar H_2 pressure and 820 K;[112] anthracite colored caked solid, sensitive to air and moisture; ordered structure (Figure 34) from npd on deuteride: *I*4/*mcm*, $Z = 4$; contains $[Pt_2H_9]^{5-}$ dimer with *m.mm* symmetry in which four D surround each Pt in spl configuration and one D bridges two Pt; 2 Li sites; diamagnetic; lif: $5M^+\cdot[T_2H_9]^{5-}$; Pt^{II}, d^8.

Distances (Å): Pt–D = 1.64(4×), 1.85; Pt - Li = 2.64; Pt–Pt = 3.71; Li–D = 2.13; D–D = 2.28.

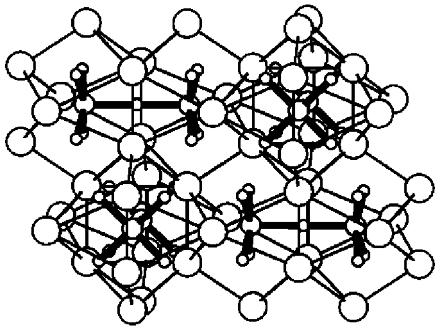

Figure 34 Structure of $Li_5Pt_2D_9$

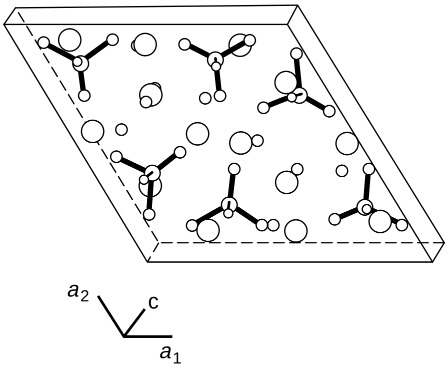

Figure 35 Structure of $Ba_7Cu_3D_{17}$

3.35 $Ba_7Cu_3H_{17}$

By hydrogenation of Ba–Cu alloys at 10 bar H_2 pressure and room temperature, followed by annealing at 643 K under 160 bar H_2 pressure;**[113]** dark brownish powder sensitive to air and moisture; ordered structure (Figure 35) from npd on deuteride: $P31c$, $Z = 2$; contains distorted 18-electron tet-$[CuD_4]^{3-}$ complexes (symmetry 1) surrounded by nine Ba (three sites) in ttp configuration; seven D sites, of which three anionic D^- tetrahedral surrounded by four M^{2+}; lif: $7Ba^{2+}{\cdot}3[CuH_4]^{3-}.5H^-$; Cu^I, d^{10}.

Distances (Å): Cu–D = 1.64–1.75; Cu–Ba = 3.19; Cu–Cu = 5.07; Ba–D = 2.36; Ba–D^- = 2.59; D–D = 1.94.

3.36 $LiMg_4Os_2H_{13}$ ($LiMg_4Ru_2H_{13}$)

By sintering of mixtures of LiH, Mg, and Os (Ru) powders at up to 833 K under hydrogen pressure between 70 and 155 bar;**[95]** powders having light green (low pressure) and grey (high pressure) color; sensitive to air; Os sample pyrophoric; ordered structure (Figure 36) by npd on deuteride of Os compound: $P6_3/mmc$, $Z = 2$; octahedral $[OsH_6]^{4-}$ 18-electron units having T site symmetry $3m$ surrounded by six Mg^{2+} and two Li^+ in nearly cubic configuration; one Mg and one Li site; three D sites, of which an anionic D^- in trigonal bipyramidal coordination with two short linear Mg–D and three long triangular Li–D bonds; structure derives from Mg_2OsH_6 by intercalation of LiH sheets; intermediate between Mg_2OsH_6 (II) and $LiMg_2OsH_7$ (XXVII); lif: $Li^+{\cdot}4Mg^{2+}{\cdot}2[TH_6]^{4-}{\cdot}H^-$; Os^{II}, d^6.

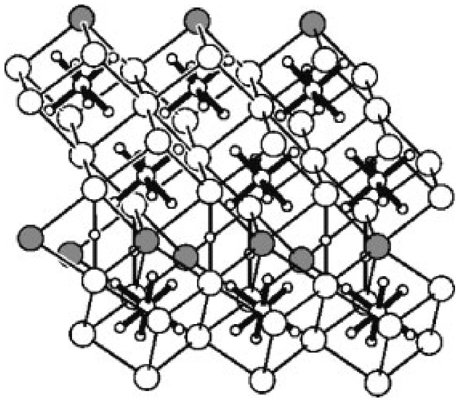

Figure 36 Structure of $LiMg_4Os_2D_{13}$

Distances (Å): Os–D = 1.69(3×) and 1.70 (3×); Os–Li = 2.69; Os–Mg = 2.85; Mg–Li = 3.31; Mg–Mg = 3.26; Li–D = 2.13; Li–D^- = 2.73; Mg–D = 2.24; Mg–D^- = 1.87; D–D = 2.31.

3.37 Li_2PtH_2

By thermal decomposition of $Li_5Pt_2H_9$ (XXXIV) at 493 K under argon;**[114]** ordered structure (Figure 37) from npd on deuteride: $Immm$, $Z = 2$; contains linear $[PtD_2]^{2-}$ 14-electron complexes with mmm symmetry; orthorhombic distortion of tetragonal Pd analog Li_2PdH_2 (VII); lif: $2Li^+{\cdot}[PtH_2]^{2-}$; Pt^0, d^{10}.

Distances (Å): Pt–D = 1.64(2×); Pt–Pt = 2.99; Pt–Li = 2.61; Li–Li = 2.75; Li–D = 2.01; D–D = 2.82.

3.38 $BaMg_2RuH_8$ ($BaMg_2OsH_8$)

By sintering powder mixtures of $BaMg_2$ alloy, BaH_2, and Ru with LiH flux at temperatures of up to 803 K and H_2 pressures of up to 150 bar;**[115]** greenish powder;

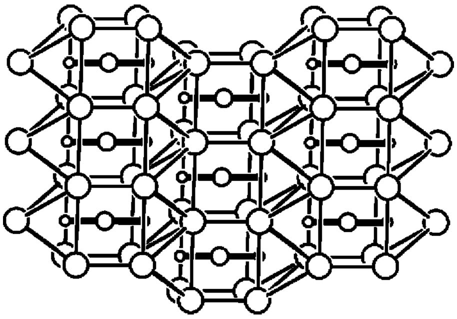

Figure 37 Structure of Li_2PtD_2

ordered structure (Figure 38) by npd on deuterides of Ru and Os compounds at room temperature: $P4_2/mmc$, $Z = 2$; octahedral $[TH_6]^{4-}$ 18-electron units having T site symmetry $\bar{4}m2$ surrounded by four Mg^{2+} and four Ba^{2+} forming two interpenetrating tetrahedral; similarity to iron analog $BaMg_2FeH_8$ (XVI); three D sites, of which one hydridic D^- is tetrahedral coordinated by two Ba and two Mg; lif: $Ba^{2+}\cdot 2Mg^{2+}\cdot[TH_6]^{4-}\cdot 2H^-$; T^{II}, d^6. Interatomic distances are given in Table 18.

3.39 $NaBaPdH_3$

By sintering of compacted powder mixtures of NaH, BaH_2, and Pd at temperatures of up to 783 K under H_2 pressures of 90 bar;[116] solid having metallic luster, sensitive to air and moisture, contains ruby-red single crystals; ordered structure (Figure 39) from single-crystal X-ray diffraction on hydride and npd on deuteride: $P6_3/mmc$, $Z = 2$; contains trigonal planar $[PdH_3]^{3-}$ 16-electron complexes with $\bar{6}m2$ symmetry; surrounded by five Ba in trigonal bipyramidal configuration; one Pd site, one Na site, one Ba site and one D site;

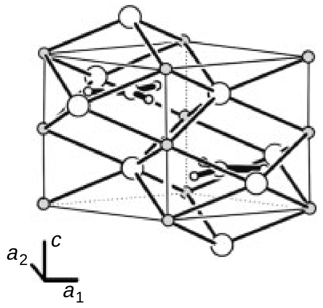

Figure 39 Structure of $NaBaPdD_3$

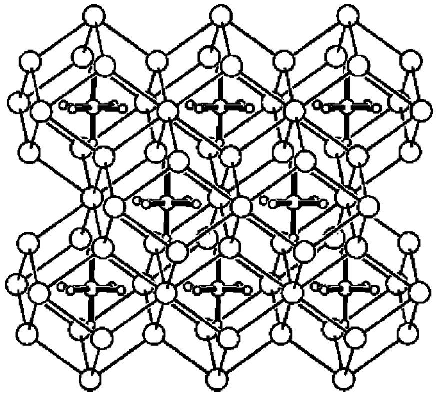

Figure 40 Structure of K_3ReD_6

lif: $Na^+\cdot Ba^{2+}\cdot[PdH_3]^{3-}$; Pd^0, d^{10} (supported by ac-magnetic susceptibility measurements).

Distances (Å): Pd–D = 1.72(3×); Pd–Ba = 3.04; Pd–Na = 3.81; Pd–Pd = 4.63; Ba–Na = 3.81; Na–Na = 3.04; Na–D = 2.33; Ba–D = 3.03; D–D = 2.98.

3.40 K_3ReH_6

By hydrogenation of powder mixtures of KH and Re at 850 K and H_2 pressures of up to 3500 bar.[117] Reaction product has olive green color, is unstable in air and moisture, and decomposes under vacuum; ordered structure (Figure 40) from npd on deuteride: cubic variant of cryolite type (K_2NaAlF_6), $Fm\bar{3}m$, $Z = 4$; Re site forming oct-$[ReH_6]^{3-}$ 16-electron complexes with site symmetry $m\bar{3}m$; surrounded by 14 K^+ forming a bicapped cuboctahedron (of which the closest K^+, site K1, in eightfold cubic configuration); lif: $3K^+\cdot[ReH_6]^{3-}$; Re^{III}, d^4 (consistent with experimentally measured weak temperature independent paramagnetism).

Distances (Å): Re–D = 1.71(6×); Re–D = 3.73; Re–Re = 6.10; K–D = 2.60; K–K = 3.73; D–D = 2.41.

3.41 $Ca_8Rh_6H_{24}$

From calcium hydride and rhodium metal by sintering powder mixtures at temperatures of up to 1133 K under

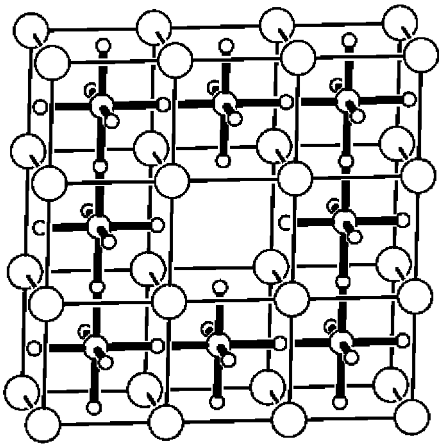

Figure 41 Structure of $Ca_8Rh_6D_{24}$

5 bar hydrogen pressure;[93] powder of metallic brass-like appearance, sensitive to moisture and air; ordered structure (Figure 41) closely related to partially disordered more Rh poor $Ca_8Rh_5H_{23}$ (XXVI), intermediate to anion deficient K_2PtCl_6 type (II) and perovskite type; from npd on deuteride: $Im\bar{3}m$, $Z = 1$; three-dimensional network of Rh centered, corner-sharing D octahedra (site symmetry 4/*mm.m*) consisting of four bridging (D2) and two terminal (D1); Ca surrounds octahedra in eightfold cubic configuration; lif: $4nCa^{2+}\cdot[Rh_3H_{12}]_n{}^{8n-}$, mixed valence Rh'1.33'

Distances (Å): Rh–D = 1.73(2×) and 1.82 (4×); Rh–Ca = 3.15; Rh–Rh = 3.64; Ca–D = 2.58; Ca–Ca = 3.64; D–D = 2.51.

3.42 Rb_3ReH_{10} (K_3ReH_{10}, Cs_3ReH_{10})

By hydrogenation of powder mixtures of alkali hydrides and Re up to 870 K and H_2 pressures of up to 3500 bar (K,[9,118] Rb,[118] Cs[119]); reaction products are light grey and unstable in air and moisture; disordered structure (Figure 42) from npd on Rb deuteride: cubic room temperature variant: $Pm\bar{3}m$, $Z = 1$; described as ReO_3 type framework containing strongly disordered $[ReH_9]^{2-}$ 18-electron complexes (average site symmetry $m\bar{3}m$) with two 24-fold disordered D sites (occupancies 0.187 and 0.194), and hydride anions H^- in octahedral M^+ environment; transforms below 110 K into presumably ordered ttp-$[ReH_9]^{2-}$ complexes (described as 'monocapped square antiprisms'[9,118]) having rhombohedral symmetry; lif: $3M^+\cdot[ReH_9]^{2-}\cdot H^-$; Re^{VII}, d^0 (consistent with experimentally measured diamagnetism on Rb compound).

Distances for disordered structure (Å): Re–D = 1.70 (24×, dis) and 1.71 (24×, disordered); Re–Rb = 4.18; Rb–Rb = 4.18; Re–Re = 6.10; Rb–D = 2.83; Rb–D^- = 2.96; D–D = 0.58 (dis).

3.43 Na_3OsH_7 (Na_3RuH_7)

By sintering powder mixtures of NaH and Os (Ru) at temperatures of up to 870 K and H_2 pressures of up to 1500 (Os) and 6000 (Ru) bar.[120] ordered structure (Figure 43) by npd on deuteride of Os compounds at room temperature: $P4_2/mnm$, $Z = 4$; contains isolated distorted pentagonal bipyramid $[OsH_7]^{3-}$ 18-electron units having Os site symmetry $m.2m$ surrounded by eight Na^+ (from two Na sites) forming a distorted cube; four D sites; transforms into a HT modification at 459 K; lif: $3Na^+\cdot[TH_7]^{3-}$, T^{IV}, d^4 (supported by experimentally measured weak temperature independent paramagnetism on Os compound). Diffraction evidence[120] for the existence of cubic phases $M_{3-\delta}$ $TH_{7-\delta}$ (M = K, Rb, Cs; T = Ru, Os; $\delta \sim 0.12$ for the K–Ru compound).

Distances (Å): Os–D = 1.62–1.70; Na–Os = 3.15; Os–Os = 5.35; Na–D = 2.21; Na–Na = 3.12; D–D = 1.84.

3.44 Cs_3OsH_9 (Rb_3OsH_9)

By sintering powder mixtures of alkali hydrides and Os under conditions similar to Na_3OsH_7 (XLIII).[120] Partially disordered structure (Figure 44) by npd on deuteride of Cs compound at room temperature: $Pm\bar{3}m$, $Z = 1$; contains

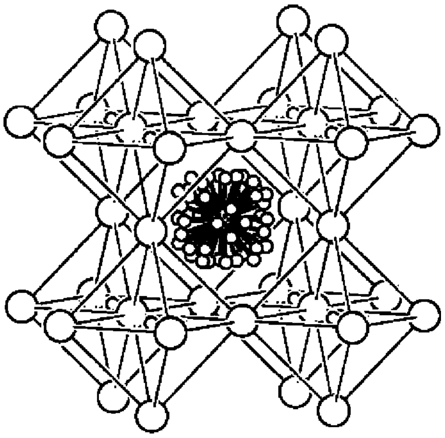

Figure 42 Structure of Rb_3ReD_{10}

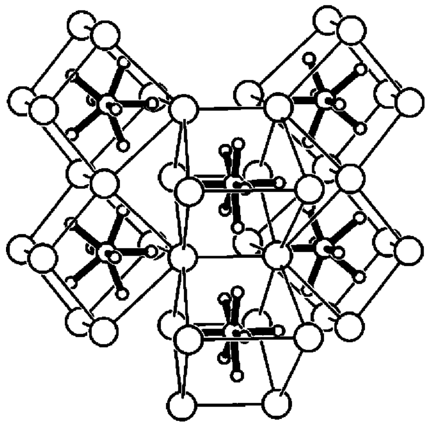

Figure 43 Structure of Na_3OsD_7

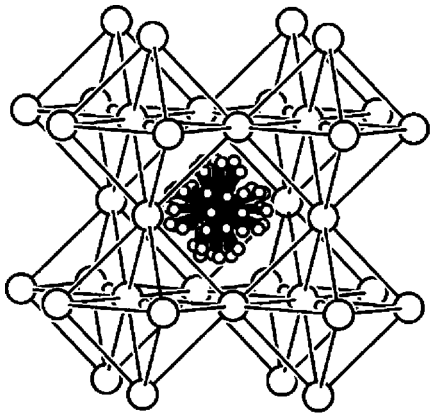

Figure 44 Structure of Cs_3OsD_9

isolated $[OsH_8]^{3-}$ 18-electron units having strongly disordered D ligands at room temperature as described by two partially occupied 24-fold D sites (occupancy = 1/6, not refined), and one D^- site in octahedral M^+ surrounding; Os (average site symmetry $m\bar{3}m$) surrounded by eight M^+ in cubic configuration; lif: $3M^+ \cdot [OsH_8]_{av}{}^{2-}.H^-$; Os^{VI}, d^2.

Distances (Å): Os–D = 1.59 (24×, dis) −1.70 (24×, dis); Os–Cs = 4.33; Os–Os = 6.13; Cs–D = 2.91; Cs–D^- = 3.06; Cs–Cs = 4.33; D–D = 0.70 (dis).

3.45 $Mg_6Ir_2H_{11}$

From either hydrogenated binary Mg_3Ir alloy or by sintering powder mixtures of the elements at up to 773 K under a H_2 pressure of up to 150 bar.[121] Red colored hydride; partially disordered structure (Figure 45) from npd on deuteride,: $P2_1/c$, $Z = 8$; contains four symmetry independent Ir hydride complexes: a spy $[IrH_5]^{4-}$ and three sad $[IrH_4]^{5-}$ complexes of which two are disordered, and five hydride anions are exclusively bonded to Mg; all complexes are surrounded by Mg in distorted cubic configurations; metal substructure represents a monoclinic distortion of orthorhombic Co analog $Mg_6Co_2D_{11}$ (XVII); lif: $12Mg^{2+} \cdot [IrH_5]^{4-} \cdot [IrH_4]^{5-} \cdot 2[IrH_4]_{av}{}^{5-} \cdot 5H^-$; mixed valence Ir^I, d^8 and Ir^{-I}, d^{10}.

Distances (Å): Ir1–D = 1.67–2.07, Ir2–D = 1.66–1.74, Ir1a–D = 1.67–1.99, Ir2a–D = 1.64–1.90; Ir–Mg = 2.65; Ir–Ir = 4.62; Mg–Mg = 2.79; Mg–D = 1.79; Mg–D^- = 1.74; D–D = 2.11.

3.46 $NdMgNi_4H_{3.6}$ ($LaMgNi_4H_{\sim 3.6}$)

From hydrogenation of intermetallic compounds $NdMgNi_4$ and $LaMgNi_4$ at 323 K under H_2 pressure of up to 7–8 bar;[122] metallic powders decompose in air by catalytic water formation; nearly ordered structure of $NdMgNi_4H_{3.6}$ (Figure 46) from npd on deuteride; $Pnm2_1$, $Z = 4$; contains three Ni sites and three almost fully occupied D sites (occupancies 0.89–0.92) forming $[Ni_4H_{\sim 4}]^{5-}$ tetramers in which three edges and one face of the Ni tetrahedron is bridged by hydrogen; tetramers are surrounded by monocapped trigonal prisms formed by four Nd and three Mg; lif: $M^{3+} \cdot Mg^{2+} \cdot [Ni_4H_{\sim 4}]^{5-}$.

Distances (Å): Ni–D = 1.64–1.72; Ni–Ni = 2.44; Ni–Mg = 2.83; Ni–Nd = 2.90; Mg–Mg = 4.92; Mg–Nd = 3.14; Mg–D = 2.17; Nd–Nd = 4.98; Nd–D = 2.34; D–D = 2.47.

3.47 $LaMg_2NiH_7$

From hydrogenation of ternary metal compound $LaMg_2Ni$ below 473 K under H_2 pressure of up to 8 bar;[123] dark grey colored powder sable in air; ordered structure (Figure 47) from npd on deuteride: $P2_1/c$, $Z = 8$; contains two symmetry independent tet-$[NiH_4]^{4-}$ 18-electron complexes having eight terminal D atoms, and six hydride anions bonded to two Mg and two La only; Ni (site symmetry 1) surrounded by three La (two sites) and six Mg (four sites) in monocapped square antiprismatic configuration;

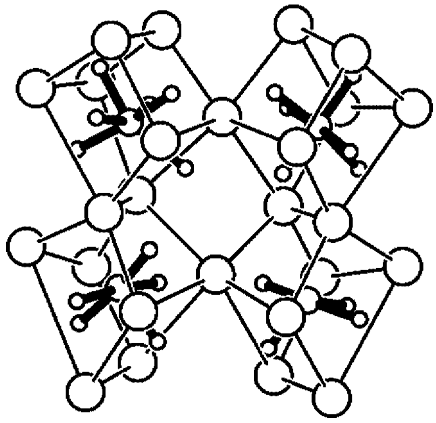

Figure 45 Structure of $Mg_6Ir_2D_{11}$

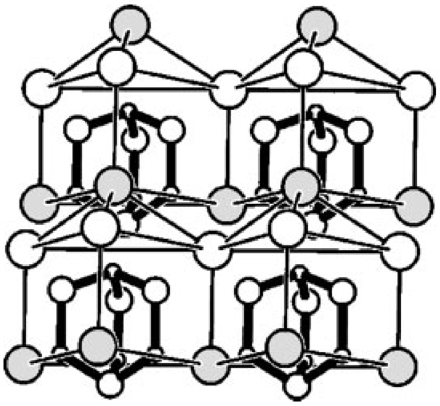

Figure 46 Structure of $NdMgNi_4D_{\sim 4}$

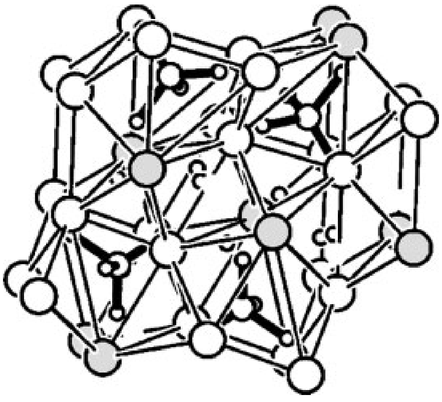

Figure 47 Structure of $LaMg_2NiD_7$

lif: $La^{3+}\cdot 2Mg^{2+}\cdot[NiH_4]^{4-}\cdot 3H^-$; Ni^0, d^{10}; hydride is nonmetallic; provides example for hydrogation induced metal ($LaMg_2Ni$) – to – nonmetal ($LaMg_2NiH_7$) transition.

Distances (Å): Ni1–D = 1.49–1.63, Ni2–D = 1.48–1.63; Ni–Mg = 2.59; Ni–La = 3.36; Ni–Ni = 4.14; Mg–Mg = 3.02; Mg–La = 3.42; La–La = 4.06; Mg–D = 1.94; $Mg–D^-$ = 1.82; La–D = 2.39; $La–D^-$ = 2.33; D–D = 2.12.

4 CRYSTAL CHEMISTRY

4.1 Hydride Complexes

Occurrence. At present, some 50 different homoleptic hydride complexes have been identified in over 127 compounds that cover 47 structure types. Their occurrence across the 3d, 4d, and 5d transition metal series is summarized in Table 19. The complexes form with transition elements from group seven (Mn), eight (Fe), nine (Co) and ten (Ni), to closed d-shell elements of group eleven (Cu) and twelve (Zn). Hydride complexes have not been characterized as yet for elements of group four (Ti), five (V) and six (Cr), and none for Ag, Au, and Hg. Interestingly, most complexes contain T-metals that do not form stable binary hydrides such as iron, cobalt, and congeners, or form relatively unstable hydrides such as nickel and congeners. While the great majority of complexes are centred by one T-metal atom ('mononuclear' complexes) and display terminal hydrogen ligands only, some are centred by two (Ru, Pt), four (Rh, Ni) or more (Ru, Rh) and display both terminal and bridging hydrogen ligands, and/or T–T metal–metal bonds ('polynuclear' complexes).

Mononuclear Complexes. They show at least 10 different geometries that are represented in Table 20. They range from tricapped trigonal prismatic (e.g. $[ReH_9]^{2-}$), pentagonal bipyramidal (e.g. $[OsH_7]^{3-}$), octahedral (e.g. $[FeH_6]^{4-}$, $[ReH_6]^{3-}$), square pyramidal (e.g. $[CoH_5]^{4-}$), planar (e.g. $[RhH_4]^{3-}$), tetrahedral (e.g. $[NiH_4]^{4-}$), saddle-like (e.g. $[IrH_4]^{5-}$), triangular (e.g. $[PdH_3]^{3-}$), T-shaped (e.g. $[RuH_3]^{6-}$) to linear (e.g. $[PdH_2]^{2-}$). Generally speaking, the ligand geometries resemble those of transition metals in 'inorganic molecules[124]'and coordination compounds such as metal carbonyls and cyanides, and are consistent with conventional electron counts, that is, they are octahedral (usually 18 electrons and d^6), such as $Mo(CO)_6$; square planar (usually 16 electrons, d^8), such as $Ni(CN)_4{}^{2-}$; square pyramidal (18 electrons, d^8), such as $[Ni(CN)_5]^{3-}$; saddle-like, such as the binuclear nonbridged structure of $Co_2(CO)_8$ (formally 17 electrons, d^9) or the trinuclear structure of $Ru_3(CO)_{12}$ (formally 16 electrons, d^8); tetrahedral (usually 18 electrons, d^{10}), such as $Ni(CO)_4$; or linear (usually 14 electrons, d^{10}), such as the usual ligand geometry of Ag^I (d^{10}) and congeners. Complexes having less than 13 electrons or more than 18 electrons have not yet been reported. The tetrahedral 13-electron $[MnH_4]^{2-}$ complex in K_3MnH_5 (XXX) is remarkable because it displays a half-filled d shell and leads to a pink colored hydride that orders magnetically. Other interesting cases are the T-shaped formally 17-electron $[RuH_3]^{6-}$ complex in Mg_3RuH_3 (XV) and the saddle-like formally 16-electron $[RuH_4]^{4-}$ complex in Mg_2RuH_4 (XVIII), because they provides possible links to polynuclear complexes (see below). Some complex geometries represent only averages such as $[CoH_4]_{av}{}^{5-}$, $[RuH_5]_{av}{}^{5-}$, $[OsH_8]_{av}{}^{2-}$ (not included in Table 20), $[PdH_3]_{av}{}^{3-}$, and $[IrH_3]_{av}{}^{6-}$ (not included in Table 20), because of structural disorder. A five-coordinate trigonal bipyramidal hydrogen configuration similar to the ligand geometry in $Fe(CO)_5$ has not yet been reported. The presumably square antiprismatic configuration in Cs_3OsH_9 (XLIV) has not yet been ascertained.

Some T-metals adopt one type of ligand geometry only, such as Fe that forms exclusively oct-$[FeH_6]^{4-}$ complexes (occurring in three hydride structure types, see Table 19), while others adopt two geometries, such as Co that forms sad-$[CoH_4]^{5-}$ and spy-$[CoH_5]^{4-}$ complexes (either ordered or disordered), or three or more geometries, such as Ru that forms five: ts-$[RuH_3]^{6-}$, sad-$[RuH_4]^{4-}$, spy-$[RuH_5]_{av}{}^{4-}$, oct-$[RuH_6]^{4-}$, and pbp-$[RuH_7]^{3-}$. Each hydride structure usually contains one crystallographic T-metal site. Exceptions are K_2ReH_9 (I), $Mg_6Co_2H_{11}$ (XVII), and $LaMg_2NiH_7$ (XLVII) that contain two, K_3PdH_3 (IX), $Sr_8Rh_5H_{23}$ (XXVI), and $LaMgNi_4H_4$ (XLVI) that contain three, and $Mg_6Ir_2H_{11}$ (XLV) that contains four independent T-metal sites. Among these $Mg_6Co_2H_{11}$ (XVII) and $Mg_6Ir_2H_{11}$ (XLV) are remarkable because the T-metal sites display different complex geometries in the same structure: one sad-$[TH_4]^{5-}$ and three spy-$[TH_5]^{4-}$ of which two are disordered (T = Co, Ir). T-metal complexes having a given geometry usually occurs in different structure types such as oct-$[FeH_6]^{4-}$ in Mg_2FeH_6 (II), $SrMg_2FeH_6$ (XVI) and $Ca_4Mg_4Fe_3H_{22}$ (XX), and tet-$[NiH_4]^{4-}$ in Mg_2NiH_4 (V) $CaMgNiH_4$ (XIX) and $LaMg_2NiH_7$ (XLVII). Complexes centred by different T-metals in the

same structure have not yet been reported. 'Composite' hydride structures made up by covalent bonded hydride complexes and ionic bonded hydrogen occur with $SrMg_2FeH_8$ (XVI), Ba_2PtH_6 (XXI), $LiSr_2PdH_5$ (XXII), Mg_3ReH_7 (XXIII), Mg_3RuH_6 (XXV), $LiMg_2RuH_7$ (XXVII), $LiMg_4Os_2H_{13}$ (XXXVI), $LaMg_2NiH_7$ (XLVII), and can be studied on Figures 16, 21, 22, 23, 25, 27, 36, and 47, respectively. Those belonging to the series $LiH{\cdot}nMg_2TH_4$ (T = Ru, Os; $n = 1, 2, \infty$, groups XXVII, XXXVI, and II, respectively) are made up by slabs of $[TH_6]^{4-}$ complexes and sheets of ionic Li^+H^-. Finally, only relatively few 3*d* analogs exist to the more numerous 4d and 5d hydrides, that is, four Mn *versus* eight Re compounds, five Co *versus* twelve Rh and ten Ir compounds, and ten Ni *versus* twenty-one Pd and seventeen Pt compounds. In particular, no iron analog exists for the ruthenium (osmium) series of composite structures, and no nickel analogs exist for any of the palladium and platinum compounds.

Polynuclear Complexes. Dinuclear complexes occur in nonmetallic $Li_5Pt_2H_9$ (XXXIV) and metallic Mg_3RuH_3 (XV). The former displays planar PtH_4 units that are connected *via* Pt–H–Pt bridges to $[Pt_2H_9]^{5-}$ complexes, and the latter display T-shaped RuH_3 units that are possibly connected *via* Ru–Ru bonds to $[Ru_2H_6]^{12-}$ dimers. Tetranuclear complexes occur in metallic $MgRhH_{0.94}$ (XIV) and $NdMgNi_4H_{\sim4}$ (XLVI). The former displays cyclic tetramers $[Rh_4H_{\sim4}]^{8-}$ having nearly linear T-H-T bridges, and the latter tetrahedron shaped $[Ni_4H_{\sim4}]^{5-}$ units in which three edges and one face of the Ni tetrahedron are bridged by hydrogen. Quasi one-dimensional $[Ru_nH_{4n}]^{4n-}$ polymers displaying T–T bonds can be formulated in Mg_2RuH_4 (XVIII), and a two-dimensional disordered $[Rh_4H_{17}]_n{}^{13n-}$ network of corner-sharing RhH_6 octahedra occurs in $Ca_8Rh_5H_{23}$ (XXVI). Three-dimensional ordered networks of corner-sharing TH_6 octahedra occur in brass colored $Ca_8Rh_6H_{24}$ (XLI; $[Rh_3H_{12}]_n{}^{8n-}$ anion), and the perovskite structure of metallic $EuPdH_3$ (X; $[PdH_3]_n{}^{2n-}$ anion). Polynuclear complexes with mixed T-metals such as in metal carbonyls have not been reported as yet.

Complex Formation In Intermetallic ('Interstitial') Hydrides. The historically first example for a hydrogenation induced complex formation is Mg_2NiH_4 (V). The brownish colored hydride derives by hydrogenation of the intermetallic compound Mg_2Ni and was originally classified as an 'interstitial' hydride. It contains an ordered array of $[NiH_4]^{4-}$ complexes, is stoichiometric and nonmetallic, and shows a relatively important but reversible rearrangement of its metal atom substructure. Complex formation also occurs in other metal-rich metal framework structures such as the palladium compounds $CaPdH_2$ (X and analogs) and $LiSr_2PdH_5$ (XXII). The hydrides have CsCl-type metal substructures and can be described in terms of isolated, partially disordered $[PdH_2]_{av}{}^{2-}$ and $[PdH_3]_{av}{}^{3-}$ groups, respectively, but the data are also compatible with 3-dimensional networks of Pd–H–Pd bridges as in 'interstitial' hydrides.[23] More palladium rich hydrides based on close-packed metal atom arrangements are $NaPd_3H_2$[125] and $LiPdH_{0.7}$[126] (not included in this review). While the former shows an ordered array of well-defined linear H–Pd–H

[a]In decreasing coordination number, CN; only structurally characterized, essentially ordered monomers having terminal H ligands are included; av: average due to disorder.

groups, the latter is disordered and shows only a weak tendency for complex formation. As to the above mentioned metallic hydrides $MgRhH_{\sim 0.9}$ (XIV) and $NdMgNi_4H_{\sim 4}$ (XLVI), their hydrogen distributions can be described as 'interstitial', but the stereochemical activity of the tetramers $[Rh_4H_4]^{8-}$ and $[Ni_4H_4]^{5-}$, respectively, is evident. These findings suggest that hydride complex formation could be a general phenomenon in interstitial hydrides, at least on a local level. Some striking examples for hydrogenation induced complex formations and metal-insulator transitions have been recently reported in the systems $Mg_3Ir–H_2$[121] and $LaMg_2Ni–H_2$.[123] The former contains the intensely red colored hydride $Mg_6Ir_2H_{11}$ (XLV) the structure of which can be rationalized in terms of pyr-$[IrH_5]^{4-}$ and sad-$[IrH_4]^{5-}$ 18-electron complexes and hydride anions H^-, in agreement with the limiting ionic formula $4Mg_6Ir_2H_{11} = 5MgH_2 \cdot 19Mg^{2+} \cdot 2[IrH_5]^{4-} \cdot 6[IrH_4]^{5-}$. The latter contains the grey colored hydride $LaMg_2NiH_7$ (XLVII) that is nonmetallic. Its structure contains tetrahedral $[NiH_4]^{4-}$ complexes and hydride anions H^- corresponding to the limiting ionic formula $LaH_3 \cdot 2Mg^{+2} \cdot [NiH_4]^4$. Thus both compounds can be considered as 'complex' hydrides for which the 'interstitial' concept fails.

Order–Disorder Transitions. The mobility of the hydrogen ligands (or of the entire complexes) at room temperature is generally high. Well-characterized order–disorder transitions within the complexes near room temperature occur in Mg_2CoH_5 (III), Mg_2NiH_4 (V), K_3PdH_3 (IX), Na_2PtH_4 (IV), M_3PtH_5 (M = Rb, Cs; VIII), and M_2PtH_4 (M = K, Rb, Cs; VI). Complexes that are partially disordered at room temperature and do not readily order at low temperature occur in $CaPdH_2$ (X), $LiSr_2PdH_5$ (XXII), Mg_4IrD_5 (XXIV), Mg_3RuH_6 (XXV), M_2TH_5 (T = Rh, Ir; M = Mg, Ca, Sr, Eu; III) and $Mg_6T_2H_{11}$ (T = Co; XVII, and Ir; XLV). In some structures, the hydride complexes undergo rigid motions, such as in K_2PtH_4 for which LT-NMR data suggest rotational jumps of the spl-PtH_4 units in the plane of the square.[8]

4.2 Cation Configurations

The cations M (alkali, alkaline earth, lanthanide) surrounding the complexes have various configurations, of which the eightfold cubic (or approximately cubic) is by far the most common. Depending on the metal ratios M/T the cubes are joined via corners, edges, or faces. Edge sharing occurs in Sr_2RuH_6 (II), Sr_2IrH_5 (III), Na_2PtH_4 (IV), Mg_2NiH_4 (V), K_2PtH_4 (VI), and K_3ReH_6 (XL) that adopt one arrangement, and $Ca_4Mg_4Fe_3H_{22}$ (XX) and $Ca_4Mg_4Co_3H_{19}$ (XXXII) that adopt another. Corner sharing occurs in Li_4RuH_6 (XI). Corner and edge sharing occurs in Mg_3ReH_7 (XXIII), $Mg_6Co_2H_{11}$ (XVII), Mg_3RuH_6 (XXV), $LiMg_2RuH_7$ (XXVII), and $Mg_6Ir_2H_{11}$ (XLV) that adopt one arrangement, and Sr_2MgFeH_8 (XVI), $LiMg_4Os_2H_{13}$ (XXXVI), and $LiMg_4Os_2H_{13}$ (XXXVI) that adopt another. Sheets of face-sharing cubes occur in Mg_2RuH_4 (XVIII) and $Ba_3Ir_2H_{12}$ (XXXI) for which the sheets are connected via edges, and in $LiSr_2PdH_5$ (XXII) for which the sheets are connected via additional M atoms, and in Na_2PdH_2 (VII), Ba_2PtH_6 (XXI), and Li_2PtH_2 (XXXVII) that have other arrangements. Three-dimensional arrays of face-sharing cubes occur in $CaPdH_2$ (X) and $MgRhH_{1-x}$ (XIV) where all faces are shared, in $Sr_8Rh_5H_{23}$ (XXVI) where edges, edges and faces, or faces are shared, and in $Ca_8Rh_6H_{24}$ (XLI) where edges and faces are

shared. Face-sharing configurations are of particular interest because they favor interactions between neighboring hydride complexes.

The distortion of the M cube depends mainly on the symmetry and dynamics of the hydrido complex. This can be seen in Mg_2CoH_5 (III) and Mg_2NiH_4 (V), whose T-metal centered Mg cubes are regular in the disordered cubic HT structure (such as in Mg_2FeH_6; II), and strongly distorted in the tetragonal (Mg_2CoH_5) and monoclinic (Mg_2NiH_4) LT structures owing to ordering of the spy-CoH_5 and tet-NiH_4 units, respectively. Another example is Mg_2RuH_4 (XVIII) whose Mg cubes surrounding the sad-RuH_4 units are strongly distorted compared to the regular Mg cubes surrounding the oct-RuH_6 units in Mg_2RuH_6 (II). The influence of the complex geometry on the metal atom array is also apparent in $Mg_6Co_2H_{11}$ (XVII), $Mg_6Ir_2H_{11}$ (XLV), and Mg_3RuH_6 (XXV). They contain various nonoctahedral TH_4 and TH_5 units, and their metal substructure derives from that of trigonal Mg_3ReH_7 (XXIII) containing octahedral ReH_6 units by an orthorhombic (or monoclinic) distortion. Finally, the atomic size difference between alkaline earths also plays a role, as can be seen from the severe distortions of the partially substituted M cubes in the quaternary hydrides $Ca_4Mg_4Fe_3H_{22}$ (XX) and $CaMgNiH_4$ (XIX) that derive from Mg_2FeH_6 (II) and Mg_2NiH_4 (V), respectively.

4.3 Bond Distances

Metal–Hydrogen Bonds. The T–H bond distances of the complexes can be rationalized in terms of covalent radii and a fixed hydrogen radius of 0.28 Å. The distances range from 1.50–1.60 Å for 3d metals, to 1.70–1.80 Å for 4d and 5d metals, except for Pd (1.60–1.70 Å) and Pt (1.58–1.67 Å), the T–H bonds of which are shortened owing to low-coordination numbers. Apparent bond shortening may also occur as a result of partial hydrogen site occupancy in disordered HT structures. On the other hand, the relatively long Pd–D distances in disordered $CaPdD_2$ (X) (Pd–D = 1.84 Å) and $LiSr_2PdD_5$ (XXII) (Pd–D = 1.95 Å) are only averages, and are presumably shortened locally owing to the formation of linear PdD_2 groups. Owing to matrix effects,[127] the T–D bond lengths generally increase with the size of the M cations.

The M–H distances are consistent with tabulated ionic radii. Those involving hydride anions H^- surrounded by cations M only (occurring in some 25 compounds from 19 different structure types) are generally shorter than those involving hydrogen ligands of the complex. Exceptions are found in K_3PdH_3 (IX), K_3ZnH_5 and K_3MnH_5 (XXX), $Ba_7Cu_3H_{17}$ (XXXV), Rb_3ReH_{10} (XLII), and Cs_3OsH_9 (XLIV). Unlike the complex hydrogen ligands, the hydride anions are neither mobile nor disordered. Their metal configurations range from octahedral in $LiSr_2PdH_5$ (XXII), K_3PdD_3 (IX), K_3ZnH_5 (XXX), Rb_3ReH_{10} (XLII), Cs_3OsH_9 (XLIV), and $LaMg_2NiH_7$ (XLVII), to trigonal bipyramidal in $LiMg_2RuH_7$ (XXVII) and $LiMg_4Os_2H_{13}$ (XXXVI), tetrahedral in $SrMg_2FeH_8$ (XVI), $Ca_4Mg_4Fe_3H_{22}$ (XX), $Ca_4Mg_4Co_3H_{19}$ (XXXII), $Ba_7Cu_3H_{17}$ (XXXV), and $BaMg_2RuH_8$ (XXXVIII), triangular in $Mg_6Co_2H_{11}$ (XVII) and $LaMg_2NiH_7$ (XLVII), and linear in Mg_3ReH_7 (XXIII) and Mg_3RuH_6 (XXV). As expected, low-coordinate M–H bonds are significantly shorter, for example, Mg-H = 1.74 Å in $Mg_6Ir_2H_{11}$ (XLV) and K–H = 2.73 Å in K_3PdH_5 (VIII) compared to higher coordinate M–H bonds such as in binary MgH_2 (1.95 Å), BaH_2 (2.57 Å) and KH (2.85 Å). As in saline ternary hydrides, the Yb–D distances are close to Ca–D distances and the Eu–D distances close to Sr–D distances.[128]

Metal–Metal Bonds. The T- and M-metals are likely to interact in complex hydride structures because of their proximity. The shortest M–T distances are in the range 2.5–3.5 Å and give rise to metallic properties in metal-rich compounds, such as $MgRhD_{1-x}$ (XIV) (Mg–Rh = 2.66 Å) and Na_2PdH_2 (VII) (Na–Pd = 3.13 Å). The shortest M–M distances are in the range 2.5–4.5 Å and come close to the sum of covalent radii, such as Mg–Mg = 2.75 Å in Mg_4IrH_5 (XXIV), 2.78 Å in $Mg_6Co_2H_{11}$ (XVII) or 2.79 Å in $Mg_6Ir_2H_{11}$ (XLV). Clearly, these M–T and M–M interactions are not taken into account by a limiting ionic bond description and require more sophisticated electron counting schemes (see 4.4). Interactions between T-atoms are less common, because the T–T distances usually exceed 3.5 Å. However, T–T interactions do occur in metallic Li_2PdH_2 (VII) (Pd–Pd = 3.11 Å) and Na_2PdH_2 (VII) (Pd–Pd = 3.60 Å), and possibly also in Mg_2RuH_4 (XVIII) (Ru–Ru = 3.24 Å) and Mg_3RuH_3 (XV) (Ru–Ru = 3.31 Å) as suggested by their stereochemistry and the existence of carbonyls displaying such interactions across similar long distances.

Hydrogen–Hydrogen Contacts. The H–H contacts in ordered hydride structures usually exceed 2.1 Å, and thus indicate nonbonding (or repulsive) H–H interactions. In disordered structures, H sites closer than 2.1 Å are always half (or less) occupied. The shortest H–H contact occurs in K_2ReD_9 (I) for which the most recently reported value is D–D = 1.90 Å.[24] Thus, there is no evidence for hydrogen pairing in homoleptic solid-state T-metal hydrides, unlike in molecular T-metal hydride complexes for which dihydrogen groups with H–H distances as short as 0.82 Å do occur.[10,129]

4.4 Bonding

The compositions and ligand geometries of most mononuclear T-metal hydride complexes can be rationalized in terms of conventional electron counts based on full charge

transfer from the surrounding cation matrix M, and s-p-d hybridization schemes that involve two-center-two-electron (2c–2e) bonds, such as $(d^0)d^5sp^3$ for 18-electron ttp-$[ReH_9]^{2-}$, $(d^6)d^2sp^3$ for octahedral 18-electron $[FeH_6]^{4-}$, $[MnH_6]^{5-}$, and $[ReH_6]^{5-}$, $(d^8)dsp^3$ for square-pyramidal 18-electron $[CoH_5]^{4-}$, $(d^{10})sp^3$ for 18-electron tetrahedral $[NiH_4]^{4-}$ and $[PdH_4]^{4-}$, $(d^8)dsp^2$ for planar 16-electron $[PdH_4]^{2-}$ and $[RhH_4]^{3-}$, $(d^{10})sp^2$ for triangular 16-electron $[PdH_3]^{3-}$, and $(d^{10})sp$ for linear 14-electron $[PdH_2]^{2-}$. However, for some hydrides, in particular those containing early T-metals and/or showing metal–metal interactions, more elaborate electron counting schemes evoking s-d hybridization only, three-center-four-electron (3c–4e) bonds, and partial charge transfer from the cation matrix M are also possible, as was shown by Firman and Landis.[13] Mg_2CoH_5 (III), for example, can be formulated in terms of univalent Mg^+ and sd^2 hybridized 16-electron $[CoH_3\ 2H^-]$ complexes having two 3c–4e bonds. The merits and limitations of this bonding model have been discussed by King.[16] For polynuclear hydride complexes, the bonding situation is more difficult to describe. Some can be rationalized by mixtures between two-center-two-electron and three-center-two-electron (3c–2e) bonds, such as dinuclear $[H_4Pt–H–PtH_4]^{5-}$ in $Li_5Pt_2H_9$ (XXXIV) for which eight 2c–2e bonds (terminal H's) and one 3c–2e bond (bridging H) can be formulated, while for others such as tetranuclear $[Ni_4H_{\sim 4}]^{5-}$ in $LaMgNi_4H_{\sim 4}$ (XLVI) a similar bond description is less apparent.

As expected from its small atomic size and high-field ligand character, hydrogen favors 18-electron complexes (about 40 representatives with groups 7, 8, 9, and 10 elements). Complexes with 16 electrons (some 11 representatives with Re, Ru, Rh, Pd, and Pt), or 14 electrons (4 representatives with Pd and Pt) are less numerous. The only octahedral 16 electron $(d^4)d^2sp^3$ bonded complex is $[ReH_6]^{3-}$ in K_3ReH_6 (XL), and the only tetrahedral 13-electron $(d^5)sp^3$ bonded complex is $[MnH_4]^{2-}$ in K_3MnH_5 (XXX) that displays a half-filled d shell. On the other hand, the relative softness of hydrogen as a ligand and its stability as an anion favors structural diversity. This is illustrated by 'composite' hydrides such as quaternary $Ca_4Mg_4Fe_3H_{22}$ (XX) that derives from ternary Mg_2FeH_6 (II) by partial substitution of a fourfold negative $[FeH_6]^{4-}$ by four H^-, and Mg_3ReH_7 (XXIII), $Mg_6Co_2H_{11}$ (XVII), and Mg_3RuH_6 (XXV) that have a common metal substructure and are capable of accommodating various complex geometries and H^- ions.

The formal oxidation numbers of the T-metal in most hydride structures range between –I (Co, Rh), zero (Ru, Ni, Pd), I (Mn, Re, Co, Ir, Rh, Cu), II (Fe, Ru, Os, Pd, Pt, Zn), III (Ir, Rh), IV (Ru, Os, Pt), VI (Os) and VII (Re). They are consistent with configurational differences as found, for example, in palladates that change from tetrahedral as in $[Pd^0H_4]^{4-}$ to planar as in $[Pd^{II}H_4]^{2-}$. As expected, high formal oxidation numbers occur mainly with heavier T elements such as Re^{VII} in $[ReH_9]^{2-}$, Os^{VI} in $[OsH_8]^{2-}$, and Pt^{IV} in $[PtH_6]^{2-}$, for which no 3d analogs exist. As the H/M ratios decrease, the systems tend to become metallic and electron counting becomes less obvious. Illustrative examples are Mg_3RuH_3 (XV) and Mg_4IrH_5 (XXIV) for which the neglect of Mg–Mg bonding leads to unreasonable electron configurations and formal oxidation numbers (–III for Ru and Ir). Clearly, limiting ionic formulas for such hydrides are misleading, at least from a bonding point of view, but they are still useful for rationalizing hydrogen contents, which is generally not possible with 'interstitial' (metallic) metal hydrides.

Finally, an important bonding feature of complex metal hydrides are the interactions between the complex hydrogen ligands and the surrounding cation matrix. As can be seen from the isoelectronic series Mg_2FeH_6 – Mg_2CoH_5 – Mg_2NiH_4, the cations adopt cubic – or nearly cubic – configurations that maximize the Mg–H interactions. Clearly such M–H interactions not only help stabilizing the complexes but also contribute to the thermal stability of the overall structure, as shown by the desorption enthalpies of substitution pairs such as Mg_2NiH_4–$CaMgNiH_4$ and Mg_2FeH_6–$Ca_4Mg_4Fe_3H_{22}$ (see Section 5). On the other hand, T–H interactions do not much contribute to thermal stability as suggested by the relatively weak force constants as measured in metal hydrides such as Mg_2FeH_6 (Fe–H stretching mode $\sim$1.9 mdyne Å^{-1}; Fe–H = 1.56 Å),[38] and the significant elongation of the T–H bonds in the thermally more stable analog Ca_2FeH_6 (Fe–H = 1.62 Å). Theoretical band structure calculations are available for some of these systems, for example, Mg_3MnH_7 (XXIII),[90] Na_2PdH_4 (IV), Na_2PdH_2 (VII), Li_2PdH_2 (VII), $NaBaPdH_3$ (XXXIX), and Ba_2PdH_4 (XXIX),[14] Mg_2NiH_4 (V), Mg_2CoH_5 (III), Mg_2TH_6 (II; T = Fe, Ru, Os), M_2FeH_6 (II; M = Mg, Ca, Sr),[37] $APdH_3$ (X; A = Sr, Eu, Yb),[71] $BaReH_9$ (XXVIII),[98] and Eu_2PdH_4 (XXIX),[103] but have not yet addressed the issue of thermal stability.

5 PROPERTIES

In contrast to their 'interstitial' counterparts, complex metal hydrides have no apparent homogeneity range and are usually nonmetallic. Many are colored (greenish: Mg_2FeH_6, Na_4RuH_6, $SrMg_2FeH_8$, $LiSr_2PdH_5$; reddish: Eu_2RuH_6, Mg_2RuH_4; red-violet: Na_2PtH_4; yellow: K_3PdH_3; yellow-green: K_2PdH_4; brownish: Mg_2RuH_6, Mg_2NiH_4, Mg_3RuH_6, $Ca_4Mg_4Fe_3H_{22}$, $BaMg_2FeH_8$), while some are colorless (K_2PtH_4, K_3PtH_5, Na_3RhH_6), or appear as white (Mg_2OsH_6, Li_4RuH_6) or gray powders (Ca_2RuH_6, Mg_3RuH_3, Mg_3ReH_7). Only few are black (Yb_2RuH_6, $Mg_6Co_2H_{11}$, Mg_2CoH_5, $YbMgNiH_4$, $Yb_4Mg_4Fe_3H_{22}$) or have metallic luster (Li_3RhH_4, Na_2PdH_2). Relatively well-characterized complex hydrides having metallic properties are Li_2PdH_2 and Na_2PdH_2 that are considered to be two-dimensional metals.

Among complex hydrides that derive from intermetallic compounds, some show hydrogenation induced metal to nonmetal transitions such as brownish-red Mg_2NiH_4 (Mg_2Ni), red $Mg_6Ir_2H_{11}$ (Mg_3Ir), and dark grey $LaMg_2NiH_7$ ($LaMg_2Ni$). Such transitions are of both fundamental and technological interest as shown for binary systems like Y–H_2 (switchable mirrors) and ternary systems like Mg_2Ni–H_2 (tuneable optic windows).[130]

Many hydrides are diamagnetic, as expected for closed-electron shells associated with low-spin d^6 (oct), d^8 (spl), and d^{10} (tet, lin) configurations. Others show weak temperature independent paramagnetism such as the d^4 systems K_3ReH_6 (XL) and Na_3OsH_7 (XLIII). Finally, systems containing magnetic ions tend to order magnetically at low temperature, such as rose colored K_3MnH_5 (Mn(II), $\mu_{eff} = 4.5\mu_B$, $T_N = 28$ K) and faint violet colored Eu_2PdH_4 (Eu(II), $\mu_{eff} = 8\mu_B$, $T_C = 15$ K).

Vibrational spectra as measured by INS on hydrides such as M_2TH_6 (II, M = Mg, Ca, Sr, Ba; T = Fe, Ru, Os),[28,38] Mg_2NiH_4 (V) and Rb_3ZnH_5 (XXX)[54] indicate T–H stretching and bending modes in the expected ranges of 1600–2000 cm^{-1} and 800–1000 cm^{-1}, respectively. These modes correlate with bonding properties, such as the T–H stretching frequencies in the K_2PtCl_6 type series (II) that increase in the sequence T = Fe, Ru, Os, and decrease as the M–H bond lengths increase. Their theoretical band gaps show the opposite trend, that is, they increase in the sequence Mg_2TH_6 (T = Fe, Ru, Os) owing to the increasing atomic number of T, and that decrease in the sequence M_2FeH_6 (M = Mg, Ca, Sr) owing to the increased participation of M d orbitals.

Properties of relevance for hydrogen storage applications, such as desorption enthalpies and weight and volume efficiencies, are summarized in Table 21.

Clearly, some compounds have outstanding properties, such as Mg_2FeH_6, which shows the highest known volume efficiency for hydrogen storage of all materials known (120 g H_2 L^{-1}, that is, more than twice that of liquid hydrogen), and $BaReH_9$, which has an H/M ratio that surpasses the hydrogen-to-carbon ratio of methane (H/C = 4). The weight efficiencies are also remarkable as shown by Mg_2FeH_6 and Mg_3MnH_7, which can store up to 5 wt% hydrogen, that is, more than currently used interstitial hydrides such as $AB_5H_{\sim 6}$ (A = La, etc., B = Ni, etc.) and $AB_2H_{\sim 4}$ (A = Ti, etc., B = Mn, etc.), which store only up to ~2 wt% hydrogen. Unfortunately, regarding thermal stability complex metal hydrides perform less well than their interstitial counterparts. Only few hydrides decompose near room temperature such as $BaReH_9$ and $Ba_7Cu_3H_{17}$ that are, however, relatively heavy and expensive and not completely reversible. Mg_2NiH_4, which is the only commercialized hydride of this class, decomposes only above 523 K, corresponding to a desorption enthalpy of $\Delta H = 64$ kJ mol^{-1} H_2. Most other complex metal hydrides are more stable (decomposition temperatures >573 K, $\Delta H > 80$ kJ/H_2) and must be heated to yield hydrogen at useful pressures, which represents a penalty in energy. On the other hand, compounds such as Mg_2FeH_6 are of interest for high-temperature applications[39] because of their high thermal stability and ease of cycling.

Owing to the scarcity of thermodynamic data, empirical models such as that used to rationalize thermal stabilities of interstitial metal hydrides[131] do not exist for complex metal hydrides. Metal–hydrogen interactions obviously play a role, as can be seen from the substitution pairs Mg_2NiH_4–$CaMgNiH_4$ and Mg_2FeH_6–$Ca_4Mg_4Fe_3H_{22}$, whose stabilities increase strongly as one goes from the ternary Mg compounds to the quaternary Ca compounds (see Table 21). This trend correlates with the relatively strong interactions between hydrogen and calcium that forms a very stable binary hydride, compared to the relatively weak interactions of hydrogen with magnesium that forms a less stable binary hydride. This suggests that interactions between hydrogen and metal cations govern to a large extent the thermal stability of complex metal hydrides.

Table 21 Desorption enthalpies and hydrogen storage efficiencies

	ΔH kJ mol^{-1} H_2	Weight efficiency wt%	Volume efficiency gH_2L^{-1}
Complex hydrides			
Mg_2NiH_4	64	3.6	18
Mg_2CoH_5	86	4.5	126
Mg_2FeH_6	98	5.5	150
$CaMgNiH_4$	129	3.2	87
$Ca_4Mg_4Fe_3H_{22}$	122	5.0	121
Binary hydrides			
MgH_2	74	7.7	109
CaH_2	184[a]	4.8	92
Metallic hydride			
$LaNi_5H_6$	31	1.4	93

[a]Model prediction.[131]

6 CONCLUSIONS

Solid-state transition metal hydride complexes occur mainly with the late transition elements. The complexes are usually mononuclear (centred by one T-metal atom only) and contain between two and nine terminal hydrogen ligands, while some are polynuclear (centred by more than one T-metal atom) and display bridging hydrogen ligands. The ligands tend to be disordered at higher temperatures and ordered at lower temperatures. The structural and electronic configurations of the hydrido complexes are consistent with those usually found in coordination compounds. They are stabilized by charge transfer from the surrounding cation matrix, are often 18-electron, and less often 16- or 14-electron. Some hydride structures show evidence for metal–metal interactions, as

in typically interstitial metal hydrides, while others contain additional hydride anions (H^-) bonded to electropositive metals only, such as in saline hydrides. In metal-rich systems, hydrogen has interstitial character, as in typically metallic transition metal hydrides. No H–H bond formation is observed. Most complex hydride systems are nonmetallic and many are colored. Some systems, however, show hydrogenation induced complex formation and metal-to-insulator transitions. They generally display very high volume efficiencies for hydrogen storage but are thermally too stable and/or too expensive for practical applications. Thermodynamic data suggest that their enthalpy of formation scales with the thermal stability of the binary hydrides of the electropositive metal constituents.

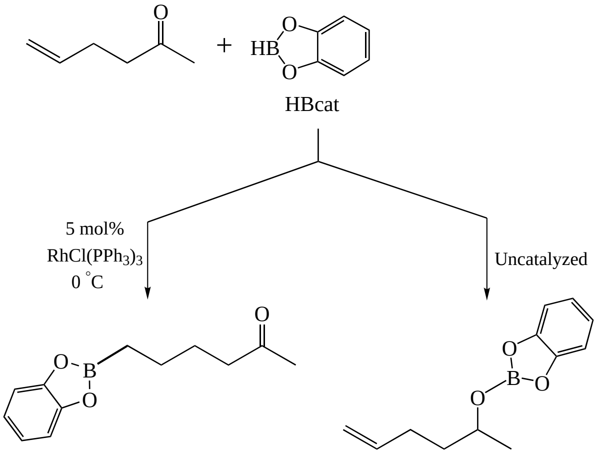
1 INTRODUCTION

One of the most important synthetic methodologies to emerge from organic chemistry in the last century has been the discovery that boron–hydrogen bonds add to unsaturated organics to form a class of compounds known as organoboranes (*see* ***Boron: Organoboranes***). That transition metals (*see Transition Metals*) accelerate the addition of boron hydrides (*see* ***Boron Hydrides***) to unsaturated organic moieties was initially reported for catalyzed hydroborations (*see Hydroboration*) of alkenes and alkynes using polyhedral boranes (*see* ***Boron: Polyhedral Carboranes***).[1,2] Männig and Nöth then demonstrated that $RhCl(PPh_3)_3$ (*see Wilkinson's Catalyst*) could be used to catalyze the hydroboration of alkenes with catecholborane (HBcat) under mild conditions and with *chemoselectivity differing from that of the uncatalyzed reaction* (equation 1).[3] Indeed, in the catalyzed hydroboration of 5-hexen-2-one, addition of HBcat occurred preferentially at the C=C double bond, even in the presence of the more reactive ketone group.



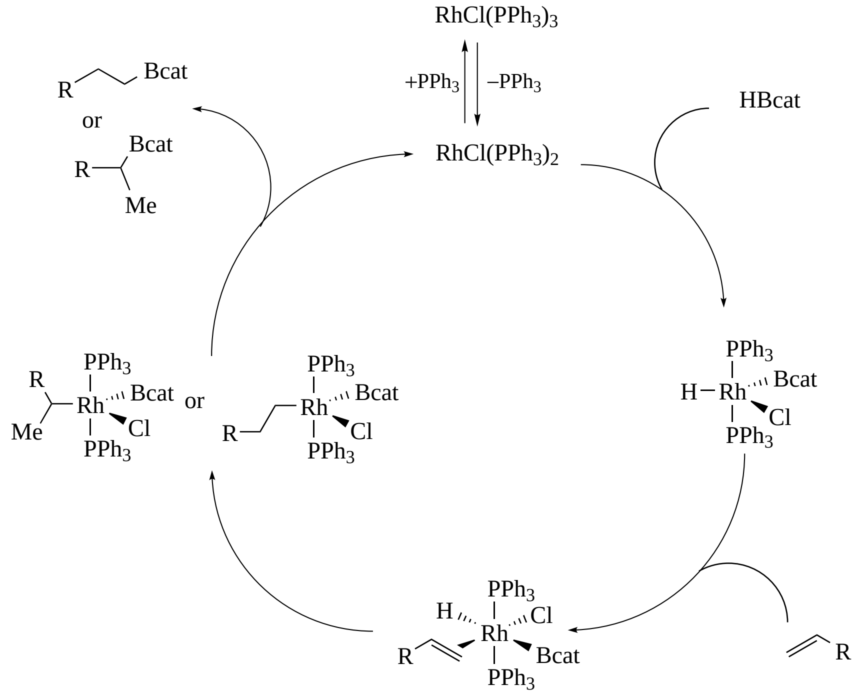
(1)

Since this seminal discovery, a considerable amount of research has focused on investigating the mechanism and scope of these catalyzed hydroboration reactions. Several reviews have already been published in this area.[4–8]

2 MECHANISM

Although other transition metals have been found to catalyze hydroborations with HBcat, early studies have shown that rhodium complexes are the most effective for reactions of simple alkenes. The catalytic cycle proposed resembles one suggested previously[2] for the rhodium-catalyzed addition of carborane B–H bonds to the C=C unit in acrylate esters. The reaction is believed to proceed via initial loss of phosphine and oxidative addition (*see Oxidative Addition*) of the B–H bond of HBcat to the coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*) rhodium center.[9,10] Coordination of the alkene (*see Alkene Complexes*) and subsequent insertion (*see Insertion*) into the Rh–H bond and reductive elimination (*see Reductive Elimination*) of the B–C bond then generates the organoboronate ester product(s) (Scheme 1).

Mechanistic work by Evans and Fu[11] has shown that hydroboration of 1-decene with deuteriocatecholborane (DBcat) using Wilkinson's catalyst gave predominant formation of 1-decanol, upon oxidation with NaOH/H_2O_2, where the expected regiospecific incorporation of deuterium at the β-carbon of the alkene was not observed. Indeed, a significant amount of deuterium was observed at the hydroxyl-bearing carbon of the isolated alcohol (ca. 14%) and in the recovered alkene. These observations were rationalized in terms of both the alkene binding and migratory insertion steps being reversible. A number of theoretical studies[12–18] have examined the metal catalyzed hydroboration and Ziegler and coworkers[12] have suggested that the hydride and the boryl fragment (Bcat) are probably trans to one another in reactions



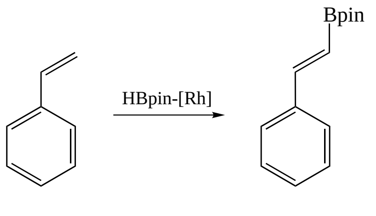
Scheme 1 A general proposed mechanism for the rhodium-catalyzed hydroboration of alkenes using HBcat

with Wilkinson's catalyst, leaving the coordinated alkene cis to both of these reactive moieties.

3 RHODIUM COMPLEXES

3.1 Neutral Complexes

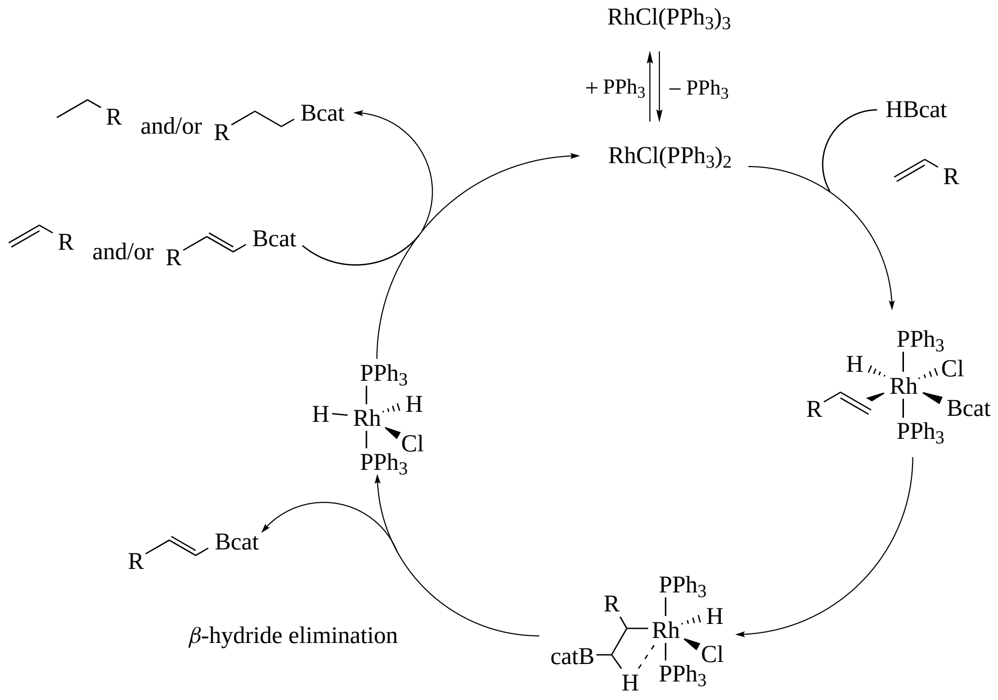
As mentioned previously, early work has focused on the use of $RhCl(PPh_3)_3$ to catalyze hydroborations of alkenes using HBcat. However, competing reactions, such as hydrogenation (*see* ***Hydrogenation & Isomerization of Alkenes***), and degradation of the borane[19,20] have resulted in considerable research into the development of other rhodium complexes as possible catalyst precursors for this important reaction. For instance, while hydroborations of vinyl arenes ($ArCH=CH_2$) with HBcat catalyzed by most rhodium complexes give the unusual branched products ($ArCH(Bcat)CH_3$) selectively, use of $[RhCl(coe)_2]_2/2PPh_3$ gave exclusive formation of the linear isomer ($ArCH_2CH_2Bcat$).[21] The unexpected branched product is presumed to result from the rhodium's ability to stabilize a benzylic intermediate during the catalytic cycle.[22] Interestingly, reactions of vinyl arenes with pinacolborane (HBpin) catalyzed by phosphine-free $[RhCl(cod)]_2$ gave the corresponding (*E*)-2-arylethenylboronates ($ArCH=CHBpin$) in high yields (equation 2).[23] Similar chemistry has also been observed for reactions with HBcat, although hydrogenation and/or subsequent hydroboration of the resulting alkenylboronate ester is frequently observed.[20,24–27] These dehydrogenative borylation reactions are believed to proceed via initial oxidative addition of HBcat to the rhodium center, followed by coordination of the alkene and regioselective insertion into the Rh–B bond. A subsequent β-hydride elimination (*see β-Hydride Elimination*) would then generate the desired alkenyl boronate ester along with a rhodium dihydride intermediate, which can act as an active hydrogenation catalyst (Scheme 2).[20]



(2)

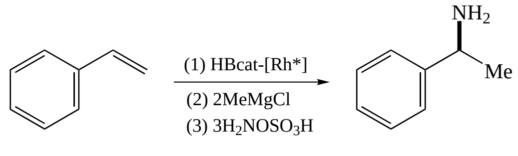
3.2 Cationic Complexes

Probably the most important developments in this field over the past 10 years, however, have been in the area of enantioselective (*see Enantioselectivity*) hydroborations using cationic rhodium complexes of the type $[Rh(diene)L^*]^+$ ($L^* =$ chiral ligand). An excellent review on this topic has recently been published.[5] New chiral (*see Chiral*) catalyst systems are typically tested in hydroborations of vinyl arenes. Although catalyzed hydroboration of vinyl arenes can be used as a mild and efficient route to preparing 1-arylethanol



Scheme 2 A general proposed mechanism for the rhodium-catalyzed dehydrogenative borylation of alkenes using HBcat

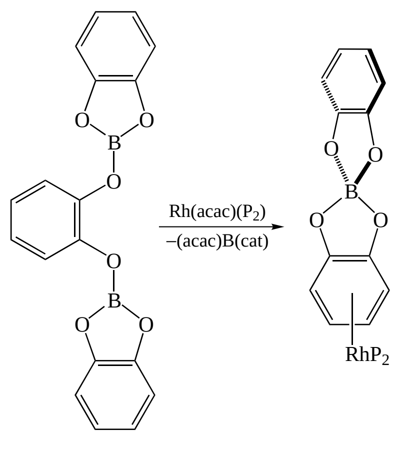
derivatives, J. M. Brown has applied this methodology, in conjunction with a subsequent electrophilic amination, to generate primary and secondary amines. These reactions proceed with essentially complete retention of configuration and lead to a wide range of primary α-arylalkylamines in up to 98% enantiomeric excess (equation 3).[28,29] An elegant recent study by Crudden and coworkers has shown that hydroborations of vinyl arenes with HBpin using a chiral rhodium catalyst leads to products with enantioselectivities opposite to those obtained in analogous reactions using HBcat.[30]



(3)

3.3 Zwitterionic Complexes

A unique zwitterionic (*see Zwitterion*) catalyst of the type Rh(η^6-catBcat)(dppe), derived from the addition of HBcat to Rh(acac)(dppe), has been found to selectively catalyze the hydroboration of a wide variety of substrates, including the first examples of a tetrasubstituted alkene (2,3-dimethylbut-2-ene).[21] The P_2Rh fragment is bound to the $[Bcat_2]^-$ anion in an η^6-fashion (*see Arene Complexes*) through one of the catecholato groups. Remarkably, the zwitterionic complexes $Rh(Bcat_2)(P_2)$ (P_2 = diphosphine) can also be prepared by the addition of B_2cat_3 (equation 4), a redistribution product arising from the nucleophilic degradation of HBcat, to $Rh(acac)(P_2)$.[31]

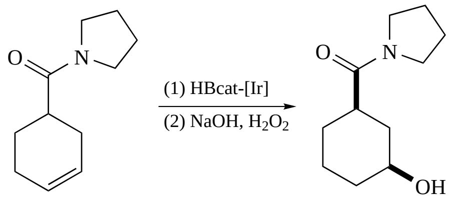


(4)

4 IRIDIUM COMPLEXES

Although early reports suggested that iridium complexes were ineffective catalysts for the hydroboration reaction, subsequent work has shown that Crabtree's catalyst (*see Crabtree's Catalyst*), $[Ir(cod)(py)(PCy_3)]PF_6$, can be used for ether or amide-directed hydroborations.[32,33] For instance, iridium catalyzed hydroborations of pyrrolidinyl amides with HBcat gave *syn* 1,3-hydroxyl amides with high levels of regio- and stereocontrol (equation 5). In contrast, reactions

catalyzed by neutral and cationic rhodium complexes afforded a nearly statistical mixture of the four possible isomers. Likewise, both indenylrhodium[34] and iridium[35] complexes have been used in the ether-directed hydroboration reactions. In other studies, either $[IrCl_2(\eta^5\text{-}C_5Me_5)]_2$[36] or $[IrCl(coe)_2]_2/4PPh_3$[30,36] could be used to effectively catalyze the hydroboration of vinyl arenes to give the corresponding linear products and $[IrCl(cod)]_2/4P^ipr_3$ catalyzes the trans-hydroboration of alkynes with HBcat or HBpin.[37] Previous studies by Sneddon and Mirabelli have shown that $[IrCl_2(\eta^5\text{-}C_5Me_5)]_2$ can also be used to facilitate the addition of polyhedral boranes to alkynes.[38]

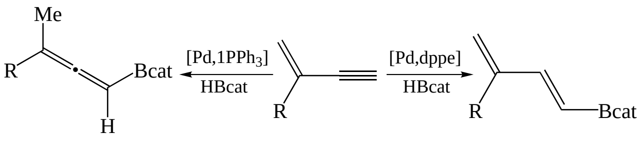


(5)

diastereoselection 95:5 (44%)

5 OTHER LATE METAL COMPLEXES

Conventional hydroboration of 1,3-dienes with dialkylboranes generally affords products derived from addition of the borane at the terminal C=C double bond. In contrast, catalytic 1,4-hydroboration of 1,3-dienes with HBcat using $Rh_4(CO)_{12}$ or $Pd(PPh_3)_4$ gave (Z)-allylic boronates with high isomeric purity.[39] The reaction is believed to go through a π-allyl intermediate that reductively eliminates to give the allylic boronate ester. Nickel (*see* ***Nickel: Organometallic Chemistry***) and cobalt (*see* ***Cobalt: Organometallic Chemistry***) complexes have also been used in the catalyzed hydroboration of conjugated dienes, where 1,2 addition products were observed.[40] Related hydroborations of conjugated enynes using $Pd(PPh_3)_4$ afforded allenic boronate esters and isomers derived from 1,2 addition of HBcat to the triple bond (equation 6).[41] Product distributions were a sensitive function of catalyst precursor employed. For instance, while reactions of 2-methyl-1-buten-3-yne with the palladium (*see* ***Palladium: Organometallic Chemistry***) catalyst generated in situ by addition of bis(phosphines) to $Pd_2(dba)_3{\cdot}CHCl_3$ gave exclusive formation of the (E)-dienyl boronate ester, hydroborations with one equivalent of PPh_3 per palladium gave the desired allenyl boronate ester in high yield (92%). Finally, $NiCl_2$(dppe) and $NiCl_2$(dppf) have been found to effectively catalyze the hydroboration of thioacetylenes with HBcat.[42]

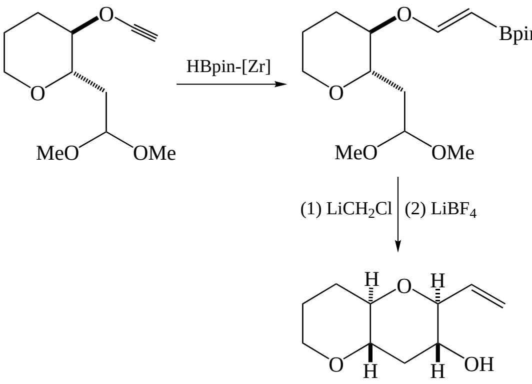


(6)

6 EARLY METAL COMPLEXES

While organoscandium,[43] lanthanide[44] (*see* ***Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry***), niobium[45] (*see* ***Niobium & Tantalum: Organometallic Chemistry***), and titanium[46,47] (*see* ***Titanium: Organometallic Chemistry***) complexes have all been examined for their ability to catalyze hydroborations, their utility in organic synthesis has remained somewhat limited. Reactions with these catalysts are generally believed to proceed via insertion of the alkene into the M-H bond, followed by a four-centered metathesis (*see Metathesis*) reaction with HBcat to generate the linear product (Scheme 3). For example, complexes of the type $Cp^*{}_2LnR$ (Ln = La, Sm; R = H, $CH(SiMe_3)_2$) were found to be effective catalyst precursors for a wide range of substrates, including trisubstituted alkenes 1-methylcyclopentene and 1-methylcyclohexene.[44]

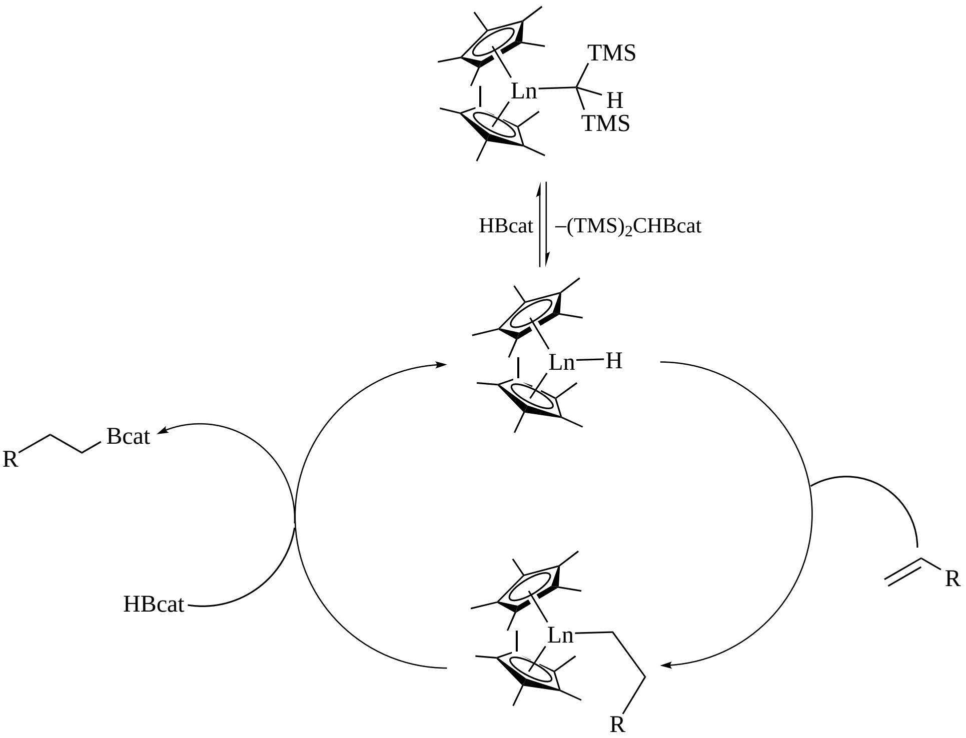
Interestingly, Schwartz's reagent, Cp_2ZrHCl (*see Schwartz's Reagent*), has found significant use for its ability to catalyze the hydroboration of alkynes selectively with HBpin.[48–50] For example, alkoxyalkynes have been hydroborated with HBpin using Cp_2ZrHCl to give the corresponding alkenylboronates, which were further subjected to the Matteson–Brown homologation (*see Homologation Reactions*) with $LiCH_2Cl$ to give (E)-γ-alkoxyallylboronates in good yield.[48] Liberation of the aldehyde with $LiBF_4$ in moist acetonitrile gave bicylic *bis*-tetrahydropyrans, arising from an intramolecular allylboration reaction (equation 7).



(7)

7 CATALYZED HYDROBORATIONS IN ORGANIC CHEMISTRY

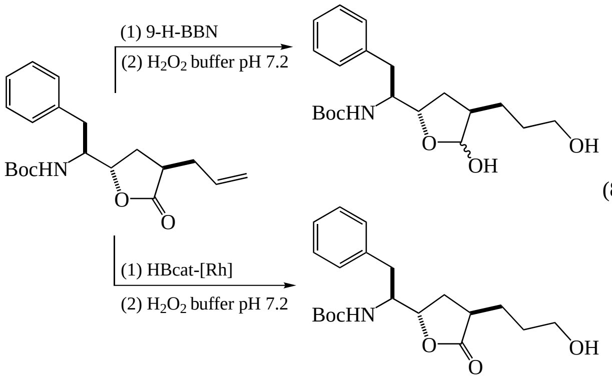
The use of transition metal catalysts for the hydroboration of unsaturated substrates offers many advantages to the synthetic chemist, as products formed from this reaction can have regio-, chemo-, and/or stereoselectivities different to those obtained from the uncatalyzed variant. The selectivities can often be altered by using a different metal catalyst to affect these transformations. In this section, an overall account will be provided of the recent advances in the application of catalyzed hydroborations in organic syntheses.



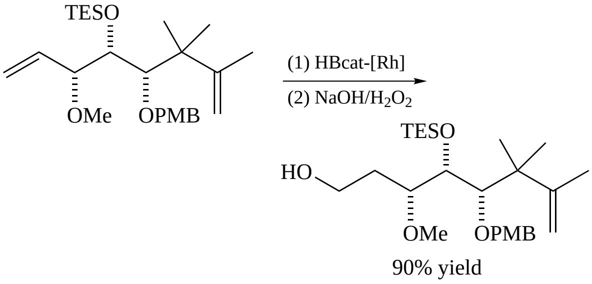
Scheme 3 A general proposed mechanism for the organolanthanide catalyzed hydroboration of alkenes using HBcat

7.1 Chemoselectivity

An important aspect of the metal catalyzed hydroboration reaction is its ability to selectively reduce certain functionalities within a molecule. For instance, a key step in the synthesis of a tripeptide derivative containing the Phe-Arg hydroxyethylene dipeptide iosostere is the selective rhodium-catalyzed hydroboration of a lactone.[51] The use of disiamylborane, 9-H-BBN, dicyclohexylborane, and (*S*)-alpineborane, however, gave only low to variable yields of the alcohol due to competitive reduction of the γ-lactone to the hemiacetal (equation 8). In another example, hydroboration of the diene illustrated in equation (9) with HBcat and $RhCl(PPh_3)_3$ gave exclusive formation of the terminal alcohol derived from reaction of the less substituted alkene. Interestingly, uncatalyzed reactions failed to hydroborate this substrate selectively.[33]



(8)

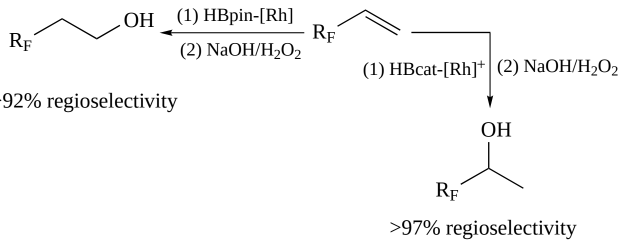


(9)

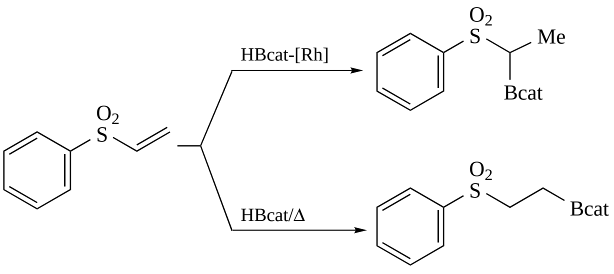
7.2 Regioselectivity

The ability to alter the regiocontrol of the hydroboration reaction by using a metal catalyst offers innumerable advantages to the synthetic chemist. In recent work, cationic rhodium complexes have been used in the hydroboration of perfluoroalkylethylenes ($R_FCH=CH_2$) with either HBcat or HBpin to give selective formation of the branched regioisomers (equation 10).[52,53] This reversal of regioselectivity has been attributed to the directing effect of the electronegative 2-substituted fluorine atoms. Conversely, reactions employing a neutral rhodium catalyst gave predominant formation of the expected linear product. In a similar study, the directing effect of the sulfone oxygen gave rise to the branched product exclusively in the rhodium-catalyzed hydroboration of vinyl sulfones using

HBcat (equation 11).[54]

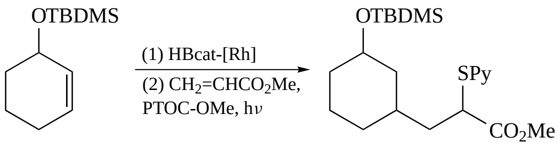


(10)



(11)

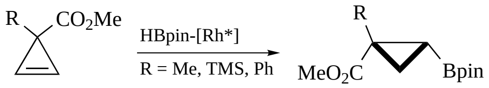
Renaud and coworkers have also recently found that related TBDMS-protected *B*-alkylboronate esters are suitable radical (*see Radicals*) precursors for conjugate addition to activated olefins such as methyl acrylate (equation 12).[55] Catalyzed hydroborations gave the 1,3-addition products with regioselectivity opposite to those obtained in uncatalyzed reactions.



(12)

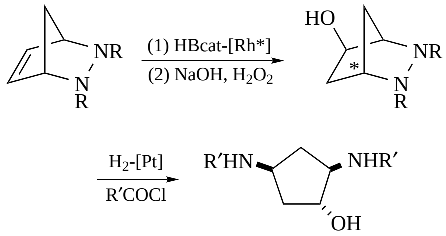
7.3 Stereoselectivity

Without question, the most important developments in this field over the past 10 years have been in the area of enantioselective hydroborations.[5,56] New chiral catalyst systems are typically tested in hydroborations of vinyl arenes, as reactions using HBcat and a cationic rhodium catalyst are well known to give selective formation of the unusual branched isomer. In related studies, enantiopure 2,2-disubstituted cyclopropyl boronates were easily prepared via the catalytic asymmetric hydroboration of 3,3-disubstituted cyclopropenes using a number of chiral neutral rhodium complexes (equation 13).[57] Directing groups, such as esters and alkoxymethyl substituents, were necessary for achieving high degrees of enantioselectivity.



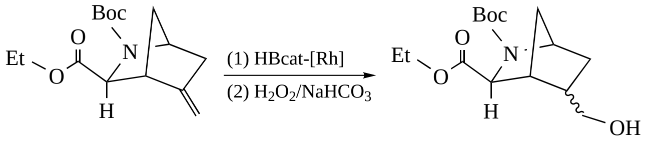
(13)

The catalytic asymmetric hydroboration reaction can also be applied to *meso*-bicyclic hydrazines. The resulting alcohols are of great synthetic interest and can lead to cyclopentanic diamino alcohols with good enantiomeric purity (equation 14). Interestingly, a reversal of enantioselectivity is observed between reactions employing rhodium and iridium catalysts.[58]



(14)

The first facially selective hydroboration of a 5-methylidene[2.2.1]bicyclic intermediate has also recently been reported.[59] The rhodium-catalyzed hydroboration of the methylidene group with HBcat proved superior to stoichiometric borane or dialkylborane reagents, in terms of higher diastereomeric excess and chemical yields (equation 15). For instance, while borane gave 89% of the desired 5-*endo* product along with 11% of the 5-*exo* product, the catalyzed variant with HBcat gave 95% for the desired 5-*endo* product when the reaction was run at room temperature. No improvement in diastereoselectivity was observed when reactions were run at lower temperatures.

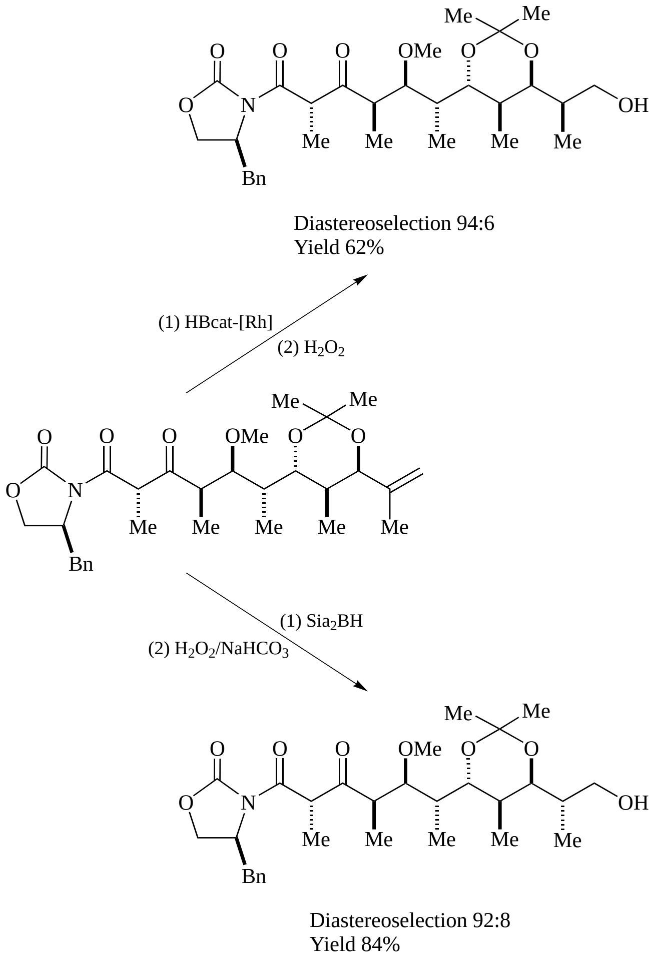


(15)

7.4 Natural Products

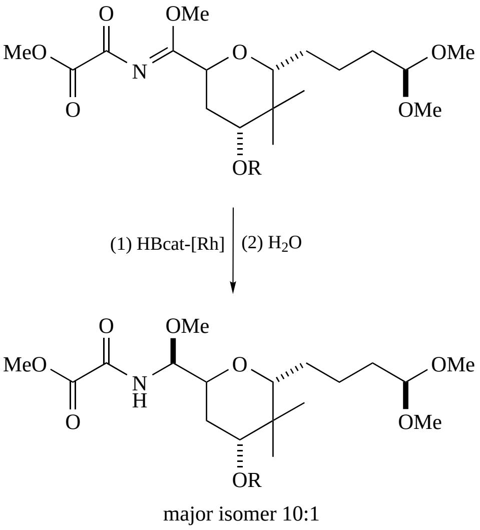
Lonomycin A is a structurally complex polyether antibiotic whose array of sensitive functionalities poses a considerable synthetic challenge. A rhodium-catalyzed hydroboration of a 1,1-disubstituted alkene has been applied by Evans and Sheppard to the penultimate step in the construction of a lonomycin C_1-C_{11} synthon.[60] High diastereoselectivities were observed for the desired C_{11}

alcohol in reactions using HBcat and $RhCl(PPh_3)_3$, while uncatalyzed reactions with disiamylborane gave the other diastereomeric alcohol in high yields (equation 16). These results were somewhat surprising as catalyzed hydroborations of a closely related model compound proceeded with little stereocontrol.



(16)

Pederin is a vesicant from the beetle *Paederus fuscipes* and is one of a small class of potent biologically active natural products whose complicated structure presents a substantial challenge as a target for synthesis. An account on the total synthesis of this insect toxin incorporated the use of a rhodium-catalyzed hydroboration reaction.[61] Stereoselective reduction of an *N*-acylimidate to the desired *N*-acyl aminal was achieved via a 1,4-hydroboration with HBcat carried out in the presence of a catalytic amount of $RhCl(PPh_3)_3$ (equation 17). Interestingly, a variety of reducing agents failed to generate the desired diastereomer selectively and catalyzed hydrogenations were equally ineffective. Other accounts using the metal catalyzed hydroboration in the total synthesis of natural products have also recently been published.[62,63]



(17)

8 CONCLUSIONS AND PROSPECTS

In summary, the potential utility of the metal catalyzed hydroboration reaction is vast. Future work will focus on its applicability in the synthesis of biologically active compounds where conventional electrophilic additions have proven ineffective. Convenience and mild conditions required for these reactions provide the organic chemist with a valuable synthetic tool.

Glossary

Anti-Markovnikov addition: addition that puts the X of HX on the end carbon of a terminal alkene (cf. Markovnikov addition below)
ee (enantiomeric excess): the excess of (R) or (S) enantiomers given by the equations $(N_R - N_S)/(N_R + N_S)$ or $(N_S - N_R)/(N_R + N_S)$, where N_R and N_S are the amounts of R and S enantiomers, respectively
Enantioselectivity: the degree of preference for (R) or (S) enantiomeric products in a chemical reaction
Epoxidation: the addition of an oxygen atom across a C=C bond to give a three-membered ring
Markovnikov addition: addition of the elements of HX to a terminal alkene such that the H goes on the end carbon and the X on the carbon next to the end
Phosphinites: compounds of P^{III} with two P–C bonds and one P–O bond
$(R)/(S)$*:* designations given to the right-handed and left-handed enantiomers in the traditional Cahn–Ingold–Prelog system
Regioselectivity: the degree of preference for reaction at different positions in a molecule when more than one structural isomeric product can be formed as a product (*see Regiochemistry*)

Abbreviations

A = a Lewis acid such as $AlCl_3$, $ZnCl_2$, or BR_3; ADN = Adiponitrile, $NC(CH_2)_4CN$; BD = 1,3-butadiene, $(CH_2{=}CH)_2$; *ee* = Enantiomeric excess; ESN = Ethylsuccinonitrile, $NCCH_2CH(CN)CH_2Me$; L = A P-donor ligand such as a phosphite or phosphine; 2M3BN = 2-methyl-3-butenenitrile, $NCCH(Me)CH{=}CH_2$; MGN = 2-methylglutaronitrile, $NC(CH_2)_2CH(CN)Me$; 2PN = 2-pentenenitrile, $MeCH_2CH{=}CHCN$; 3PN = 3-pentenenitrile, $MeCH{=}CHCH_2CN$; 4PN = 4-pentenenitrile, $CH_2{=}CHCH_2CH_2CN$.

1 INTRODUCTION

Organic compounds containing nitrile (–CN) groups are commercially important intermediates, because they can be converted into a variety of useful compounds, and because nitrile groups can be converted to other functional groups. Acrylonitrile ($CH_2{=}CHCN$), the largest volume organonitrile, is an important monomer for polymers (*see Polymer*) used for both plastics and synthetic fibers. Hydrogenation of dinitriles to diamines provides important intermediates both for polyurethanes ($–NH(CH_2)_mNHCO_2(CH_2)_nCO_2–$) and polyamides ($–NH(CH_2)_mNHCO(CH_2)_nCO–$); adiponitrile ($NC(CH_2)_4CN$), after hydrogenation to hexamethylenediamine and reaction with adipic acid (equation 1), gives 6,6-nylon, so named because there are six carbon atoms in both the diamine and diacid parts of the polyamide. More than 4 billion pounds of 6,6-nylon are produced this way annually.

$$H_2N(CH_2)_6NH_2 + HO_2C(CH_2)_4CO_2H \longrightarrow [–NH(CH_2)_6NHCO(CH_2)_4CO–]_n + H_2O \quad (1)$$

Further examples of organonitriles include cyanohydrins, important intermediates in the production of acrylates (equation 2), and aminonitriles, intermediates in the synthesis of chelates such as EDTA (equation 3) and nitrilotriacetate (NTA) (equation 4). A host of smaller volume commercial processes use nitrile intermediates for the production of pharmaceuticals, agrichemicals, cosmetics, and other consumer products.

$$Me_2C(CN)(OH) + H_2SO_4 + H_2O \longrightarrow H_2C{=}C(Me)CO_2H + (NH_4)HSO_4 \quad (2)$$

$$(NCCH_2)_2NCH_2CH_2N(CH_2CN)_2 + NaOH \longrightarrow \underset{\text{EDTA}}{(NaO_2CCH_2)_2NCH_2CH_2N(CH_2CO_2Na)_2} \quad (3)$$

$$N(CH_2CN)_3 + H_2O \longrightarrow \underset{\text{NTA}}{N(CH_2CO_2H)_3} \quad (4)$$

While hydrocyanation, the addition of HCN to an unsaturated substrate, is not the only method of producing an organonitrile, it is often the easiest and most economical. The addition of HCN to aldehydes and ketones is readily accomplished with simple base catalysis, as is its addition to activated alkenes (Michael addition). However, the addition of HCN to unactivated alkenes and dienes is best accomplished with a transition metal catalyst.[1] The hydrocyanation of alkenes and dienes is the most important way to prepare nitriles and is the focus of this article.

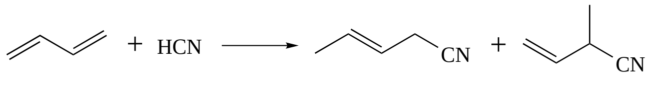
1.1 Safety Considerations in Using HCN

Great care must be used in handling HCN. The lack of reported incidents, coupled with the widespread commercial use of volatile and highly toxic HCN, points to the respect and care with which it is treated within industry. In a laboratory, HCN should be used only in small quantities in a well-ventilated fume hood. Vapors may be scrubbed or small samples (up to a few milliliters) may be disposed of by treatment with an equimolar mixture of caustic (NaOH) and hypochlorite bleach (NaOCl). Larger samples or vapor streams should be burned. The use of a 'buddy system' and first response training is essential when using HCN.[2]

2 THE HYDROCYANATION OF BUTADIENE TO ADIPONITRILE

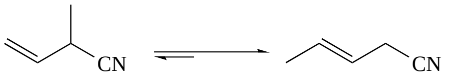
The DuPont ADN process[3] involves hydrocyanation of butadiene (equations 5–8), catalyzed by air- and moisture-sensitive triarylphosphite–nickel(0) complexes [$Ni(P(OAr)_3)_4$]. The nickel is zero valent (*see Oxidation Number*) because it has its full complement of 10 electrons beyond the preceding inert gas (Ar) configuration, and the catalysts can actually be made directly from nickel metal and the phosphite ligands (*see* ***P-donor Ligands***).[4] The four phosphorus atoms each contribute an electron pair to give a total of 18 electrons, corresponding to the next inert gas (Kr), (*see Effective Atomic Number Rule* and ***Electronic Structure of Organometallic Compounds***).

The first HCN addition (equation 5) occurs at practical rates above 70 °C under sufficient pressure to keep butadiene condensed in solution and produces the 1,4- and 1,2-addition products (3PN and 2M3BN) in a 2:1 ratio. Fortunately, thermodynamics favors 3PN (about 9:1), and 2M3BN may be isomerized to 3PN (equation 6) in the presence of the nickel catalyst. (The relative lengths of the arrows in the forward and reverse directions are meant to indicate the relative interconversion rates at equilibrium.)



3PN 2M3BN

(5)



(6)

The selective addition of the second HCN to provide ADN requires the concurrent isomerization of 3PN to 4PN (equation 7), and anti-Markovnikov HCN addition to 4PN (equation 8). A Lewis acid promoter is added to improve the selectivity and increase the rates of these latter steps. Temperatures for the addition of the second HCN are significantly lower than for the first, and practical rates may be achieved above 20 °C at atmospheric pressure. MGN (**1**), ESN (**2**), and 2PN (**3**) are produced as byproducts of the process.

2.1 Chemical and Mechanistic Information

Though most chemical and mechanistic studies related to the 1971 DuPont ADN process[5] have been published only recently, many of the fundamental studies done as part of the development of the process have greatly advanced our understanding of the organometallic chemistry of nickel (*see* ***Nickel: Organometallic Chemistry***) and other transition metals (*see* ***Mechanisms of Reaction of Organometallic Complexes***) and of their roles in homogeneous catalysis. Some of the more well known concepts to arise from this work include the discovery and quantification of the importance of phosphorus ligand steric effects using ligand cone angles[6] (*see Cone Angle*), the proposal that most transition metal catalyzed processes occur through discreet 16- and 18-electron intermediates[7] (*see Counting Electrons*), and the pictorial use of catalytic cycles in describing the sequence of reactions in catalytic systems.[8]

Some of these features are illustrated in Figure 1, which shows the reactions involved in the addition of the first HCN to butadiene using an NiL_4 catalyst.

Ligand dissociation from the 18-electron NiL_4 complex (L is a phosphite ligand) in step 1 allows *Oxidative Addition* of HCN to the 16-electron NiL_3. (NiL_3 complexes can be isolated for very bulky ligands like P(O-*o*-tolyl)$_3$,[9] but not for smaller ligands.) Step 2 gives hydrido–nickel–cyanide complexes ($HNiL_3CN$) (*see* ***Hydride Complexes of the Transition Metals*** and ***Cyanide Complexes of the Transition Metals***),[10,11] characterized by a strong CN stretching vibration in the IR spectrum and 1:3:3:1 quartet in the proton NMR spectrum. Ligand dissociation in step 3 gives a highly reactive 16-electron $HNiL_2CN$ complex which reacts rapidly with butadiene in step 4 to give a π-allyl (*see* π*-Bond*) nickel cyanide complex observable by NMR and IR spectroscopy at ambient temperature. The hydrogen which was formerly attached to nickel is now found in the terminal CH_3 group of the π-allyl, which is written with a curved line to show that the Ni is bound to all three carbons in the $CH_2CHCH–CH_3$

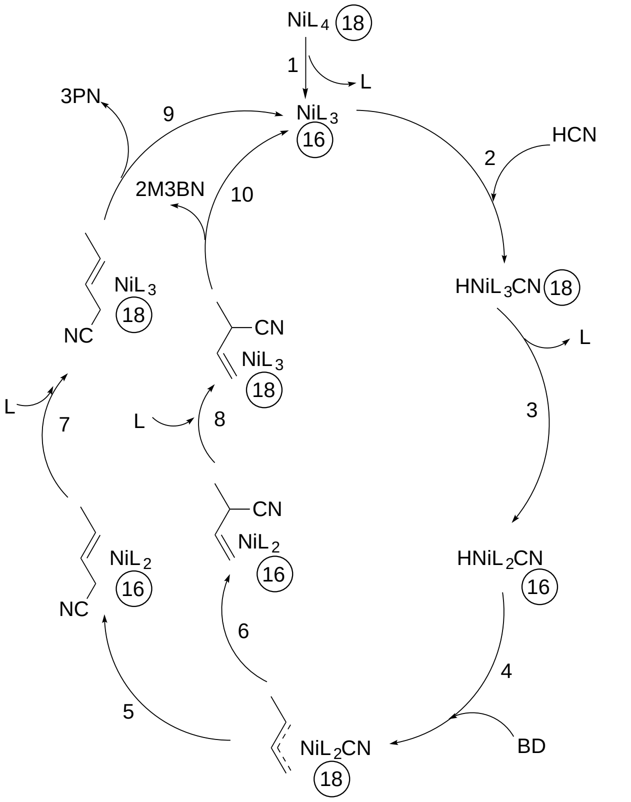

Figure 1 Proposed mechanism of butadiene hydrocyanation with Ni catalysts showing the pathway that introduces the first CN group

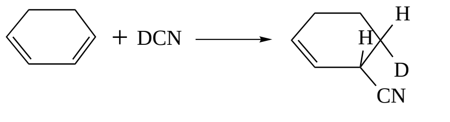
chain. Coupling of the CN carbon with carbons 1 or 3 of the chain by *Reductive Elimination* in steps 5 or 6 first gives alkene complexes of 3PN or 2M3BN, and eventually the free products. Steps 5–10 are reversible and provide a mechanism for the isomerization of 2M3BN to 3PN[12] that we saw earlier (equation 6).

This mechanism predicts that the hydrogen atom and cyanide group of HCN will be added across the same side of the carbon–carbon double bond and, consistent with this prediction, the addition of DCN (*see Isotopes & Isotope Labeling*) to cyclohexadiene (equation 9) has been shown to occur stereospecifically *cis* (*see Stereochemistry*).[13]

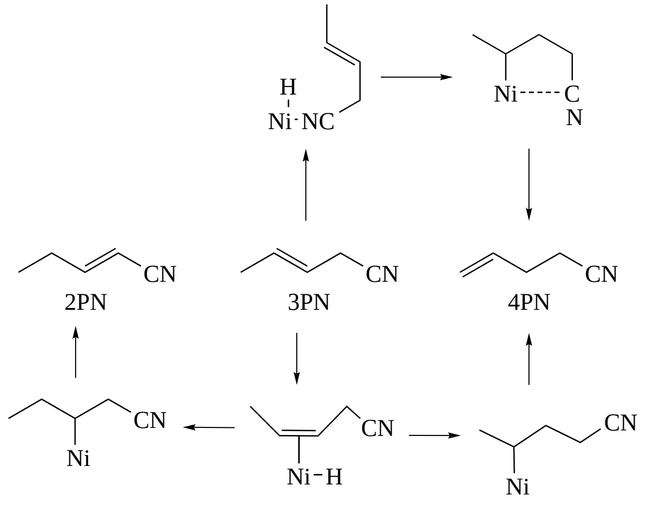


(9)

The isomerization of 3PN to 4PN (equation 7) is catalyzed by a cationic nickel–hydride complex generated by removal of cyanide by a Lewis acid promoter (equation 10).

$$HNi(CN{\cdot}A)L_3 \rightleftharpoons HNiL_3{}^{+}CN{\cdot}A^{-} \qquad (10)$$

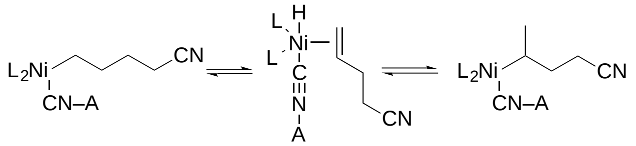
A remarkable feature of this isomerization is the kinetic control which allows 4PN to be made more than 70 times



Scheme 1

faster than the thermodynamically favored 2PN. The ability of the nitrile group to coordinate to the catalyst and direct the insertion (Scheme 1) is believed to be responsible.[14]

Alkene bonding to nickel, the *Insertion* of an alkene into the nickel–hydride bond, and the reductive elimination of ADN (or MGN or ESN) from the resulting alkylnickel cyanide complex are the principal features of the second HCN addition in the ADN process. All of the ADN and most of the MGN produced in this process arise from hydrocyanation of 4-PN, even though MGN can be made from hydrocyanation of 3-PN and there is a much greater amount of 3-PN present in the reaction mixture. This result is most likely due to the preferred bonding of 4-PN with the nickel catalyst. One study of a nickel catalyst suggests that the catalyst prefers to bond with 4-PN over 3-PN by about a factor of 200.[15] Insertion of the 4-PN internal alkene carbon into the nickel–hydride bond gives a linear alkylnickel cyanide (**4**; Figure 2), whereas insertion of the terminal alkene carbon gives a branched alkylnickel cyanide (**5**). Reductive elimination from (**4**) yields ADN, while reductive elimination from (**5**) yields MGN. The role of the Lewis acid promoter A in this reaction remains under study, but it is clear that the Lewis acid prefers to bind to an electron pair of the nitrogen of a CN bound to nickel, and that the size of the Lewis acid has a direct bearing on the



(**4**) A = Lewis acid (**5**)

Figure 2 Proposed mechanism of butadiene hydrocyanation with Ni catalysts showing the alternate insertion modes that prepare the way for introduction of the second CN group

selectivity of products, with bulkier Lewis acids favoring the production of linear nitriles.[16,17]

The exact nature of the complex from which the final reductive elimination occurs remains subject to speculation. The involvement of a five-coordinate nickel complex $RNiL_3CN{\cdot}A$ appears likely, based on the observation that reductive elimination of benzonitrile from $PhNi(Et_3P)_2(CN)$ is promoted by adding triethyl phosphite,[18] and that reductive elimination of propionitrile from EtNi[P(O-*o*-tolyl)$_3$](C_2H_4)(CN) is first order in triaryl phosphite concentration.[19]

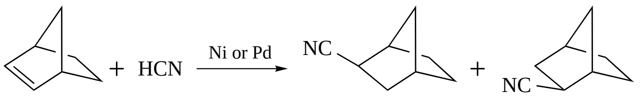
2.2 Hydrocyanation of Other Alkenes

The use of similar catalyst systems allows the selective HCN addition to many other unsaturated substrates; primary alkenes such as those obtained from the Shell Higher Olefin Process, represented by the formula $CH_2{=}CH(CH_2CH_2)_nCH_2Me$, are readily hydrocyanated under conditions similar to those described above for the second step of the ADN process, and can lead to primary amines (RNH_2), amides ($RCONH_2$), and acids (RCO_2H) containing odd numbers of carbons. Addition of HCN to styrene or other vinylarenes leads to high yields of 2-arylpropionitriles[20] (ArCH(Me)CN), the Markovnikov addition products, which are excellent intermediates for 2-arylpropionic acids (ArCH(Me)CO_2H), members of a class of nonsteroidal antiinflammatory drugs which includes ibuprofen and naproxen. The hydrocyanation of dienes, trienes,[21,22] and other polyenes leads to polyfunctionalized molecules which have many potential applications, including polymers and lubricants.

Some metal complexes of metals other than nickel are known to catalyze the hydrocyanation of alkenes, among the best being those of palladium and cobalt.[1]

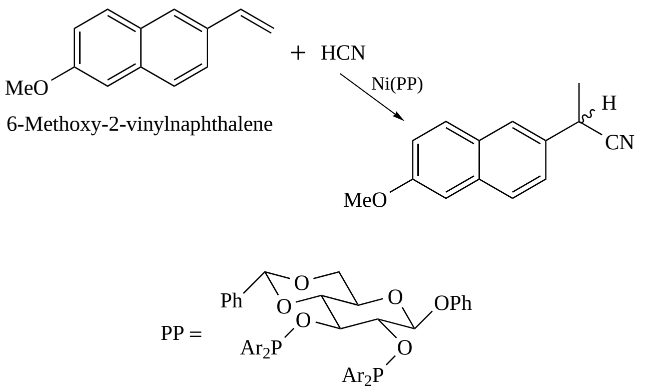
3 ASYMMETRIC HYDROCYANATION

Asymmetric catalysis (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***), the selective synthesis of left- or right-handed enantiomers using chiral catalysts, has become an important field of research that promises to greatly enhance our ability to make optically pure products for such diverse areas as pharmaceuticals, agrichemicals, and plastics. Impressive advances have been made in asymmetric hydrogenation, epoxidation, and dihydroxylation catalysis, while catalytic asymmetric carbon–carbon bond-forming reactions, such as asymmetric hydrocyanation, have proven more difficult. Until recently, the highest selectivity obtained for the asymmetric hydrocyanation reaction was 40% *ee* for a norbornene substrate. This result was achieved by using nickel or palladium complexes of chiral bidentate phosphines or phosphites as catalysts (equation 11).[23–25]

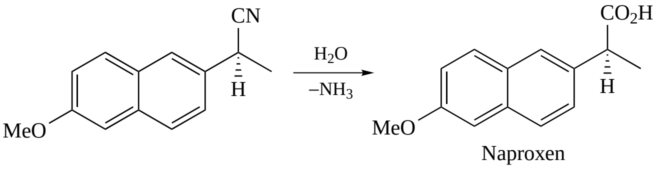


(11)

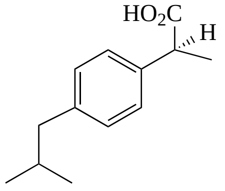
Recently, *ee*'s of 85–90% have been obtained for the asymmetric hydrocyanation of 6-methoxy-2-vinylnaphthalene using nickel complexes of chiral bidentate phosphinites derived from glucose (abbreviated PP, equation 12).[26] This reaction is of great interest to the pharmaceutical industry because the (*S*) enantiomer of the product nitrile is a useful precursor for the widely marketed antiinflammatory drug naproxen (equation 13). The same reaction can be applied to a number of other vinyl aromatic compounds, including the precursor for the antiinflammatory drug ibuprofen (**6**); however, the *ee* is not as high.



(12)



(13)

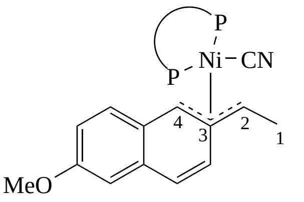


(**6**) (*S*)-Ibruprofen

HCN addition to 6-methoxy-2-vinylnaphthalene occurs readily at 25 °C in the presence of these optically active Ni complexes to give the branched nitrile exclusively and in high yield. The enantioselectivity (*R* versus *S*) of the

reaction can be increased by lowering the temperature or decreasing the solvent polarity, but is most dramatically affected by the electronic properties of the aryl group Ar on phosphorus. Thus, the *ee* increases from 16 to 78% upon changing from the relatively electron-donating 3,5-dimethylphenyl group to the relatively electron-withdrawing 3,5-bis(trifluoromethyl)phenyl group (Table 1). A study of a number of other substituted styrene substrates confirms that this electronic effect is general.

The active nickel catalyst contains one bidentate phosphinite ligand and the overall mechanism of the reaction is believed to be similar to butadiene hydrocyanation except that the final reductive elimination step is irreversible under the conditions of the reaction. π-Allyl intermediates (**7**) are believed to play an important role in the exclusive formation of the branched nitrile product observed. Formation of the C–CN bond in the final reductive elimination from the π-allyl intermediate occurs at C(2) and not C(4), because the aromaticity of the naphthalene ring is preserved only when the bond forms with C(2). A σ-alkyl complex (*see σ-Bond*) with the Ni bound to C(1), which could give the linear (anti-Markovnikov) nitrile product, does not contribute because of the much greater stability of intermediate (**7**), accounting for the high regioselectivity observed.



(**7**)

High enantioselectivity results when the reaction proceeds much faster through one of two competing reaction pathways in which Ni(PP) is bound to opposite sides of the plane defined by the atoms C(2)–C(3)–C(4). Although both sides of this plane appear equivalent, the Ni(PP) group distinguishes between the two sides because of the chirality of the PP ligand. While the mechanistic implications of the electronic effect are not clearly understood, deuterium-labeling studies suggest that insertion of the alkene into the nickel hydride bond is nearly irreversible for the electron-poor Ni phosphinite complexes and that this step controls the relative rates of the (R) and (S) pathways.

Table 1 Effect of ligand P–Ar group on enantioselectivity of methoxyvinylnaphthalene hydrocyanation

Ar	*ee* (%)	Solvent
3,5-$Me_2C_6H_3$	16	Benzene
C_6H_5	40	Benzene
3,5-$F_2C_6H_3$	77	Hexane
3,5-$(CF_3)_2C_6H_3$	78	Benzene
3,5-$(CF_3)_2C_6H_3$	85–90	Hexane

1 INTRODUCTION

Hydrodesulfurization (HDS) and hydrodenitrogenation (HDN) are the processes by which sulfur and nitrogen are removed from various petroleum feedstocks.[1–4] Both reactions occur during hydrotreating, which is practiced on an enormous scale, 38.3 million barrels per day worldwide in 2002.[5] The sulfur content of crude oils usually ranges from 0.2 to 4%,[6–9] while nitrogen is approximately 0.1–0.9%. Both elements are present as a plethora of organosulfur and organonitrogen compounds. Under typical conditions, the reactions (equations 1 and 2)

$$C_aH_bS + cH_2 \longrightarrow H_2S + C_aH_d \quad (1)$$

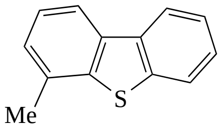
$$C_aH_bN + cH_2 \longrightarrow NH_3 + C_aH_d \quad (2)$$

are performed at 300–450 °C and H_2 pressures of up to 200 atm. The catalysts are often Al_2O_3-supported oxides of Mo and Co or Mo and Ni (*see Catalysis*). During the reactions the transition metals are converted to their sulfides; thus, MoS_2 is a major component of molybdenum-containing catalysts. Under HDS and HDN conditions, these catalysts also promote the hydrogenation of unsaturated hydrocarbons (*see* ***Hydrogenation & Isomerization of Alkenes***); this is often considered to be a disadvantage of the process because of the relatively high cost of H_2. Oxygen removal from organooxygen compounds also occurs, but oxygen is present in only small amounts initially and is not a pollutant; so hydrodeoxygenation (HDO) is not normally the goal of hydrotreating.

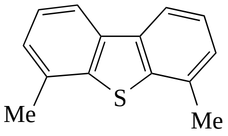
There are two major reasons for reducing sulfur and nitrogen levels in petroleum feedstocks: (1) to minimize the amounts of sulfur and nitrogen oxides introduced into the atmosphere by the combustion of petroleum-based fuels, and (2) to prevent poisoning of reforming and cracking catalysts that are used to upgrade feedstocks to product fuels. Since new drilling techniques allow the recovery of heavier crude oils that contain higher levels of sulfur and nitrogen, removal of these elements is becoming even more important. In general, sulfur removal is more important than nitrogen because sulfur levels are higher and governments have put limits on sulfur levels in transportation fuels. For example, sulfur in diesel fuel is currently limited by the U.S. Environmental Protection Agency to 500 ppm; however, in 2006, the limit will be only 15 ppm.[10] Since diesel is a higher boiling fraction than gasoline, it contains higher levels of dibenzothiophenes (DBTs), which are the most difficult organosulfur molecules to desulfurize under standard HDS conditions. It is the hindered or refractory DBTs, 4-MeDBT, and 4,6-Me_2DBT, which contain methyl groups near the sulfur, that are especially slow to undergo HDS.[10,11] Because it is necessary to desulfurize these refractory DBTs or remove the molecules from diesel fuels in order to achieve the 15 ppm limit, there is a great deal of interest in developing improved HDS processes or other methods for removing these compounds.

Lower sulfur and nitrogen levels are also necessary for both the catalytic hydrocarbon cracking and reforming processes. Basic nitrogen compounds, such as amines and pyridines, are severe poisons of the active acidic sites of zeolite cracking catalysts, which convert larger hydrocarbon molecules to those that can be used in gasoline. The reforming process isomerizes gasoline-range hydrocarbons to those with higher octane numbers. It is also the major process for the synthesis of benzene, toluene, and xylenes. With a worldwide capacity of 11.2 million barrels per day,[5] the reforming process requires large quantities of desulfurized feedstocks. It uses an Al_2O_3-supported Pt/Re catalyst that is poisoned by large amounts of sulfur; however, a low sulfur level is actually beneficial because it reduces hydrogenolysis of the hydrocarbons to smaller molecules.

It is the need for improvements in the HDS and HDN processes or the development of new methods for the removal of sulfur and nitrogen from fuels that has attracted the interest of inorganic and organometallic chemists. Their investigations have been directed toward understanding how organosulfur and organonitrogen compounds bind in transition metal complexes as models for their adsorption on active sites of catalyst surfaces; such studies have also provided



4-MeDBT



4,6-Me_2DBT

a basis for designing metal ion extractants that remove refractory DBTs from fuel feedstocks. In addition, studies directed at understanding how metal ion binding activates organosulfur and organonitrogen compounds to undergo reactions that lead to their desulfurization or denitrogenation have been pursued in an effort to understand details of the heterogeneously catalyzed HDS and HDN processes. All of these investigations have led to the introduction of new approaches to the desulfurization and denitrogenation of petroleum feedstocks.

2 HYDRODESULFURIZATION

The types of organosulfur compounds found in petroleum feedstocks are shown in Table 1.[12,13] Of them, the alkyl and aryl thiols (RSH), sulfides (RSR′), and disulfides (RSSR′) are the most rapidly desulfurized (equation 1). It is the broad class of thiophenes, stabilized by their aromatic character, that are most difficult to desulfurize and require relatively severe temperatures (≈400 °C) and H_2 pressures (≈100 atm). Thus, it is the HDS of thiophenes that has been of greatest interest to inorganic and organometallic chemists. There are fewer model studies of the HDS of thiols, sulfides, and disulfides.[14–16] Organometallic aspects of HDS and HDN have been summarized most comprehensively in a recent book by Sanchez-Delgado.[17] A briefer overview has also been published.[18] More specific reviews are cited in later sections of this chapter.

While commercial HDS catalysts are based on Mo, other transition metals are also active, some more active than Mo. In Figure 1 is a plot of the HDS activities of transition metal

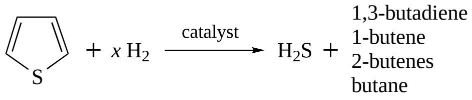
sulfides (*see* ***Chalcogenides: Solid-state Chemistry***) in the conversion of DBT to biphenyl at 400 °C.[19] A similar 'volcano plot' of catalyst activity versus various carbon-supported transition metals is observed in the HDS of thiophene.[20,21] In each study the most active catalysts are the second and third row metals Ru, Os, Rh, and Ir. While their high cost prevents them from being used commercially, their high activity makes them of interest to those who seek to understand the role of the metal as a catalyst. In fact, many of the model organometallic complex studies have been done with these metals.

Under HDS conditions, thiophene is converted to H_2S and C_4 products (equation 3).[22] Often 1,3-butadiene is not observed, but there is evidence to support the suggestion that it is the initial product of the desulfurization and is then hydrogenated to the observed more saturated C_4 products.[23] This is consistent with the fact that most HDS catalysts are also alkene hydrogenation catalysts under HDS

conditions.



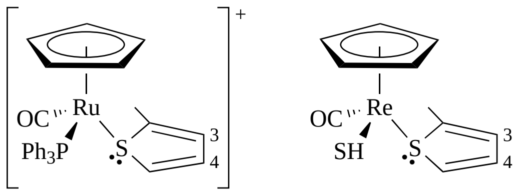
(3)

In order to understand details of the mechanism of thiophene HDS (equation 3), it is necessary to establish the mode of thiophene binding to a metal site on the catalyst surface and to understand how this adsorption activates the thiophene in a way that leads to the final products. Although there is some information on the modes of thiophene binding on clean metal surfaces,[15] there are few studies of thiophene adsorbed on MoS_2/Al_2O_3 catalysts themselves. However, a recent vibrational investigation[24] of thiophene adsorbed on MoS_2/Al_2O_3, in which infrared and Raman bands are compared with those of model transition metal complexes containing η^1(S)- and η^5-coordinated thiophene, indicates that the thiophene is coordinated through its sulfur η^1(S) to a Mo site. Theoretical treatments[25] of thiophene adsorption on cluster MoS_2 models of HDS catalysts show that both η^1(S) and η^5 adsorption modes are favorable. DFT calculations[26] of DBT adsorbed on a MoS_2 nanocluster show that the 4,6-methyl groups in 4,6-Me_2DBT do not interfere with adsorption when it is adsorbed parallel to the surface, but η^1(S) adsorption is considerably weaker for 4,6-Me_2DBT than for DBT.

2.1 Thiophene Binding at Metal Centers

Thiophene is known to coordinate in metal complexes in the four ways shown in Figure 2.[17,27,28] In the η^1(S) bonding mode, the sulfur acts as a two-electron donor; the metal does not lie in the plane of the thiophene as the ring is tilted. The angle between the M–S bond and the vector from the S to the midpoint of the C(3)−C(4) bond is 119.1° in $Cp(CO)(PPh_3)Ru(2\text{-MeT})^+$ (**1**)[29] and 140.4° in $Cp^*(CO)_2Re(T)$ (**2**).[30] The thiophene ligand itself remains planar, but the C–S bond distances increase about 0.04 Å from 1.71 Å in free T to 1.75 Å in the η^1(S) complexes. The tilt at the S and the C–S bond lengthening suggest that the sulfur is approximately sp^3 hybridized (*see Hybridization*) and π-bonding of sulfur within the thiophene ring is reduced. The tilted η^1(S) coordination[18,31,32] is common to all thiophenes, benzothiophenes, and DBTs, and even thiophenes incorporated into a porphyrin ring.[33] This strong preference for a tilted structure in which the metal does not lie in the plane of the thiophene ligand suggests that η^1(S) thiophene adsorbed at a metal site on a catalyst surface would also be tilted.

The η^1(S) thiophene ligand is very weakly coordinated (equation 4).[29] Thiophene itself is bound less



(**1**) (**2**)

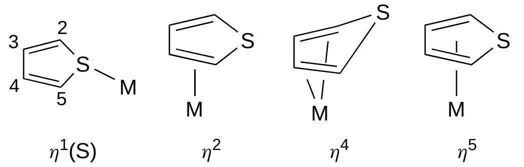


Figure 2 Known modes of thiophene coordination in transition metal complexes

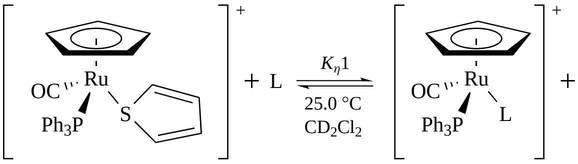
strongly than even MeI. Much more strongly coordinating are tetrahydrothiophene (THT) and acetonitrile. The binding ability of thiophene is generally increased by adding methyl groups to the ring; this makes the sulfur a stronger σ-donor ligand. Only when there are Me groups at both the 2- and 5-positions do steric repulsions reduce the $K_{\eta 1}$ values in $Cp(CO)(PPh_3)Ru(\eta^1\text{(S)-thiophene})^+$, although not in $Cp(CO)_2Ru(\eta^1\text{(S)-thiophene})^+$ complexes.[34]

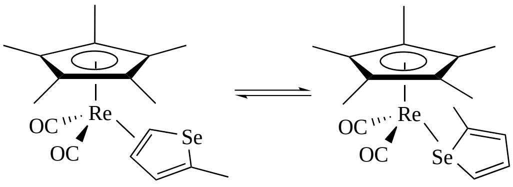


(4)

$K_{\eta 1}$ for the following L ligands: T (1.0) < MeI (2.0) < 2,5-Me_2T (2.76) < 2-MeT (4.11) < 3-MeT (6.30) < BT (29.9) < Me_4T (57.4) < DBT (74.1) << THT and MeCN (7.1×10^6)

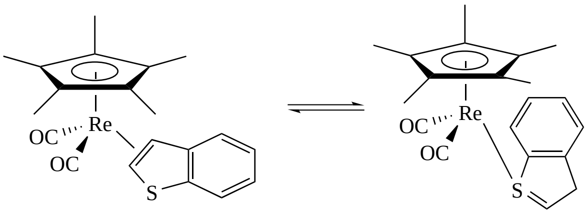
The η^2 coordination mode (Figure 2) was first identified[35–37] in $(NH_3)_5Os(\eta^2\text{-T})^{2+}$. It is also known in $Tp(CO)(L)Re(\eta^2\text{-T})$, where Tp = hydrotrispyrazolylborate and L = PMe_3, py, or CN–Bu^t,[38] but in the less electron-rich complex, $Tp(CO)_2Re(\eta^1\text{(S)-T})$, T is η^1(S)-coordinated.[39] Selenophene (Sel) in $Cp^*(CO)_2Re(\eta^2\text{-Sel})$ is η^2-coordinated;[40] however, in $Cp^*(CO)_2Re(\eta^1\text{(Se)-2,5-}Me_2Sel)$, the 2,5-$Me_2$Sel is coordinated through Se. $Cp^*(CO)_2Re(2\text{-MeSel})$ is a tautomeric mixture of the η^2 and η^1(Se) isomers in rapid equilibrium (equation 5). The η^2 isomer is favored in $Cp^*(CO)_2Re(2\text{-MeSel})$, but the η^1(Se) isomer dominates in the η^5-C_5H_5 analog $Cp(CO)_2Re(2\text{-MeSel})$. Cp* stabilizes η^2 coordination by promoting π *Back Bonding* from the Re to the alkene and by disfavoring Se → Re

electron donation in the η^1(Se) isomer.

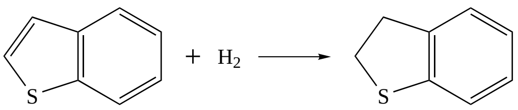


(5)

An η^1(S) $\rightleftharpoons$ η^2 equilibrium (equation 6) is observed in the benzo[*b*]thiophene (BT) complexes Cp′(CO)$_2$Re(BT), where Cp′ is Cp or Cp*.[41] As for selenophene, the Cp* ligand favors η^2-BT, while Cp favors the η^1(S) form; it should be noted that 2-MeBT and 3-MeBT form only the η^1(S) complexes. The formation of the η^2 form from the η^1(S) is important for understanding the first step in the HDS of BT, which gives dihydrobenzothiophene (equation 7). This alkene hydrogenation reaction is catalyzed by homogeneous catalysts[42] and may occur similarly on heterogeneous HDS catalysts. While there is no evidence that there is an η^2 $\rightleftharpoons$ η^1(S) equilibrium in thiophene complexes, both thiophene species *may* exist on a catalyst surface. Low metal oxidation states would favor η^2 coordination, which could lead to the initially observed alkene hydrogenation products.

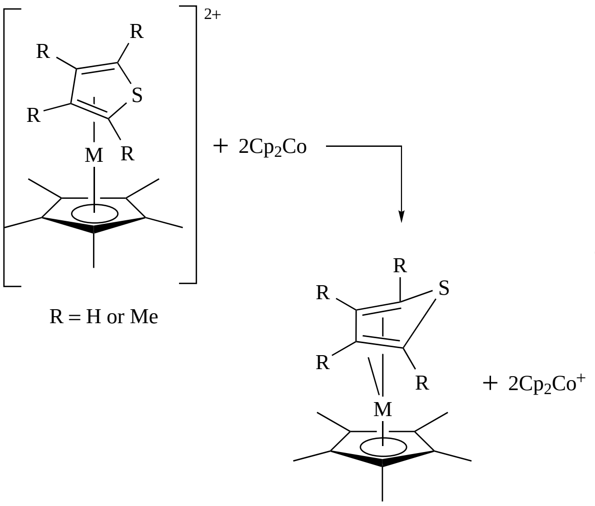


(6)



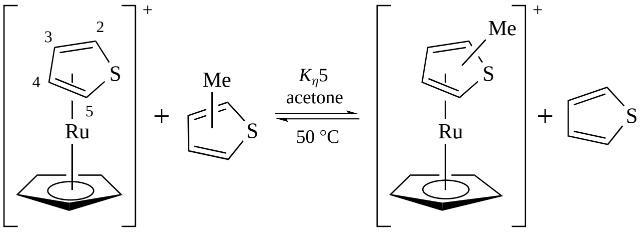
(7)

Complexes with η^4-thiophene ligands have been prepared by a two-electron reduction of η^5-thiophene complexes of Ir[43] and Rh[44] (equation 8) and Ru.[45] Reduction releases the coordinated sulfur in order to maintain the 18-electron configuration (*see Electron Configuration*); the η^4-thiophene ligand acts as a four-electron donor. A structural determination of Cp*Ir(η^4-2,5-Me$_2$T) shows the Ir–S distance (2.969(4) Å) to be substantially longer than a normal Ir–S single bond (2.35 Å). The C–S distances (1.76(2) and 1.79(2) Å) are significantly longer than those (1.71 Å) in thiophene itself; thus, η^4-bonding weakens the C–S bonds, which is partly responsible for the high reactivity of the thiophene ligand in these complexes (see Section 2.2).



(8)

The most common mode of thiophene coordination in its complexes is η^5 (Figure 2),[28] in which it acts as a six-electron donor. In an equilibrium study[46] of the displacement of thiophene in CpRu(η^5-thiophene)$^+$ by various methyl-substituted thiophenes (equation 9), the K_{η^5} values show that thiophene binding increases with increasing methyl substitution of the thiophene. This is the same trend as that observed[47] for the equilibrium adsorption of thiophenes on a Co–Mo/Al$_2$O$_3$ HDS catalyst at 350 °C: T (1.0) <2-MeT (1.6) ∼3-MeT (1.7) <2,5-Me$_2$T (2.5). While the similarity of these trends suggests that thiophene is η^5 adsorbed on the catalyst, it is not possible to exclude η^1(S) adsorption because thiophene binding in Cp(CO)$_2$Ru(η^1(S)-thiophene)$^+$ also increases (equation 4)[29,34] with the number of methyl groups in the thiophene.



K_{η^5}: T (1) < 2-MeT (6) ≤ 3-MeT (7) < 2,5-Me$_2$T (35) < 2,3-Me$_2$T (50) < 2,3,4-Me$_3$T (200) < 2,3,5-Me$_3$T (300) < Me$_4$T (1300)

(9)

However, η^5 adsorption on catalysts is also supported by deuterium exchange studies of thiophene. When thiophene and D$_2$ are passed over Mo-based HDS catalysts at temperatures below which substantial HDS occurs, the thiophene protons exchange with deuterium. This exchange occurs much more rapidly at the 2- and 5-positions than at the 3- and 4-sites. When CpRu(η^5-T)$^+$ (equation 9) is dissolved in CD$_3$OD in the presence of OD$^-$ at 23 °C, the 2,5-hydrogens of thiophene

undergo exchange with deuterium at a rate that is more than 1500 times faster than that of the 3,4-hydrogens.[48] The rate of exchange of the 3,4-hydrogens is first order each in the complex and base (OD^-) concentrations. Thus, η^5-thiophene coordination in $CpRu(\eta^5\text{-T})^+$ activates the thiophene to undergo base-promoted exchange preferentially at the 2,5-positions. This presumably occurs as a result of the metal withdrawing electron density from the thiophene ring, which makes the hydrogens susceptible to deprotonation by the base; the resulting deprotonated carbon is then rapidly deuterated by the CD_3OD solvent. A similar mechanism could account for the deuteration of thiophene on HDS catalysts. After initial η^5 adsorption, the thiophene would be deprotonated by a basic oxide or sulfide site; transfer of a deuterium from a surface OD or SD group to the deprotonated carbon would give the deuterated thiophene. Indeed, when $[CpRu(\eta^5\text{-T})]BF_4$ is adsorbed on Al_2O_3 that contains surface OD groups, partial exchange of the 2,5-hydrogens in the η^5-T ligand occurs.[49]

Considering the importance of removing DBTs from petroleum feedstocks, one might note that these molecules bind in metal complexes primarily through the sulfur η^1(S)[50–52] or η^6 [17,31] through an arene ring. There is no evidence for η^5 coordination through the thiophene ring although there are a few examples[53] of η^4-coordinated DBT (through four nonthiophenic benzocarbons). As described in equation (4), DBT binds in the η^1(S) mode to $Cp(CO)(PPh_3)Ru^+$ more strongly than T. However, equilibrium studies[54,55] of the reaction in equation (10) show that methyl substitution in the 4,6-positions substantially decreases the

$$Cp^*(CO)_2Ru(DBT)^+ + Me_xDBT \xrightleftharpoons{K_{DBT}} Cp^*(CO)_2Ru(Me_xDBT)^+ + DBT$$

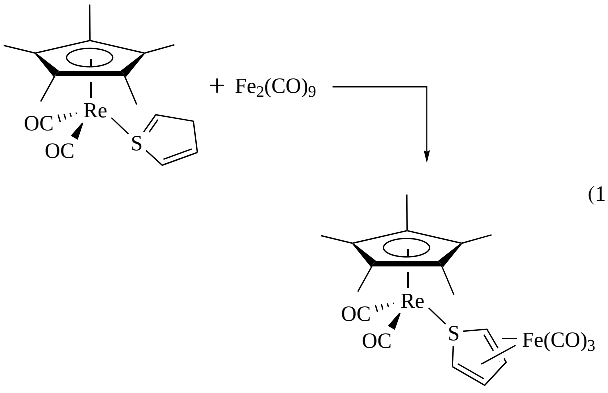
$$K_{DBT} \text{ for the following } Me_x \text{ DBT ligands: } 2,8\text{-}Me_2DBT(3.6) > DBT(1.0) > 4\text{-}MeDBT(0.32) > 4,6\text{-}Me_2DBT(0.016) \qquad (10)$$

coordinating ability of the DBT ligand, which is consistent with the conclusion[25] that 4,6-methyl groups decrease binding of DBTs on metal sites of HDS catalysts. It is interesting that methyl groups in the 2,8-positions, away from the sulfur coordination site, actually increase the binding ability of the DBT due to the electron-donating ability of the methyl groups.

2.2 Reactions of Coordinated Thiophenes

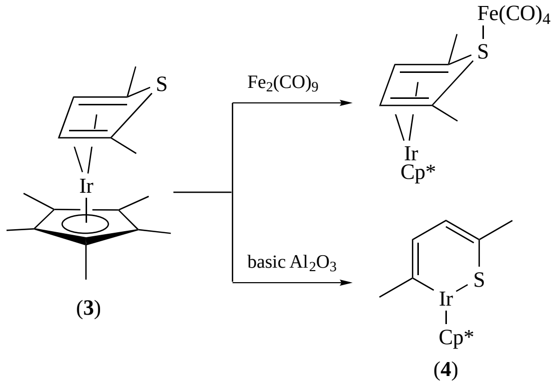
In order to understand the mechanism(s) of thiophene HDS, it is useful to know how thiophene can be activated to react by coordination to a metal; many of these reactions have been reviewed.[56] Of particular interest are reactions that lead to cleavage of the C–S bonds.

Although η^1(S) coordination of thiophene might be expected to make the C_4 portion of the ligand behave like a diene, only one example of this behavior is known (equation 11).[30] Other reactions of η^1(S)-thiophene are unknown, perhaps because the weak coordinating ability of thiophene (Section 2.1) results in its facile displacement.



(11)

η^4-Thiophenes are substantially more reactive. The sulfur in $Cp^*Ir(\eta^4\text{-}2,5\text{-}Me_2T)$ (**3**) is a much stronger Lewis base than free thiophene or even Me_2S. Thus, (**3**) forms adducts with Lewis acids such as BH_3 and $Fe(CO)_4$ (equation 12).[57] The sulfur in other η^4-thiophene ligands form similar adducts.[58] Bases such as basic Al_2O_3 and Et_3N catalyze the isomerization (equation 13) of (**3**) to the ring-opened isomer $Cp^*Ir(C,S\text{-}2,5\text{-}Me_2T)$ (**4**).[43] Although the mechanism of this reaction is not known, it illustrates a remarkably facile cleavage of a thiophene C–S bond. Product (**4**) has a structure in which the six-membered ring is planar. This, together with other features of the structure and its ^1H NMR spectrum, suggests that the ring has a delocalized π-system.[59] This is supported by the observation that the six-membered ring in (**4**) forms η^6-complexes analogous to those of η^6-benzene.[59,60]

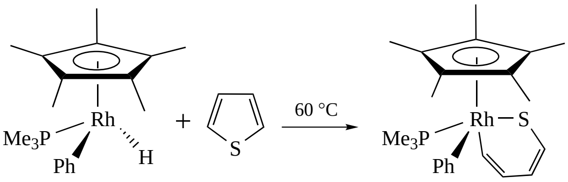


(12)

(13)

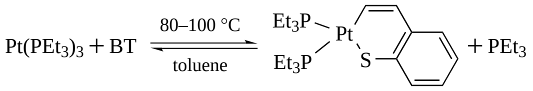
While the Rh analog of (**3**) has not been reported to undergo the ring-opening reaction in equation (13), related ring-opened products, including those of benzothiophenes and DBTs,[61] have been obtained by the reaction in equation (14).[62,63] The reaction proceeds by initial *Reductive Elimination* of benzene (PhH) to give an unsaturated $Cp^*Rh(PMe_3)$ intermediate that reacts with thiophene to give the ring-opened product.

The analogous Ir product is obtained from the reaction of Cp*Ir(C,S-2,5-Me_2T) (**4**) with PR_3.[59] Unlike the structure of (**4**), the phosphine adduct structures contain a six-membered ring which is no longer planar or delocalized. Thiophene ring-opening reactions with molybdenum,[52] iron and ruthenium carbonyls,[64,65] and Cp*Co$(C_2H_4)_2$[61] have also been reported. Related selenophene and tellurophene ring-openings occur in reactions with osmium carbonyl complexes.[64]



(14)

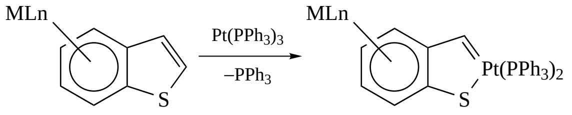
Besides the ring-opening reactions described above, there are many other examples of this type of reaction with low-valent, electron-rich metal complexes.[56] Among the more thoroughly studied systems is that involving $Pt(PEt_3)_3$, whose reaction with BT is illustrated in equation (15).[66,67] Thiophenes and DBTs also undergo analogous reactions. The



(15)

reversibility of the reactions means that one thiophene in the ring-opened complex can be replaced by another. Reaction of the ring-opened complex of DBT with H_2 results in desulfurization and the formation of biphenyl.[68]

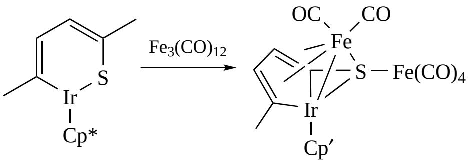
Ring-opening reactions of the type in equation (15) require the very electron-rich $Pt(PEt_3)_3$. The less electron-rich and more sterically hindered $Pt(PPh_3)_3$ does not react. However, Sweigart and coworkers[69,70] showed that electron-withdrawing ML_n metal fragments η^6-coordinated through a benzo ring of BT or DBT activate a C–S bond to ring-open as shown in equation (16). Qualitatively, the rates of these reactions at room temperature decrease



(16)

as the electron-withdrawing ability of the ML_n fragment decreases: $Ru(C_6Me_6)^{2+}$, $Mn(CO)_3{}^+ > FeCp^+$, $RuCp^+ \gg Cr(CO)_3$. If η^6-coordination of BT or DBT were to occur on an electropositive metal site of an HDS catalyst, this could facilitate ring-opening by reaction with a more electron-rich metal nearby as in equation (16). Such a ring-opening reaction would destroy the aromaticity of the thiophene ring and make the BT or DBT more susceptible to complete desulfurization.

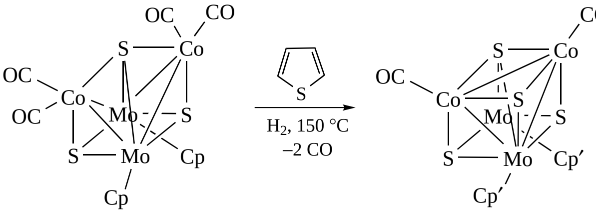
Ring-opening of thiophene involves the cleavage of one C–S bond, but the presence of another metal can lead to the cleavage of the remaining C–S bond. On a catalyst surface, several adjacent metal atoms could be available for reaction. The reaction of the ring-opened Cp*Ir(C,S-2,5-Me_2T) (**4**) with the iron carbonyls $Fe(CO)_5$, $Fe_2(CO)_9$, and $Fe_3(CO)_{12}$,[57] while complicated, gives one product (**5**) of particular interest for HDS since it includes all of the elements of 2,5-Me_2T, but both C–S bonds are cleaved (equation 17). Both C–S bond cleavage reactions (equations 13 and 17) are models for key steps in a proposed thiophene HDS mechanism (see Section 2.3).



(17)

(**4**) (**5**)

A metal sulfide cluster $Cp'_2Mo_2Co_2(CO)_4S_3$ (**6**), potentially having some structural features of a sulfided Co–Mo/Al_2O_3 catalyst surface, reacts with thiophene at 150 °C under 15 atm of H_2 (equation 18) to give an essentially quantitative yield of the cubane cluster $Cp'_2Mo_2Co_2(CO)_2S_4$ (**7**).[71,72] The thiophene sulfur is incorporated into the cluster, and the hydrocarbon portion is converted to a mixture of C_{1-4} alkanes and alkenes. The mechanism of this reaction may involve initial S-coordination of thiophene to (**6**).

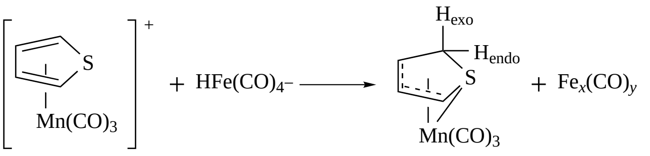


(18)

(**6**) (**7**)

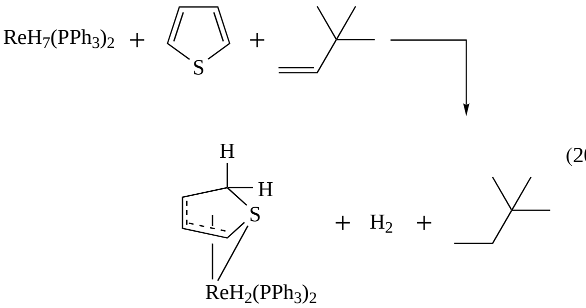
η^5-Thiophene can undergo nucleophilic attack in its cationic complexes. As a model for a hydride on the catalyst surface, $HFe(CO)_4{}^-$ reacts with (η^5-T)$Mn(CO)_3{}^+$ (equation 19) to give the hydrothiophene product (**8**).[73] When $DFe(CO)_4{}^-$ was used, both exo and endo deutero products were formed. Pure endo transfer has been established in the reaction of $ReH_7(PPh_3)_2$ with thiophene (equation 20).[74] This reaction presumably proceeds by initial dehydrogenation of $ReH_7(PPh_3)_2$ to give $ReH_3(PPh_3)_2$, which reacts with thiophene to give the hydrothiophene product resulting from the transfer of H from Re to C(2). The reaction of $RuH_2(\eta^2-H_2)_2(PCy_3)_2$ with thiophene gives an analogous product;[75] in this case, $RuH_2(\eta^2-H_2)_2(PCy_3)_2$ also catalyzes

the hydrogenation of T to THT.



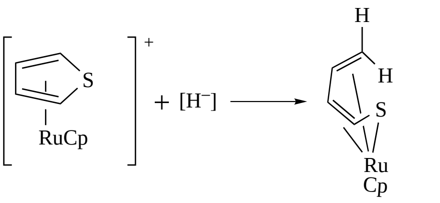
(**8**)

(19)



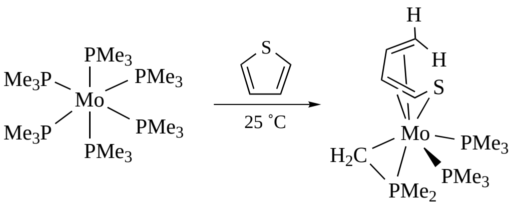
(20)

Hydride nucleophiles (*see Nucleophile*) ($H_2Al(OCH_2CH_2OMe)_2^-$, AlH_4^-, or $HBEt_3^-$) also add to the η^5-thiophene ligand in CpRu(η^5-T)$^+$ (equation 21).**[73,76]** Like the reaction in equation (19), H^- adds to C(2), but in this case the C–S bond is cleaved to give a butadienethiolate complex. An intramolecular version of H^- addition (in this case provided by a PMe_3 ligand) to thiophene to give a butadiene thiolate complex is observed in the reaction of $Mo(PMe_3)_6$ with thiophene (equation 22).**[77]** It is not clear why the C–S bond remains intact in the products of reactions 19 and 20 but is cleaved in the products of reactions 21 and 22.



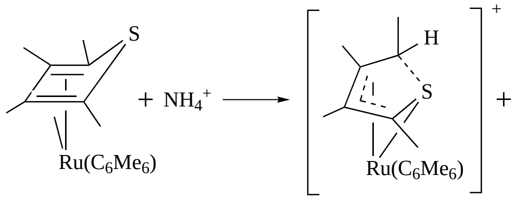
(**9**)

(21)



(22)

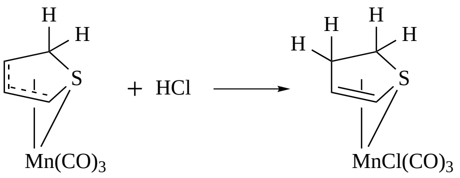
An intermediate case occurs in another Ru complex, which is formed (equation 23) by endo protonation of the η^4-Me_4T in the η^6-hexamethylbenzene complex (η^4-Me_4T)Ru(η^6-C_6Me_6).**[45]** The C(sp^3)–S distance (1.91(1) Å) in (**10**) is considerably longer than a normal C(sp^3)–S bond (1.83 Å), but this bond is not completely cleaved as in (**9**).



(23)

(**10**)

Simple protonation of (**8**) with a strong acid at 25 °C yields the 2,3-dihydrothiophene (2,3-DHT) complex (equation 24); –SH groups on MoS_2 have been proposed**[17,73]** to be strong acids and may therefore be relevant. The stepwise addition of H^- (equation 19) and H^+ (equation 24) to η^5-thiophene forms the basis of an important mechanism proposed for thiophene HDS (see Section 2.3).



(24)

(**8**) (**11**)

2.3 Mechanisms of Thiophene Hydrodesulfurization

In recent years, mechanisms based on organometallic model studies have been proposed. Several reviews give further details of these studies and proposals.**[17,73,78–83]** Prior to organometallic model studies, there was little evidence to support the few mechanisms**[2,3,17,73]** that had been proposed. Two types of mechanisms for the HDS of thiophene based on model studies have been proposed. One (Figure 3) involves initial partial hydrogenation of the thiophene prior to desulfurization.**[73,84]** Thiophene adsorbs (Figure 3) as an η^5 ligand at a metal site; as in the reaction (equation 19) of (η^5-T)$Mn(CO)_3^+$ with $HFe(CO)_4^-$, the thiophene is thereby activated to attack (step a) by an adjacent metal hydride (M–H) to give a hydrothiophene intermediate. Protonation by an acidic –SH group (step b) leads to 2,3-dihydrothiophene (2,3-DHT); this is the same type of protonation that was observed (equation 24) in the manganese system. The 2,3-DHT may be coordinated through both the alkene and the sulfur as shown in Figure 3, or it may bind just through the sulfur as observed in its transition metal complexes.**[85]** Steps (a) and (b) are equivalent to adding two hydrogen atoms, and it is therefore possible that 2,3-DHT is formed by the standard mechanism for metal-catalyzed alkene hydrogenation. The intermediacy of 2,3-DHT in thiophene HDS is supported by the result**[84]** that 2,3-DHT undergoes HDS over 5% Mo/Al_2O_3 and 5% Re/Al_2O_3 much more rapidly than does thiophene, which accounts for the fact that 2,3-DHT is not observed

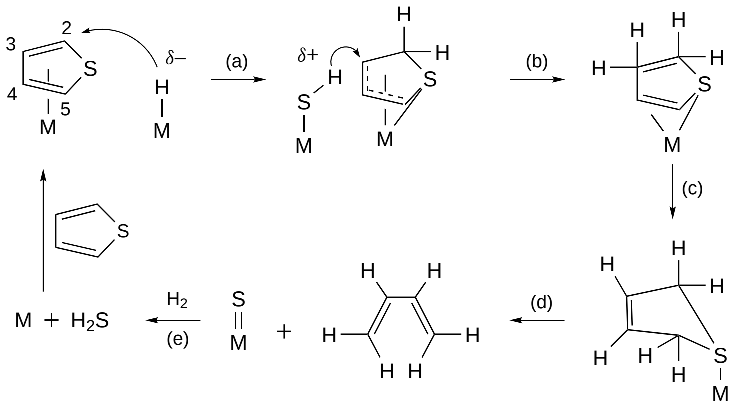


Figure 3 Hydrogenation mechanism proposed for thiophene HDS[73,84]

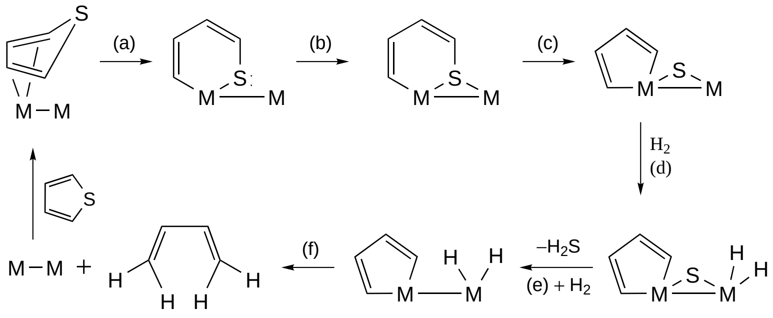

Figure 4 C–S cleavage mechanism proposed for thiophene HDS[57]

as a thiophene HDS product. In addition, the distribution of 1-butene, 2-butene, and butane products is the same for the HDS of both thiophene and 2,3-DHT over 5% Mo/Al_2O_3 at 400 °C.

In step (c) (Figure 3), 2,3-DHT isomerizes to the slightly more thermodynamically stable 2,5-DHT; this alkene isomerization has been observed on a Re/Al_2O_3 catalyst at 300 °C.[84] The desulfurization step (d) involves the elimination of butadiene from an S-coordinated 2,5-DHT; this step is modeled by the evolution of 1,3-butadiene from the S-coordinated 2,5-DHT complexes $Fe(CO)_4$(2,5-DHT), $W(CO)_5$(2,5-DHT), and $Re_2(CO)_9$(2,5-DHT), when they are heated at 110 °C.[85,86] Coordination to the metal is essential for this reaction since free 2,5-DHT does not eliminate 1,3-butadiene under these conditions. The 2,5-DHT also releases 1,3-butadiene when adsorbed on single crystal Mo(110) surfaces[15] and when passed over a 5% Re/Al_2O_3 catalyst at 300 °C under HDS conditions.[84] The more saturated C_4 products (equation 3) observed in thiophene HDS are presumably formed by hydrogenation of the 1,3-butadiene. In step (e), the active metal site is regenerated by removal of the sulfide ligand as H_2S upon reaction with H_2. The key steps (a–d) in this HDS mechanism (Figure 3) have all been observed either in reactions of thiophene complexes or on catalyst surfaces.

From a detailed study[87] of the deuterodesulfurization (DDS) of thiophene over a Chevrel-phase catalyst $PbMo_6S_8$, it was concluded that the mechanism in Figure 3 is consistent with all of the observed results. This study eliminated two other mechanisms that had been previously proposed. The mechanism described below (Figure 4) is also consistent with results of the DDS investigation.

The C–S cleavage mechanism (Figure 4)[57] involves the removal of sulfur from the thiophene ring prior to the transfer of hydrogen to the thiophene. This mechanism begins with η^4 adsorption of thiophene on a metal site. In metal complexes this binding mode is not as common as η^1(S) or η^5 coordination; it occurs when the metal requires the thiophene to act as a four-electron donor. Thus, η^4 adsorption may be demanded by the electronic state and/or the steric environment at the site. The first step (a) in this mechanism (Figure 4), which involves C–S cleavage, is based on the isomerization (equation 13) of Cp*Ir(η^4-2,5-Me_2T) (**3**) to the ring-opened product Cp*Ir(C,S-2,5-Me_2T) (**4**). This reaction may be base-catalyzed as reaction 13 is catalyzed by basic Al_2O_3. On an HDS catalyst surface, S^{2-} or O^{2-} ions may serve as the base. Rather than originating from an η^4-coordinated T, the ring-opened product of step (a) may occur by C–S bond cleavage at an electron-rich metal site, as

in equations (14) and (15). Equation (17) shows that a second metal could promote cleavage of the second C–S bond to give a metallacyclopentadiene complex (**5**). An analogous reaction is proposed in step (c). The metallacyclopentadiene could bind to one metal through two M–C σ-bonds as shown in Figure 4 or the diene portion of the ring could also bind to another metal atom as observed in (**5**). Evidence for metallacyclopentadiene units on Pt(111) has been obtained in surface studies of thiophene.[88,89] Following formation of the metallacyclopentadiene intermediate, the sulfur is removed with H_2 as H_2S (steps d and e), and 1,3-butadiene is formed in step (f). While these latter reactions are proposed to involve surface hydrides, which may be present on MoS_2 during HDS,[90] there is evidence in organomolybdenum chemistry to suggest that –SH groups might serve as the source of hydrogen in these reactions.[14,91]

Although HDS using Mo/Al_2O_3-based heterogeneous catalysts is highly effective for many thiophenes, similar reactions catalyzed by homogeneous metal complexes are very limited.[17,78–83] Bianchini and coworkers have made especially important contributions in this area. The hydrogenation of thiophene to THT is catalyzed by $[Ir(H)_2(PPh_3)_2(\eta^1(S)\text{-}T)_2]PF_6$ at 1 atm H_2 and 80 °C, but it stops after the formation of 2 moles of THT which binds strongly in $[Ir(H)_2(PPh_3)_2(\eta^1(S)\text{-THT})_2]PF_6$ and inactivates the Ir complex catalyst.[92] In general, a major problem for the development of homogeneous catalysts for HDS reactions is the strong coordinating properties of the hydrogenated organosulfur product (e.g. THT) or H_2S, which inactivates the metal complex catalyst. There is one report of the (triphos)Rh(H)/KOBu^t-catalyzed HDS of thiophene to butane, 1-butanethiol and H_2S at 160° and 30 atm H_2, although the turnover numbers are low;[93] the authors do not rule out the possibility that the reactions are catalyzed by Rh metal despite studies in the presence of excess mercury metal.[79]

The hydrogenation of benzothiophene (BT) to 2,3-dihydrobenzothiophene is catalyzed by several transition metal complexes, including $[Rh(PPh_3)_2(COD)]PF_6$, $Rh(PPh_3)_3Cl$, and $Ru(PPh_3)_3Cl_2$, at 170 °C and 110 atm pressure.[82] Using (triphos)Rh(H), where triphos = $MeC(CH_2PPh_2)_3$, as the catalyst at 160° and 30 atm H_2 pressure, the BT in the presence of an equivalent amount of KOBu^t is converted to 2-ethylthiophenol (ETP) with a turnover frequency of 90 mol ETP mol $Rh^{-1}h^{-1}$.[93] Detailed mechanistic studies[79] show that the reaction proceeds by initial Rh insertion into a C–S bond of BT followed by the hydrogenation steps in Figure 5. This catalyst has been modified by incorporating a sulfonate group into the triphos ligand as $^{-}O_3S\text{–}C_6H_4\text{–}CH_2\text{–}C(CH_2PPh_2)_3$, sulphos. The resulting (sulphos)Rh(H)$^-$ complex, together with KOBu^t in the MeOH phase of a two-phase MeOH/*n*-heptane system, catalyzes the hydrogenolysis of BT to ETP at essentially the same rate as the homogeneous reaction using (triphos)Rh(H)/KOBu^t. The triphos ligand has also been covalently attached to polystyrene and converted into [(COD)Rh(polytriphos)]PF_6, where COD = 1,5-cyclooctadiene.[94] This catalyst, which presumably is converted into (polytriphos)Rh(H) under the conditions of the reaction (160 °C, 30 atm H_2), has a slightly higher turnover frequency (124 mol ETP mol $Rh^{-1}h^{-1}$) than either the homogeneous or two-phase catalyst systems.

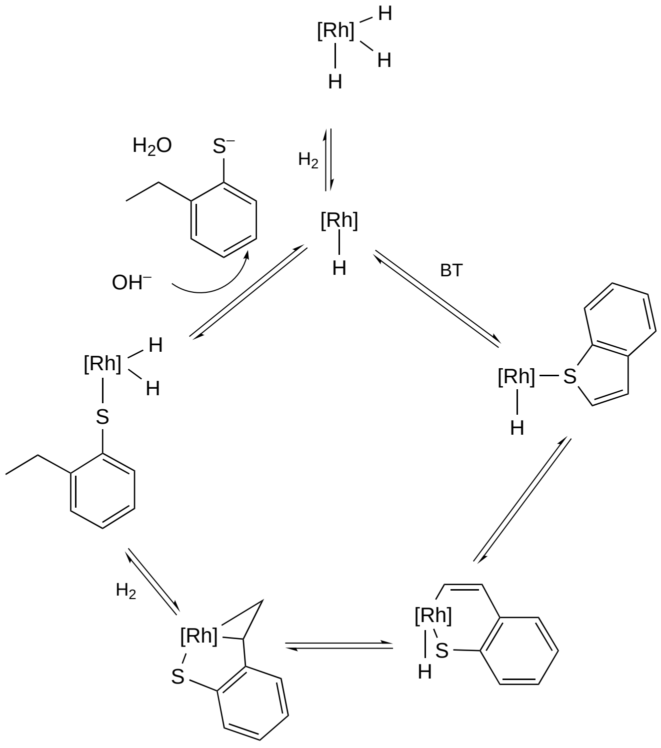

Figure 5 Mechanism for the hydrogenolysis of BT to ETP using (triphos)Rh(H) as the catalyst.[79]

The hydrogenolysis of DBT to 2-phenylthiophenol (PTP) is catalyzed by (triphos)Rh(H), generated in situ, at 160 °C and 30 atm H_2 pressure with a very low turnover frequency (2 mol TPT mol $Rh^{-1}h^{-1}$).[93] The DBT ring-opened Ir complex (triphos)Ir(H)(η^2-C,S–DBT) catalyzes the formation of PTP in only 8% yield at 170 °C under 30 atm H_2 pressure over a period of 24 h.[95] Some biphenyl (5%), the completely desulfurized form of DBT, is also formed in the reactions, but the authors do rule out the possibility that the formation of this product is due to catalysis by a heterogeneous form of Ir. Therefore, there appear to be no unequivocal examples of HDS catalyzed by a homogeneous metal complex that results in the complete removal of sulfur from T, BT, or DBT.

2.4 Extraction of Dibenzothiophenes Using Metal Ion Complexes

As described in the Introduction (Section 1), the new U.S. Environmental Protection Agency regulations for diesel

fuel require the removal of DBTs that are not desulfurized under standard HDS conditions. Considering the ability of thiophenes to bind in a variety of transition metal complexes, one can imagine that their affinity for metal ions could be used to remove DBTs, especially the hindered 4,6-Me_2DBT, from diesel fuels. Previously described studies, equations (4) and (10), showed that $Cp(CO)(PPh_3)Ru^+$ and $Cp^*(CO)_2Ru^+$, coordinate DBT much more strongly than T (equation 4); however, 4,6-Me_2DBT binds much less strongly than DBT. To take advantage of this binding ability, the complex $Cp(CO)_2Ru(BF_4)$, generated by the reaction of $Cp(CO)_2RuCl$ with $AgBF_4$, was adsorbed on a mesoporous silica.[96] The resulting solid-phase extractant $CpRu(CO)_2(BF_4)/SiO_2$ was stirred with a simulated fuel consisting of 400 ppm of sulfur (in the form of DBT) in 45% toluene/55% hexanes. Analysis of the solution showed that the DBT had been reduced to only 3.5 ppm of sulfur, that is, a 99% reduction in sulfur. Under the same conditions using 4,6-Me_2DBT instead of DBT, only 72% of the 4,6-Me_2DBT was removed. The reduced effectiveness of $Cp(CO)_2Ru(BF_4)/SiO_2$ for 4,6-Me_2DBT probably reflects steric factors in 4,6-Me_2DBT that were also observed in the solution equilibrium binding studies (equation 10).

Another approach to the extraction of DBTs from a simulated petroleum fuel was the use of the water-soluble $(NH_3)_5Ru(H_2O)^{2+}$, which is known[97] to bind to thiophene (T) as $(NH_3)_5Ru(T)^{2+}$. Because DBT binds more strongly than T in other metal complexes, it was expected that DBT would form $(NH_3)_5Ru(\eta^1(S)\text{-DBT})^{2+}$. The complex is thermally stable but is very air-sensitive, requiring manipulations to be conducted with the careful exclusion of air. The $(NH_3)_5Ru(H_2O)^{2+}$ complex dissolved in a solution of 30% H_2O and 70% dimethyl formamide was able to extract 50% of the 400 ppm of sulfur (in the form of DBT) in a 45% toluene/55% hexanes phase. An analogous extraction of 4,6-Me_2DBT was able to remove only 15% of the 4,6-Me_2DBT.

Relatively simple metal salts adsorbed on silica are able to effectively remove DBTs from hydrocarbon solutions. The extraction of DBT (400 ppm sulfur) in decane with 10% $AgNO_3/SiO_2$ reduced the sulfur level by 72%.[98] An especially interesting result was that a similar extraction of 4,6-Me_2DBT also reduced the sulfur level by 72%.

Extensive studies by Yang and coworkers[99–104] of Ag(I), Cu(I), and Ni(II) forms of zeolites show that these materials are highly effective adsorbents for the removal of DBTs from a variety of transportation fuels. Song and coworkers[10,105] have also developed a range of supports incorporating various metal salts for the removal of DBTs and their hindered derivatives such as 4,6-Me_2DBT from transportation fuels. The details of some of these investigations have either not been published or are contained in patents.

3 HYDRODENITROGENATION

Some of the major types of organonitrogen compounds found in petroleum feedstocks are shown in Table 2.[1,17,106,107] The amines undergo HDN (equation 25) under relatively mild conditions. The unsaturated indoles, pyridines, quinolines, and related derivatives are less reactive, and they consume large quantities of H_2 because hydrogenation of the unsaturated rings occurs before the nitrogen is removed. This is illustrated for the reactions of indole, pyridine, and quinoline over Ni–Mo/Al_2O_3 or Co–Mo/Al_2O_3 catalysts by the networks[22] in equations (26–28). In the case of quinoline (equation 28), not only is the nitrogen-containing ring hydrogenated, but substantial hydrogenation of the benzene ring occurs in path a → d → e → f. Clearly, path a → b → c consumes less H_2, and it produces propylbenzene which has a higher octane rating than propylcyclohexane formed by the other pathway. To reduce H_2 consumption further, it would be desirable to remove nitrogen from these rings without first hydrogenating even the nitrogen-containing ring.

Since HDN occurs in the same process as HDS, H_2S is always present. In fact, H_2S is necessary to maximize the HDN activity of the Co–Mo/Al_2O_3 and Ni–Mo/Al_2O_3 catalysts. One role of the H_2S is to maintain the catalyst in the sulfided form, but there is evidence to suggest that it is also more directly involved in the HDN mechanism. Less is known about possible mechanisms for HDN than HDS based on organometallic models,[17,106–109] but recent studies of amine, pyrrole, pyridine, and quinoline binding and reactions at metal centers offer some possibilities.

3.1 Organonitrogen Compound Binding to Metal Centers

Amines (Table 2) are relatively strong Lewis bases and are known to coordinate to metals (*see* ***Ammonia & N-donor Ligands***) in a multitude of transition metal complexes.[110] On an HDN catalyst, they are also likely to coordinate through the nitrogen lone electron pair to a metal site; as discussed in Section 3.2, this mode of coordination can activate the hydrocarbon R group in R_3N amines in ways that lead to C–N bond cleavage.

Among the unsaturated heterocyclic nitrogen compounds (Table 2), the indoles are nonbasic because there are no lone electron pairs on the nitrogen. They are, however, known[17,107] to form η^6 complexes, for example, CpRu(η^6-indole)$^+$, in which the indole coordinates as a π ligand through its benzene ring, and an η^2 complex of Cu(I) in which C(2) and C(3) are π-coordinated to the Cu(I).[111] There are also many examples of complexes in which the deprotonated nitrogen of indole is coordinated to a metal.[17,107] There is no evidence that these modes of coordination activate the indole to react in a manner that leads to C–N bond cleavage.

Pyridines in their transition metal complexes coordinate as η^1(N), η^2(C,C), η^2(N,C), or η^6 ligands (Figure 6). By far the most common coordination mode[112] is η^1(N), in which the lone electron pair on the nitrogen donates to a Lewis acidic metal center (*see Lewis Acids & Bases*). The M–N bond lies in the plane of the pyridine ring (Figure 6). Few reactivity studies of η^1(N) pyridine ligands have been reported. One of potential interest for HDN is the base-catalyzed exchange of the pyridine protons for deuterium

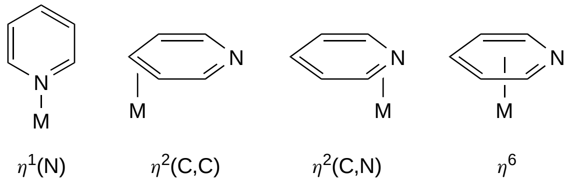

Figure 6 Known modes of pyridine coordination in transition metal complexes

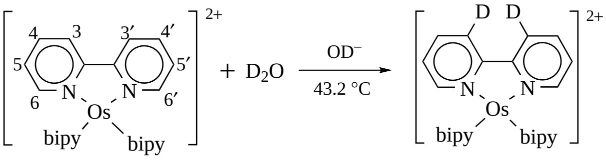
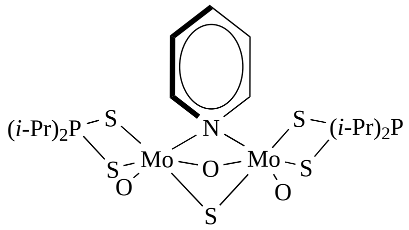
in the 2,2′-bipyridyl complex $Os(bipy)_3^{2+}$ (equation 29) in D_2O/dimethyl sulfoxide solution.[113] The rate of exchange of the 3,3′-hydrogens is first order in the osmium complex and first order in OD^-. A mechanism involving base-promoted deprotonation of the pyridine followed by rapid deuteration was proposed. Exchange of the 3,3′-protons is much faster than those of the others, which decrease in rate in the order: 5, 5′ > 6, 6′ > 4, 4′. When passed with D_2 over a Mo/Al_2O_3 catalyst at 200 °C, 4-methylpyridine undergoes preferential deuterium exchange at the 2 and 6 positions.[114] This exchange may occur by η^1(N) coordination of the pyridine to a metal on the surface, which makes the two and six protons susceptible to deprotonation by surface O^{2-} and subsequent deuteration.



(29)

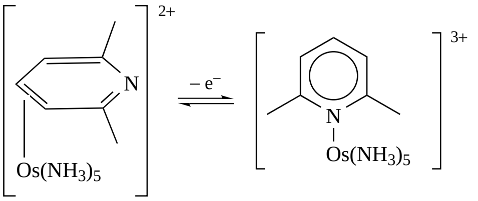
In a rare example[115] of a bridging pyridine (py) complex, {Mo(O)(S_2P-*i*-Pr_2)}$_2$(μ-O)(μ-S)(μ-py) (**12**), the pyridine ring is almost coplanar with the bridging O and S atoms and the Mo–N distances (2.95(2) and 2.93(2) Å) are very long compared with normal Mo–N bonds (2.23 Å).



(**12**)

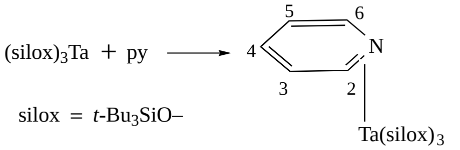
An η^2(C,C)-coordinated 2,6-dimethylpyridine (2,6-Me_2py) ligand has been observed[116] in the Os^{II} complex $Os(NH_3)_5[\eta^2$(C,C)-2,6-$Me_2py]^{2+}$ (equation 30). The Os $(NH_3)_5^{2+}$ fragment coordinates η^2(C,C) to a variety of other aromatic ligands;[35] this presumably reflects the strong π back bonding ability of the $Os(NH_3)_5^{2+}$ group. Oxidation of the Os^{II} complex to Os^{III} causes the 2,6-dimethylpyridine to rearrange to its common η^1(N) bonding mode (equation 30). This

isomerization suggests that the mode of pyridine bonding to a metal site on a catalyst may depend on the oxidation state of the metal.



(30)

One of the few examples of an η^2(N,C)-pyridine (Figure 5) is the well-characterized (silox)$_3$Ta[η^2(N,C)-py], prepared according to equation (31).[108,117] A diene-like pattern of alternating short and long double bonds is seen in the uncoordinated segment of the ring. An MO study indicates that the η^2(N,C) structure is stabilized by strong Ta(dπ) $\rightarrow$ py(π^*) back bonding. Another py complex of tantalum, (2,6-diisopropylphenoxide)$_2$(Cl)Ta[η^2(N,C)-2,4,6-*t*-Bu$_3$py], has a distorted η^2(N,C)-py ligand.[118]



(31)

Most of the known η^6-pyridine complexes contain pyridines with alkyl groups at the 2,6-positions in order to inhibit η^1(N) binding: for example, (CO)$_3$Cr(η^6-2,6-*t*-Bu$_2$py)[119,120] and (CO)$_2$(PPh$_3$)Cr(η^6-2,6-Me$_2$py).[121] Unsubstituted η^6-pyridine complexes also exist, for example, (CO)$_3$Cr(η^6-py)[122] and (PMePh$_2$)$_3$Mo(η^6-py).[123] Factors that influence η^1(N) or η^6 coordination are illustrated in studies (equation 32) of methyl-substituted pyridines (py′) with CpRu(NCMe)$_3{}^+$.[124,125] The 2-methyl- and 2,4-dimethylpyridines initially form the η^1(N)-py′ complex but then more slowly rearrange with loss of MeCN to give the η^6-py′ complex (equation 32). Pyridine itself gives the η^1(N) complex CpRu(η^1(N)-py)$_3{}^+$. If Cp is replaced by the more electron-donating Cp*, even the pyridine complex Cp*Ru(η^1(N)-py)(NCMe)$_2{}^+$ rearranges to the η^6 form Cp*Ru(η^6-py)$^+$. Thus, a relatively high electron density on the metal promotes formation of the η^6 complex. For the less electron-rich system Cp*Rh(NCMe)$_3{}^{2+}$,[126] the tendency to give η^6-py′ complexes is less. Thus, 2-methyl- and 2,4-dimethylpyridines give only the η^1(N) complexes Cp*Rh(η^1(N)-py′)(NCMe)$_2{}^{2+}$; it is only the most sterically hindered 2,4,6-trimethylpyridine that gives the η^6 complex Cp*Rh(η^6-2,4,6-Me$_3$py)$^{2+}$.

$$\mathrm{CpRu(NCMe)_3{}^+ + py' \longrightarrow CpRu(\eta^1(N)\text{-}py')(NCMe)_2{}^+ \xrightarrow{-2NCMe} CpRu(\eta^6\text{-}py')^+} \quad (32)$$

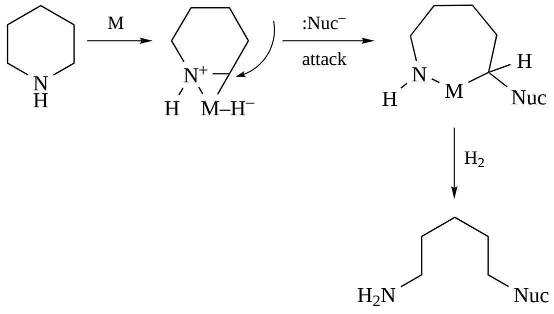
3.2 Mechanisms of Amine and Quinoline Hydrodenitrogenation

The HDN of aliphatic amines (equation 25) is relevant to the HDN of indoles (equation 26), pyridine (equation 27), and quinoline (equation 28) because these heterocycles are first hydrogenated to the aliphatic amines. A general mechanism[127] proposed for the HDN of aliphatic amines is based on metal cluster catalysis of the transalkylation reaction in equation (33) and on metal complex catalyzed exchange of deuterium for hydrogen in tertiary aliphatic amines (equation 34). There are other examples of amine activation in metal complexes.[128,129]

$$\mathrm{R_3N + R'_3N \xrightarrow[125\,^\circ C]{M_3(CO)_{12},\ M = Ru, Os} R_2NR' + R'_2NR} \quad (33)$$

$$\mathrm{Et_3N + D_2O \xrightarrow[CO/125\,^\circ C]{Rh_6(CO)_{16}} Et_2N{-}C(CD_3)(H)(D)} \quad (34)$$

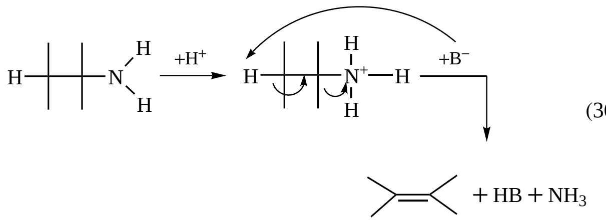
The HDN mechanism (equation 35)[127] for aliphatic amines, illustrated with piperidine, an intermediate in the HDN of pyridine (equation 27), is shown as involving only one metal atom, but more than one metal could easily be involved. The first step is an oxidative addition of a C–H bond adjacent to the nitrogen to give η^2-piperidinyl and hydride ligands. Cleavage of a C–N bond occurs by attack of a nucleophile (Nuc$^-$) at the coordinated carbon of the piperidinyl ligand to give an amido intermediate. On a MoS$_2$-based hydrotreating catalyst, Nuc$^-$ could be a surface species such as H$^-$, SH$^-$, or OH$^-$, a gas-phase species such as H_2S or NH_3, or piperidine itself. The known abilities of H_2S and H_2O to enhance the rate of HDN may be explained if it is assumed that they serve as the nucleophiles, or precursors to the nucleophiles, in the C–N cleavage step. While the mechanism in equation (35) is consistent with results from several catalytic studies,[127] variations of this mechanism cannot be ruled out. Nevertheless, it provides a useful starting point for probing the details of aliphatic amine HDN.



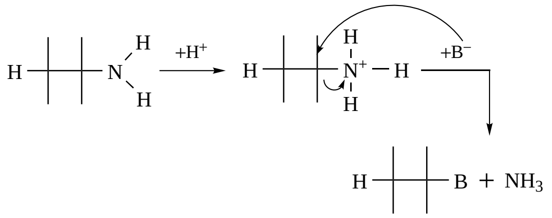
(35)

Other mechanisms for the HDN of aliphatic amines have been proposed on the basis of heterogeneous catalytic

studies.[106,107] One of them (equation 36) involves a Hofmann-type



(36)



(37)

elimination of NH_3 from the protonated amine using a basic site on the catalyst surface to remove a *β* hydrogen. The other (equation 37) again involves initial protonation of the amine which undergoes nucleophilic attack by a basic species to displace the NH_3. Both of these mechanisms are based primarily on the creation of acidic and basic sites under hydrotreating conditions.

A mechanism has also been proposed for the first step (a in equation 28) in the HDN of quinoline: the hydrogenation of Q to 1,2,3,4-tetrahydroquinoline (THQ).[42] Not only is this hydrogenation observed on heterogeneous catalysts,[106,127] but it occurs homogeneously when catalyzed by $Fe(CO)_5$,[130] $RuCl_2(PPh_3)_3$, $Ru(H)(Cl)(CO)(PPh_3)_3$, $Os(H)(Cl)(CO)(PPh_3)_3$, $Rh(Cl)(PPh_3)_3$, $Rh(cod)(PPh_3)_2{}^+$, and $Ir(cod)(PPh_3)_2{}^+$.[42,131] The most detailed studies[42] of this hydrogenation were performed with $Cp^*Rh(NCMe)_3{}^{2+}$ at 40 °C in CH_2Cl_2 under 500 psi of H_2. Results of organometallic, NMR, and catalytic reactor studies were most consistent with the mechanism shown in Figure 7. The first step involves coordination of Q through the nitrogen in $Cp^*Rh(\eta^1(N)\text{-}Q)(NCMe)_2{}^{2+}$, a complex that has been isolated and identified by NMR under catalytic conditions. It is the η^1(N)-coordinated form of Q and the availability of two easily replaceable NCMe ligands in this complex that make it catalytically active. This complex is proposed to react with H_2 to form a complex (step a, Figure 7) with η^2(N,C)-coordinated Q and hydride ligands; this intermediate is probably in low concentration as no NMR hydride signals are observed during the reaction. Therefore, hydrogen transfer to the quinoline occurs rapidly. Steps (a) and (b) must be reversible since the Q recovered from reactions using D_2 contained deuterium at the 2-position. Formation of the η^2(C,C) complex in step (c) leads

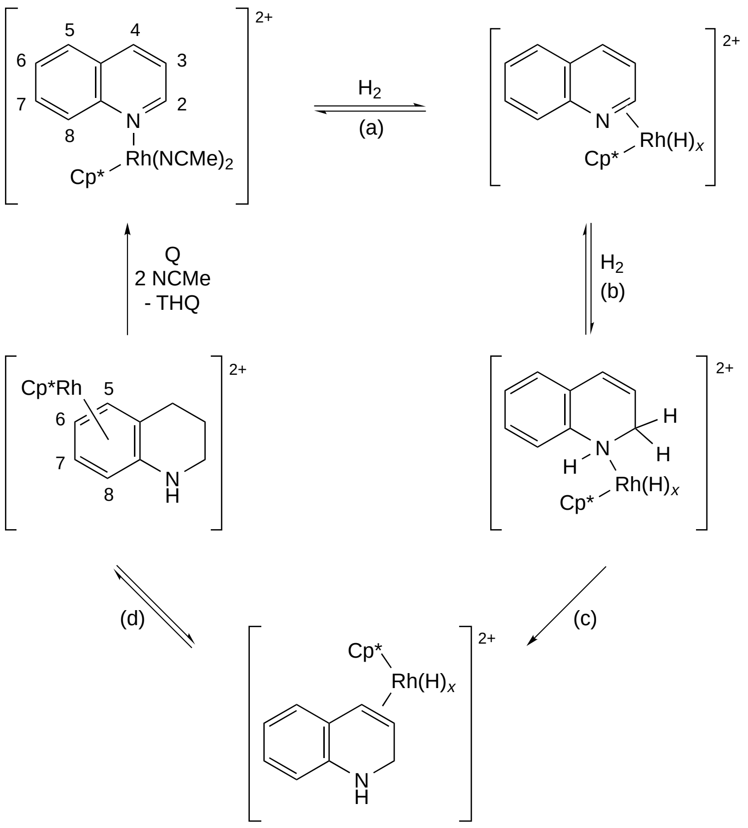


Figure 7 Mechanism for the hydrogenation of quinoline to 1,2,3,4-tetrahydroquinoline[42]

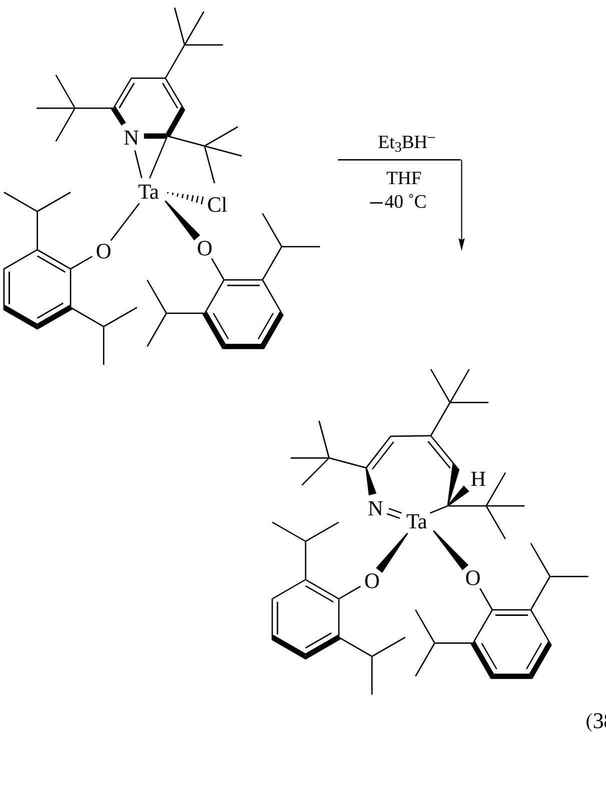
to hydrogenation of the 3,4-positions, and the THQ product remains coordinated as $Cp^{*}Rh(\eta^{6}\text{-THQ})^{2+}$, a complex that has been isolated and also identified in NMR spectra of the catalytic reaction mixtures. Displacement of the THQ ligand by Q and two acetonitrile molecules completes the catalytic cycle. The key steps involving hydrogenation of the C=N and C=C double bonds are essentially the same as in catalytic alkene hydrogenation. Complete HDN of Q requires denitrogenation of THQ; a mechanism for this process has not been proposed, but it may be similar to that suggested (equations 35–37) for the HDN of alkylamines.[106,127]

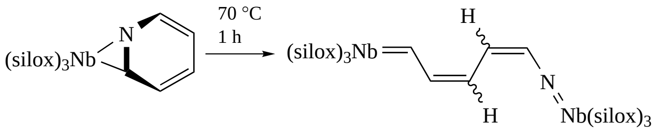
Homogeneous hydrogenation of Q to THQ is also catalyzed by $Os_3(CO)_{12}$ and its derivatives.[107,132] These studies, together with the synthesis of osmium cluster complexes of quinoline, have led to another mechanism for quinoline hydrogenation which involves more than one metal center. It is likely that reactions catalyzed by $Cp^{*}Rh(NCMe)_3{}^{2+}$ and $Os_3(CO)_{12}$ proceed by different mechanisms. Whether either of these mechanisms is consistent with the heterogeneously catalyzed conversion of Q to THQ is unknown.

While there is no evidence that Mo-based HDN catalysts promote C–N bond cleavage prior to pyridine ring hydrogenation, such a cleavage (equation 38) has been observed[133] in the reaction of the hydride (H^-) donor Et_3BH^- with (2,6-diisopropylphenoxide)$_2$(Cl)Ta[η^2(N,C)-2,4,6-t-Bu_3py] (see Section 3.1). This reaction offers the possibility that nitrogen can be removed without consuming the large quantities of H_2 that are presently required to hydrogenate pyridine, quinoline, and indole rings in the currently practiced HDN process.



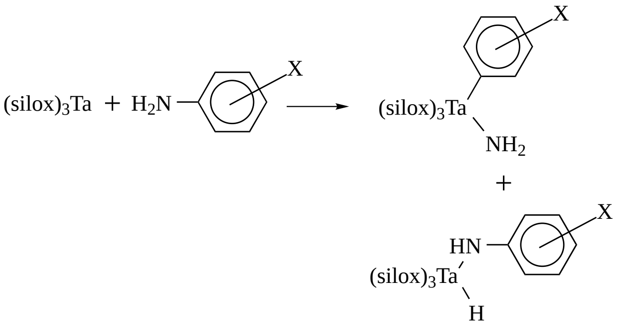
(38)

An even more remarkable pyridine C–N bond cleavage (equation 39) again begins with an η^2(N,C) complex.[134,135] Thermolysis of this complex gives the ring-opened product in which the cleaved C=N bond forms a Nb=C alkylidene complex with one Nb and a Nb=N imido complex with the other. Although the mechanism is not known, this reaction suggests new ways to think about C=N cleavage without first hydrogenating the pyridine ring.



(39)

In reactions that lead to the cleavage of C–N or N–H single bonds, Wolczanski and coworkers[136] studied the reactions of $(silox)_3Ta$ and anilines (equation 40). The C–N oxidative-addition product is favored by electron-withdrawing X groups, for example, CF_3, whereas electron-donating X groups (Me or OMe) give exclusively the N–H oxidative-addition product. This reaction is especially interesting because it demonstrates that it is possible to cleave C–N bonds even though the HDN of aniline requires hydrogenation of the arene ring before C–N cleavage occurs.[2,106,137]



(40)

These C–N cleavage reactions suggest that it may be possible to develop HDN catalysts that will eliminate nitrogen from unsaturated organonitrogen compounds without first hydrogenating the hydrocarbon framework.

1 INTRODUCTION

Hydrogen is the first element in the periodic table and has the simplest atomic structure of all the elements; its nucleus consists of a single proton and it has one outer electron. There are three isotopes of hydrogen: ^{1}H (also called protium or H), the lightest and the most abundant isotope, ^{2}H (deuterium or D), and ^{3}H (tritium or T). Terrestrial hydrogen contains about 0.0156 atom % of deuterium and a very small amount (1 atom per 10^{18} atoms of hydrogen) of tritium.

The name hydrogen was derived from the Greek words 'hydro', meaning water, and 'gene', meaning form. In 1766, Cavendish discriminated hydrogen gas as an element, by measuring its density and the volume of gas evolved from a given amount of acid and metal. In 1932, deuterium was discovered in the spectrum of the final fraction left after the evaporation of a large sample of liquid hydrogen.[1] Tritium was generated by *Deuteron* bombardment of D_3PO_4 and $(ND_4)_2SO_4$ by Oliphant *et al.*[2] in 1934. The presence of tritium in the atmosphere and in natural waters was proved in 1950 by Harteck and Faltings,[3] and in 1951 by Grosse *et al.*[4] The tritium concentration in atmospheric hydrogen molecules and in natural waters was found to be about one atom in 10^{15} protium atoms and one atom in 10^{18} protium atoms, respectively.

Hydrogen abundance in the solar system (formerly known as cosmic abundance) account for 71% of the mass fraction or 91% of all the atoms.[5] Captured by the gravitational force of the Sun, hydrogen is converted into helium by nuclear fusion, a process that supplies the energy to the Sun. Current theories consider hydrogen as the primary constituent of the universe, which were condensed into stars by gravitational forces. This condensation led to fusion reactions, converting hydrogen into helium, with the release of energy.

Molecular hydrogen is a colorless, odorless gas, and is virtually insoluble in water. It is most easily prepared on a small scale by the reaction between a dilute acid and a metal, such as Zn and Fe, and by the electrolysis of water. A large-scale production of hydrogen is available mainly from the reactions of hydrocarbons and coke. A major share of manufactured hydrogen comes from hydrocarbons. The thermal cracking of hydrocarbons is an important part of petroleum refining and produces a large amount of hydrogen. Steam passed over coke heated to more than 1000 °C undergoes the well-known *Water Gas Reaction* (equation 1). Hydrogen production is used in manufacture of Ammonia Synthesis ($N_2 + 3H_2$) and methanol synthesis ($CO + 2H_2$) gas.

$$H_2O + C \longrightarrow CO + H_2 \qquad (1)$$

Although the abundance of molecular hydrogen on the Earth is trivial (e.g. the atmosphere contains about 0.5 ppm H_2), hydrogen in the form of compound is very abundant. In the combined state, hydrogen is most commonly found in compounds with oxygen, carbon, and nitrogen. Water is the most important hydrogen compound (*see* ***Water & O-donor Ligands***). Other compounds of significance are organic ones such as hydrocarbons, ammonia, and its derivatives (*see* ***Ammonia & N-donor Ligands***), and hydroxide. In addition, hydrogen combines with a variety of elements to form compounds with widely differing properties. The combined compounds are generally known as hydrides.

The hydrogen atom is the lightest and least complex atom, and forms the most basic diatomic molecules. Consequently, the physical and chemical properties of hydrogen have been studied very thoroughly in connection with fundamental studies on atomic and molecular structures. Ortho- and para-hydrogen were discovered spectroscopically and interpreted quantum mechanically by Heisenberg in 1927.[6] The technique of nuclear magnetic resonance (NMR) spectroscopy, which was first demonstrated in 1946 using the hydrogen nucleus (proton), has revolutionized the study of structural chemistry.[7]

Hydrogen was recognized as the essential element in acid by Davy after his work on hydrohalic acid. Theories of acid and base have played an important role ever since. The electrolytic dissociation theory of Arrhenius and Ostwald, the introduction of the pH scale for hydrogen-ion concentrations by Sorensen, the theory of acid-base titration and the use of indicators, and Bronsted's concept of acid and conjugate base as proton donors and acceptors are other landmarks in the recognition of hydrogen as an acid.

Studies on energy production from hydrogen are technologically important for developing an energy source for the future.

In this article, we mainly discuss the properties and behavior of hydrogen and its isotopes, and present the various applications of hydrogen. Excellent reviews on hydrogen are given in reference books of inorganic chemistry.[8]

2 OCCURRENCE, PREPARATION, USE, AND ANALYSIS OF HYDROGEN

2.1 Natural Occurrence

The atmosphere contains only about 0.5 ppm of free hydrogen molecules owing to the chemically active nature of hydrogen. Combined hydrogen comprises 11.2% of water, and is an essential constituent of all acid, hydrocarbons, and living organisms. It is present in the great majority of organic compounds. Hydrogen is sometimes liberated during the decomposition of organic matter, and may be present in the intestinal gases of animals.

Hydrogen gas has been found occluded in meteorites, and also is present in nebulae, fixed stars, and in the Sun. Anders and Grevesse[5] calculated mass fractions of H, He, and heavier elements (Li–U) in the solar system, and derived values of 70.683, 27.431, and 1.886%, respectively. The major planets (Jupiter, Neptune, Saturn, and Uranus) contain large amounts of hydrogen in their atmospheres, along with He, CH_4, and NH_3.

2.2 Molecular Hydrogen in Nature

2.2.1 Hydrogen Content in the Atmosphere

Our knowledge about the distribution of molecular hydrogen in the atmosphere is incomplete. The first reliable analyses were made in 1923 by Schuftan, who found 0.50 ± 0.10 ppmv (parts per million by volume) for hydrogen in air samples from different liquid air plants. This concentration has since been considered constant and representative for atmospheric air.

The measurements of H_2 mixing ratios in the atmosphere, the troposphere, and the lower stratosphere were carried out by Schmidt[9] in 1974. A constant mixing ratio of 0.548 ppmv was found in the southern troposphere and in the lower stratosphere of the northern hemisphere. Higher levels of 0.558 and 0.585 ppmv were obtained in the northern hemisphere in the upper troposphere and in surface air, respectively. The data do not indicate any change in the H_2 mixing ratio of the lower stratosphere up to 4 km above the tropopause. The almost constant H_2 mixing ratio in the tropopause region indicates that the flux of H_2 between the troposphere and the stratosphere is very small.

2.2.2 Hydrogen Content in Seawater

Schmidt[9] also measured the H_2 content of surface waters in the North and South Atlantic Oceans. The data varied from 0.8 to 5.0×10^{-5} mL/L(H_2O), corresponding to saturation factors of $F = 0.8–5.4$, where $F = 1$ represents equilibrium conditions between surface water and air, while $F < 1$ or $F > 1$ indicate undersaturation or supersaturation, respectively. The H_2 supersaturation in ocean water may be due to the production of hydrogen by microbiological activity. Several vertical profiles through the ocean showed H_2 contents to decrease with depth to equilibrium values compared with surface air. These profiles also showed distinct layers slightly enriched in H_2 in the oceans.

2.2.3 Hydrogen Release in Natural Processes

It has been suggested by various authors that the origin of tropospheric H_2 might be the photolysis of water vapor in the upper atmosphere. However, on the Earth's surface, H_2 is released from volcanic gases and bubbling gases in geothermal areas (e.g. the H_2 concentration of volcanic gas of Mt. Unzen in Japan in 1992 is above 7000 ppmv and that of bubbling gas in some geothermal areas has often amounted to several thousand ppmv). The hydrogen gas-water ratio, H_2/H_2O, in fumarolic gas summarizes the available information on gas chemistry related to volcanic systems. Giggenbach[10] showed that the H_2/H_2O ratio is governed by the buffer of the system $2H_2 + O_2 \rightleftharpoons 2H_2O$ at high temperatures, and by the buffer of the system $SO_2 + 3H_2 \rightleftharpoons H_2S + 2H_2O$ at low temperatures. In addition, H_2 is released from natural gas and coal deposits, and is also generated in soils by biological activity.

A significant amount of H_2 (amounting to more than 3 vol % in soil gas) was observed in 1980 along the Yamasaki Fault, one of the active faults in southwestern Japan.[11] In order to understand the mechanism of H_2 production caused by fault movement, Kita *et al.*[12] measured the amounts of H_2 gas generated by crushing granite and quartz in laboratory experiments, and found that the amount of H_2 generated increases with temperature.

2.2.4 Hydrogen Budgets

Junge[13] showed that H_2, CH_4, CO, and N_2O belong to a group of atmospheric constituents, which are strongly influenced, by microbiological sources. Conversely, there is some evidence indicating other sources of hydrogen release, as mentioned above. The quantities of H_2 released from some sources have not been quantitatively estimated.

Assuming a concentration of 0.5 ppmv and a residence time of 8 years, the Earth's total annual emission of H_2 into the atmosphere is 20×10^6 g.[14] The annual emissions of H_2 from nongasoline fossil fuels and that from gasoline were estimated to be approximately 1×10^6 g and 4×10^6 g, respectively. These estimates of H_2 anthropogenic emission may be much too low. Schmidt[9] based his residence time of 4–7 years on a 'budget' of hydrogen consisting of sources and sinks and estimated the annual anthropogenic emission of H_2 to be 1.3×10^6 g. Annual releases of H_2 have been also estimated for the oceans (4×10^6 g), methane oxidation ($5–9 \times 10^6$ g), and volcanoes (0.2×10^6 g).

Judging from the amount of H_2 generated on the Earth's surface and from the constant mixing ratio in the atmosphere, it is considered that the quantity of H_2 released into surface air has been constant and has been maintained at a steady state

with a continual escape of H_2 from the Earth's gravitational field into space.

2.3 Preparation of Hydrogen

2.3.1 Conventional Laboratory Preparation

Hydrogen is prepared in a variety of ways, most commonly from water, acid, hydroxide bases, and hydrocarbons. The most frequently used laboratory preparations are as follows.

Electrolysis of Water. Electrolysis of acidified water at Pt electrodes is commonly used to demonstrate the composition of water, and is a small-scale production method for generating hydrogen and oxygen. Very pure hydrogen of more than 99.99% can be formed from the electrolysis of warm aqueous solutions of barium hydroxide between nickel electrodes, via the following reaction:

$$\text{Anode:} \quad 4OH^- \longrightarrow 2H_2O + O_2 + 4e^-$$
$$\text{Cathodes:} \quad 4H_2O + 4e^- \longrightarrow 2H_2 + 4OH^- \qquad (2)$$

Reaction of Metals on Water or Dilute Acid. Electropositive metals, such as the alkali metals and alkaline earth metals, are so chemically reactive that they rapidly displace hydrogen from water or dilute acid at room temperature. Convenient laboratory methods employ sodium amalgam or calcium with water, or zinc with hydrochloric acid:

$$2Na + 2H_2O \longrightarrow 2Na^+ + 2OH^- + H_2 \qquad (3)$$
$$Ca + 2H_2O \longrightarrow Ca^{2+} + 2OH^- + H_2 \qquad (4)$$
$$Zn + 2H^+ \longrightarrow Zn^{2+} + H_2 \qquad (5)$$

Reaction of Water with Hydrides of Metals. For small-scale preparations, the hydrolysis of metal hydrides is convenient and generates twice the amount of hydrogen as contained in the hydride, for example,

$$CaH_2 + 2H_2O \longrightarrow Ca(OH)_2 + 2H_2 \qquad (6)$$

Reaction of Silicon on Solutions of Alkali Hydroxides. This method is based on the reaction of a concentrated solution of sodium hydroxide on powdered silicon or ferrosilicon, where hydrogen and a solution of sodium silicate are the products of the reaction:

$$Si + 2OH^- + H_2O \longrightarrow [SiO_3]^{2-} + 2H_2 \qquad (7)$$

Reaction of Metal on Solutions of Alkali Hydroxides. The reaction of aluminum or zinc with aqueous sodium hydroxide is the most commonly used methods:

$$Al + OH^- + H_2O \longrightarrow [AlO_2]^- + H_2 \qquad (8)$$
$$Zn + 2OH^- + 2H_2O \longrightarrow [Zn(OH)_4]^{2-} + H_2 \qquad (9)$$

Other amphoteric metals can be substituted (*see Amphoterism*).

2.3.2 Industrial Production

Hydrogen is produced on a large scale by a number of industrial processes, some of which classify the produced gas as a by-product. The main production methods are as follows.

Electrolytic Decomposition of Water. This industrial process is economically feasible in localities where low-cost electricity is available, where there is a demand for oxygen as well as for hydrogen, and where the hydrogen is required to be completely free from carbon compounds. Sodium and potassium hydroxides are the practicable electrolytes in this process.

Reaction of Steam on Hydrocarbons. The catalytic interaction of steam and hydrocarbons has been used commercially on a large scale. The thermal cracking of hydrocarbons is an important part of petroleum refining and produces a large amount of hydrogen. The reaction of steam on methane from natural gas at about 1100 °C is

$$CH_4 + H_2O \longrightarrow CO + 3H_2 \qquad (10)$$

Reaction of Steam on Coke. When passes over coke heated to over 1000 °C, steam undergoes the well-known water gas reaction:

$$C + H_2O \longrightarrow CO + H_2 \qquad (11)$$

Water gas, or the methane steam gases, may be subjected to CO conversion by passing the gases and steam over an iron or cobalt oxide catalyst at 400 °C:

$$CO + H_2O \longrightarrow CO_2 + H_2 \qquad (12)$$

This is known as the water gas shift reaction. Recently this reaction has been known to be affected by low-temperature homogeneous catalysts in aqueous acid solution.[15] The extent of subsequent purification of the hydrogen depends on its intended use.

2.4 Use of Hydrogen

The largest use of industrial hydrogen is in ammonia synthesis, in the catalytic hydrogenation of unsaturated liquid vegetable oils to solid, edible fats (margarine), and in the manufacture of bulk organic chemicals, particularly methanol, by the *Oxo Process* using a cobalt catalyst:

$$CO + 2H_2 \longrightarrow CH_3OH \qquad (13)$$

Direct reaction of hydrogen with chlorine is a major source of hydrogen chloride, used in the preparation of metal hydrides and complex metal hydrides.

In nuclear science, liquid hydrogen is used in bubble chamber detectors for high-energy particles and in the space program as a rocket fuel. Hydrogen gas is potentially a large-scale fuel in future for internal combustion engines and fuel cells.

2.5 Analysis of Hydrogen

2.5.1 Analysis of a Gas Mixture

The presence of hydrogen molecules in a gas mixture can be determined by converting the gas to water overheated copper oxide at 300 °C, although the presence of volatile hydrides must first be determined. In the absence of combustible gases, the determination of hydrogen is usually made by exploding a measured volume of the gas in the presence of a large excess of oxygen, using a high-tension discharge across Pt electrodes; the contraction in volume gives a measure of the hydrogen content of the gas according to the equation:

$$2H_2 + O_2 \longrightarrow 2H_2O \qquad (14)$$

Gas chromatography (GC) is used to measure hydrogen concentration, using helium gas as a carrier gas and molecular sieve columns. Combustion plus gas chromatographic determination of the water produced is commonly used in determining the hydrogen content of organic compounds.

The hydrogen composition of subsurface gases has been measured in geochemical studies. The H_2 gas component in the gas mixture must be separated chromatographically and detected using high sensitivity instruments. The concentration of H_2, He, Ne, Ar, N_2, and CH_4 in gas samples can be directly determined under optimum conditions: use of an 8 m column packed with a 60–80 mesh 5 Å molecular sieve activated at 360 °C for 12 h, and the use of oxygen gas as the carrier gas.[16] The determination limit for H_2 is 10^{-6} mL with a preamplifier.

2.5.2 Hydrogen Analysis in Rocks and Minerals

In rocks and minerals, hydrogen may be present in several different forms and is generally classified as essential and nonessential hydrogen. Essential hydrogen is present in regular arrangement in the molecular or crystal structure, whereas nonessential hydrogen is not necessary for characterization of the mineral, for example, hydrogen held by surface forces. The determination of total hydrogen in rocks and minerals is usually based on oxidation of the sample in a stream of oxygen at about 1150 °C in the presence of a lead chromate flux. A modified form of this procedure has been applied to the determination of hydrogen in coal. The evolved water is determined and used as a basis for calculating the hydrogen content of the sample. Several dehydrating agents, such as $CaCl_2$, P_2O_5, and $Mg(ClO_4)_2$, have been used for absorbing the water.

2.5.3 Hydrogen Analysis in Metals

In metals, hydrogen occurs in the occluded and combined states. Numerous methods have been used for the determination of hydrogen in metals. Some of them are as follows.

Gravimetric Method. A method in which the metal sample is heated in atmospheric oxygen and the water formed is absorbed in a dehydrating agent such as $Mg(ClO_4)_2$.

Vacuum Extraction. Vacuum extraction requires the sample to be heated in an evacuated system with determination of the evolved gas, either volumetrically or by differential pressure measurement. This method is recommended whenever possible because of the speed and precision, particularly where the amount of hydrogen is below 0.01%.

Extraction of the Gas by Vacuum Fusion. In this procedure, which is primarily intended for the determination of oxygen in metallurgical materials, the sample is melted in a graphite crucible in an evacuated system. Oxygen is converted to CO and hydrogen is quantitatively liberated and determined as in the Section *Vacuum Extraction*.

A Method Based on Ionic Bombardment. In this procedure, the specimen is placed in a discharge tube, made into a cathode, and is then bombarded with mercury ions. The ionized gas, drawn from the metal by the high potential between the electrodes, is collected and subsequently analyzed by conventional procedures.

A Method that Utilizes Electrochemical Sensors. Various electrochemical sensors have been developed to measure hydrogen, both in the molten and solid states.[17]

3 ISOTOPES OF HYDROGEN

3.1 General

Of all the elements, isotope effects (*see Isotope Effect*) are greatest for hydrogen, justifying the use of distinctive names for the hydrogen isotopes: protium, deuterium, and tritium. However, the chemical properties of H, D, and T are essentially identical, except in matters such as equilibrium constants. The isotopes of hydrogen are extensively used as tracers in deuterium- or tritium-labeled compounds.

The atomic properties of H, D, and T and the physical properties of H_2, D_2, and T_2 are compared in Tables 1

Table 1 Atomic properties of hydrogen, deuterium, and tritium

Properties	H	D	T
Relative atomic mass (a.m.u.)	1.007825	2.014102	3.016049
Nuclear spin quantum number	1/2	1	1/2
Nuclear magnetic moment (nuclear magnetons)[a]	2.79268	0.857386	2.9788
Nuclear quadrupole moment ($e \times 10^{-28}$ m^2)	0	2.766×10^{-3}	0
Radioactive stability	Stable	Stable	β^-

[a]Nuclear magneton, $\mu_N = eh/4\pi m_p c = 5.0508 \times 10^{-27}$ J T^{-1}.

Table 2 Physical properties of isotopic molecular hydrogen[a]

Properties	H_2[b]	D_2	T_2
Melting point (K)	13.957	18.73	20.62
Boiling point (K)	20.39	23.67	25.04
Heat of fusion (kJ mol^{-1})	0.117	0.197	0.250
Heat of vaporization (kJ mol^{-1})	0.904	1.226	1.393
Critical temperature (K)	33.19	38.35	40.6
Critical pressure (kPa)	1315.20	1664.77	1834
Heat of dissociation at 25 °C (kJ mol^{-1})	435.88	443.35	446.9
Zero-point energy (kJ mol^{-1})	25.9	18.5	15.1
Internuclear distance (pm)	74.14	74.14	(74.14)

[a]All data refer to the mixture of ortho and para forms that are in equilibrium at room temperature. [b]Data refer to H_2 of normal isotopic composition (i.e. containing 156 ppm of deuterium, predominantly as HD).

and 2, respectively. Protium and deuterium are stable isotopes. Tritium is radioactive, emitting low-energy β^- particles with a half-life of 12.4 years; $^3T \rightarrow ^3He + e^-$.

Deuterium magnetic resonance spectroscopy has found wider applications since the advent of highly sensitive Fourier transform spectrometers. Deuterium is preferred choice in molecular and in ^{1}H NMR spectroscopy in order to provide additional information about proton vibrations and resonances; spectra measured before and after deuteration help to locate the exchanging hydrogen atoms.[18]

Deuterium is invariably prepared from heavy water, which itself is manufactured by the electrolytic enrichment of water, and is available for use as a moderator in nuclear reactors. D_2O is useful as a source of deuterium in deuterium-labeled compounds. Deuterium compounds such as heavy water have been extensively studied. In Table 3, a number of physical properties of normal water and heavy water are compared.

Tritium is made artificially in a nuclear reactor by the reaction of the light isotope of lithium with neutrons:

$$^6Li + ^1n \longrightarrow ^4He + ^3T \qquad (15)$$

Table 3 Major physical properties of H_2O, D_2O, and T_2O

Properties	H_2O	D_2O	T_2O
Molecular weight	18.015	20.028	22.032
Freezing point (°C)	0.00	3.81	–
Boiling point (°C)	100.00	101.42	101.51
Triple point (°C)	0.01	3.82	4.49
Critical temperature (°C)	374.15	370.9	–
Critical pressure (atm)	218.3	215.7	–

Lattice constant of solid (pm)	a451.4	451.7	–
	c735.2	735.4	–

The tritium may be purified by diffusion through palladium or separated from helium by preferential adsorption on charcoal at 77 K. The most convenient way of storing tritium gas is by reacting it with finely divided uranium to produce UT_3. The tritium may be released when required by heating the UT_3, having first removed any decay product (helium) by pumping.

Based on the value of the tritium content in atmospheric hydrogen, tritium has been produced by nuclear fusion in the upper layers of the atmosphere, and does not take part in any atmospheric circulation, but instead remains as elementary hydrogen.[3]

Grosse *et al.*[4] measured highly concentrated heavy water samples produced from surface waters that contained concentrations of natural tritium approximately one million times higher than the original water. Observations have shown that concentrated samples are indeed radioactive to a level corresponding to a natural abundance of tritium of about 10^{-18} by atomic ratio.

The radioactive emission from tritium is solely composed of low-energy β^- particles, with an average energy of 5.70 keV and a maximum energy of 18.6 keV. As this energy is of a low level, the penetrating range is very small, resulting in some difficulties in measuring the radioactivity. Thus the half-life value is slightly uncertain; the generally accepted value is 12.4 years.

By far the most important application of tritium is its use as a radioactive tracer in extensive labeling studies. The production of tritium-labeled organic compounds was greatly enhanced with the discovery that tritium could be introduced to a compound merely by storing that compound under tritium gas for a few days or weeks; the β^- radiation induces exchange reactions between the hydrogen atoms in the compound and

the tritium gas. Another widely used application of general applicability is catalytic exchange in solution using either a tritiated solution or tritium gas. This is valuable in the routine production of tritium compounds for high radiochemical yield and at high specific activity. These tritium applications are partly displacing deuterium substitution in the biological and natural product research fields.

3.2 Measurements of Hydrogen Isotopes

A large variety of methods have been proposed for determining the deuterium content of hydrogen compounds. The important methods are those used for examining H_2, HD, and D_2 mixtures and those used for H_2O, HDO, and D_2O mixtures. Deuterium samples may be converted into water or hydrogen gas; however, the isotopic composition of samples should be kept intact in the conversion step.

The deuterium content of hydrogen gas is usually determined by thermal conductivity or *Mass Spectrometry*. In the thermal conductivity method, the resistance of a heated platinum wire in a binary mixture of hydrogen isotopic molecules varies linearly with deuterium content, while a ternary mixture gives a nonlinear relation. In the low deuterium content range, this method is applicable for deuterium contents above 0.1% and has an accuracy of 0.01% by calibrating with samples of known isotopic composition. The mass spectrometer usually measures the HD^+ /$H_2{}^+$ ratio of hydrogen gas.

High deuterium content of water can be measured by a variety of techniques, such as density determinations, refractive index changes, infrared (IR), and by velocity changes of ultrasound. Specific gravity or density determinations can be made using a pycnometer, or by finding the temperature or pressure at which a float neither falls nor rises in the sample. The refractive index of H_2O is 0.0047 higher for the sodium D-line ($\lambda_D = 589.3$ nm) than for that of D_2O at 20 °C. A linear relationship exists between the change in the refractive index of H_2O and the mole fraction of D_2O present. The low deuterium content of water is determined by measuring the ratio of $m/e = 18$ (H_2O^+) and 19 (HDO^+) peaks by the use of mass spectrometry.

The deuterium content of any hydrogen compound may be detected by observing the IR spectrum in which the M–H stretching frequency shifts to lower energy by approximately $1/\sqrt{2}$ when the H atom in the M–H bond is replaced by a D atom. The IR spectrum has been used for the semiquantitative determination of deuterium contents of water by comparing the intensities of the O–H stretching mode at 3620 cm^{-1}, or the O–D mode at 2630 cm^{-1}. By calibrating with samples of known isotopic composition, the deuterium content can be measured to about 0.01% at 2630 cm^{-1} on samples containing up to 5% D on mole fraction. Similar results for the protium content of deuterium-rich samples are obtained at 3620 cm^{-1}.

Instruments that can accurately measure the velocity of ultrasound in relatively small samples of water are now available for measuring the isotopic analysis of H or D in water. The change in sound velocity from pure D_2O to pure H_2O is 97.7 m s^{-1} or some 7% of the value for pure D_2O.[19]

A useful method of measuring the deuterium content of water has been developed using a novel hydrophobic Pt catalyst consisting of dispersed platinum in a styrene/divinylbenzene copolymer. The sample water is injected into a column in which water vapor and a pure H_2 carrier gas are isotopically exchanged on the surface of the catalyst. The equilibrated hydrogen gas concentration is measured by a thermal conductivity detector (TCD) mentioned above.

GC has conventionally been used as the fundamental measurement method for isotopes of molecular hydrogen. Many experimental reports have described H_2, HD, and D_2, but only a few have provided an analytical study of hydrogen isotopes that include tritium. Gently and Schott[20] reported quantitative analysis of isotopic hydrogen molecules, H_2, D_2, T_2, HD, HT, and DT. In 1991, Uda *et al.*[21] experimentally measured the hydrogen isotopes of mixed gases by GC and attempted to identify and obtain their measurement characteristics. A liquid nitrogen-cooling column was used for isotope separation, along with a TCD and a small-volume ionization chamber. The intensity ratio of the six hydrogen isotopic species, as measured by the TCD, is H_2:HD:HT:D_2:DT:T_2 = 100:73:61:57:49:43. When the sampling volume was 1 cm^3, the estimated detection limit for H_2 and T_2 were 20 and 50 Pa partial pressure, and concentration of 200 and 500 ppm, respectively.

The content of tritium is usually determined by measuring its activity. Solid samples may be converted into liquid or gaseous compounds, and the tritium content measured by a liquid scintillation counter or a gas proportional counter, respectively.

A liquid scintillation counter for measuring tritium has been designed for 20 or 100 mL vials and minimized background fluctuations. In recent years, a popular method for measuring tritium utilizes the suspension of water in aromatic solvents using a nonionic surfactant (emulsion system). This suspension is capable of incorporating up to 40% water; thus this technique is widely used for low-level counting of tritium. Premixed aromatic solvent and surfactant-dissolving scintillation flours are available commercially.

A gas proportional counter with an anticoincidence shielding counter has also been utilized. Ethane gas is commonly used as a counting gas. A water sample is reduced to hydrogen gas using Mg or Zn powder in a furnace. Hydrogen gas thus produced is added to ‘dead’ ethylene or acetylene gas with a Pd catalyst to form ethane-counting gas.

Techniques for monitoring tritium in the atmosphere have been developed in order to prevent possible health hazards arising from tritium produced by fission and various other nuclear reactions.[22]

3.3 Deuterium in Nature

3.3.1 *Preparation Technique and Mass Spectrometer Measurements*

The deuterium content in Nature is usually expressed in D/H ratios in terms of δ values (the delta notation) defined as

$$\delta D(‰) = \left[\frac{(D/H)}{(D/H)_{standard}} - 1 \right] \times 10^3 \quad (16)$$

where $(D/H)_{standard}$ is the D/H ratio of V-SMOW (Vienna Standard Mean Ocean Water), 1.558×10^{-6}. The V-SMOW distributed by the International Atomic Energy Agency (IAEA) is a reference water sample for hydrogen and oxygen isotopes. The IAEA distributes a second water standard called SLAP (Standard Light Antarctic Precipitation), which has a δD value of −428‰.

The determination of D/H ratios of hydrogen compounds from natural sources is usually performed on hydrogen gas by a mass spectrometer. The D/H ratio of the hydrogen gas is measured as the HD^+ /$H_2{}^+$ ratio. The formation of $H_2{}^+$ and HD^+ in the ion source, together with $H_3{}^+$, are produced as by-products through the reaction

$$H_2{}^+ + H_2 \longrightarrow H_3{}^+ + H \quad (17)$$

Thus a $H_3{}^+$ correction needs to be made, utilizing the relationship that the quantity of $H_3{}^+$ produced is linear with respect to the hydrogen pressure squared.

Mass spectrometric measurements using hydrogen gas are prepared from the sample by fractionation free techniques. Water is converted into H_2 gas by being passed over uranium metal at 750 °C as a continuous method,[23] or by being reacted with heated zinc shot or melted in a Pyrex or quartz tube at approximately 450 °C as a batch method.[24]

In 1986, a new preparation method was developed, using a hydrophobic Pt catalyst, which served as the equilibration between H_2 gas and water vapor. The D/H ratio of the sample water is calculated from the measured D/H ratio in H_2 gas equilibrated with the sample water.[25] In combination with this method, the automatic CO_2-water equilibration set-up was designed for the simultaneous $^{18}O/^{16}O$ ratio measurement.[26]

Most of the hydrogen generated from hydroxyl-bearing minerals liberated in the form of water, although some is liberated as hydrogen gas. The resulting hydrogen gas is converted in many laboratories into water by the reaction with a Cu–CuO mixture. The water is then treated as described above.

The analytical errors of D/H ratio data based on the preparation method and mass spectrometer analysis varies usually from ±0.5 to 2‰.

In 1983, the first attempts to use the ion probe for D/H ratio measurements were made on meteoric samples and stratospheric dust.[27] In 1991, an analytical procedure was reported in situ measurement of D/H ratios by application of the ion probe to terrestrial hydrous minerals. This method is capable of measuring the δD values of individual minerals.[28] The δD values with a precision of ±10‰ have been measured by this method.

3.3.2 *The Natural Variation of Deuterium Content*

Most hydrogen on the Earth exists in the chemical forms H_2O, OH-bearing minerals, CH_4, and H_2. The δD values for terrestrial waters and OH minerals have been extensively measured and are generally in the range from −350 to +50‰. Ocean waters are typically 0‰ with a very narrow range of less than 10‰. The lowest values of −460 and −420‰ were reported for Antarctic ice[29] and pectolite[30] (a hydrous silicate), respectively. The δD values of OH-bearing minerals (muscovite, biotite, chlorite, and glaucophane) range from −104 to −28‰.[31] The δD values of biotites and hornblendes extracted from igneous rocks are in most cases in the range −90 to −50‰.[32] The mean δD value of atmospheric methane is −113‰,[33] and that of CH_4 from hydrothermal gases is −262‰.[34] The δD values of CH_4 from some volcanic areas in Japan fall within a range from −180 to −487‰.[35]

The δD values of molecular hydrogen are significantly different depending on its origin. The δD value of atmospheric H_2 is approximately $+70 \pm 30$‰, which has remained constant since 1957.[36] The δD values of H_2 in volcanic gases are reported to be in the range −158 to −144‰.[37] Those from some volcanic areas in Japan are in the range −515 to −220‰.[35] A value of about −660‰ was obtained for H_2 in fumarolic gases from the Yellowstone Park hydrothermal area in the United States.[34]

Molecular H_2 can be generated in soil by biological activity. Some marine bacteria have been known to produce H_2 highly depleted in deuterium in cultivating experiments. The δD value of the H_2 produced is about −800‰ (ca. 30 ppm).[38] The δD values of H_2 in soil gases obtained from sites along the active Yamasaki fault, in southwestern Japan, were in the range −770 to −470‰.[39] The source of molecular hydrogen in the atmosphere is not consistent with the δD values of the generated hydrogen gas.

During photosynthesis, plants remove hydrogen from water and transfer it into organic matter. The fixation of CO_2 and H_2 to organic compounds leads to deuterium depletion in the plants relative to environmental water.[40] After the formation of organic matter, the oxygen-bound hydrogen atoms are readily exchangeable,[41] while the carbon-bound hydrogen atoms appear to be nonexchangeable. There are systematic differences in the D/H ratios among classes of compounds in plants: lipids usually contain less deuterium than do the protein and carbohydrates of the extracted plants.

Figure 1 shows the natural variation ranges of δD values for some important reservoirs. Hydrogen has by far the largest relative mass difference between its two stable isotopes among all the elements. This difference results in the largest

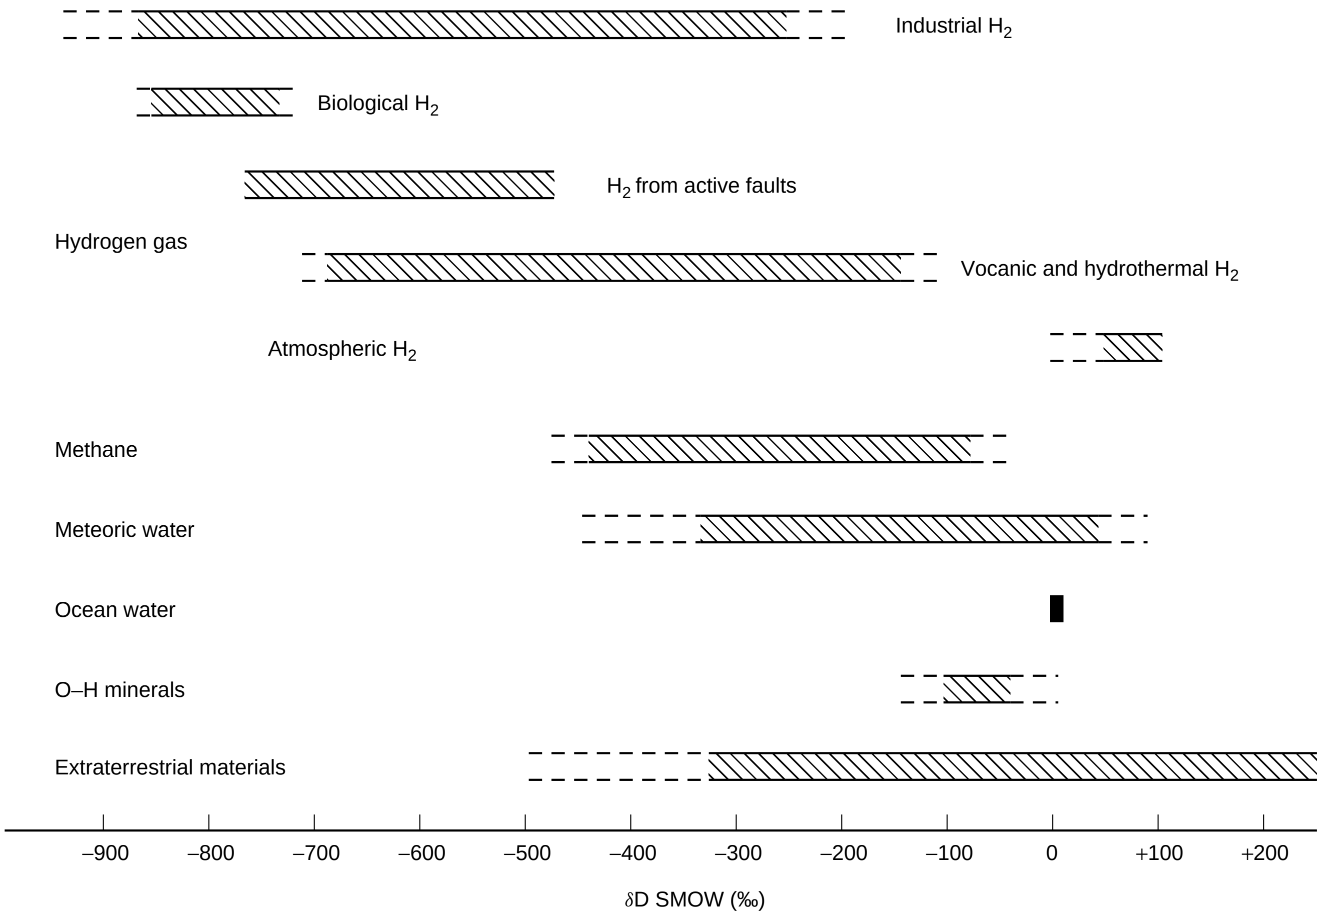

Figure 1 The ranges of D/H ratio in important hydrogen compounds (δD values relative to SMOW)

variations in stable isotope ratios of hydrogen; that is, from -900 to $+100$‰ on the Earth, and from -500 to $+4500$‰ in extraterrestrial and stratospheric materials. Geochemical reviews on stable isotopes including deuterium have been published elsewhere.[42]

3.3.3 *The Deuterium Content of Meteoric Water*

The term 'meteoric' applies to water that has recently been involved in atmospheric circulation. The natural water cycle has been compared to a multiple-stage distillation column with a reflux of the condensates to the reservoir. The oceans correspond to the reservoir, while the ice fields at the poles correspond to the highest stages of the column. The most efficient process for creating variations in the isotope ratios of water is caused by vapor pressure differences (isotope fractionations). In all processes concerning the evaporation and condensation of water, the hydrogen isotopes are fractionated in proportion to the oxygen isotopes, as a corresponding difference in vapor pressures or fractionation factors exists between H_2O and HDO in one case and $H_2{}^{16}O$ and $H_2{}^{18}O$ in the other case. Hence, the distribution of hydrogen and oxygen isotope can be correlated in meteoric waters. Craig[43] first gave the following relationship

$$\delta D = 8\delta^{18}O + 10 \qquad (18)$$

The slope of 8 in this relationship corresponds approximately to the ratio of the D/H and $^{18}O/^{16}O$ fractionation factors between vapor and liquid water at 25 °C, and the intercept corresponds to the kinetic effect of evaporation from the ocean. Dansgaard[44] interpreted the variation of the hydrogen and oxygen isotopic composition in precipitation.

Isotopic data (D, ^{18}O, and T contents) of meteoric waters, such as precipitation, rivers and groundwater, are commonly combined with geological, hydrological, and hydrochemical evidence in order to determine fluid sources and flow patterns of groundwater.

3.4 Tritium in Nature

3.4.1 *Preparation Technique and Measurements*

The measurement of low levels of tritium has become important in the studies related to hydrology, meteorology,

and monitoring programs of health physics for tritium released from nuclear power facilities.

Tritium is naturally produced to the extent of about 1 atom per 10^{18} hydrogen atoms as a result of nuclear reactions induced by cosmic rays in the upper atmosphere:

$$^{14}\text{N} + {}^{1}\text{n} \longrightarrow {}^{12}\text{C} + {}^{3}\text{T} \tag{19}$$

The natural inventory of tritium produced by this reaction is about 4×10^{18} Bq (11 kg), of which 90% is contained in the ocean as HTO. The tritium produced by man's activities (largely thermonuclear weapons testing) has increased to approximately 2×10^{20} Bq. Although most of this tritium has been transferred to the oceans, environmental tritium is still half an order of magnitude higher than was present before nuclear testing.

Tritiated-water standards have been distributed by the National Bureau of Standard (NBS), USA, and IAEA, meeting the demands from laboratories measuring the natural tritium.

The concentrations of tritium in natural waters are expressed by the atomic ratio of T to H: a ratio of $\text{T/H} = 10^{-18}$ is defined as 1 tritium unit (1 TU or 1 TR). 1 TU in water corresponds to approximately $0.12\,\text{Bq}\,\text{dm}^{-3}$ ($1\,\text{Ci} = 3.7 \times 10^{10}$ Bq). In the early 1990s, the tritium content of water in Nature was at a low level (under 20 TU), so it becomes necessary to enrich the tritium in order to obtain precise measurements. Measurement of tritium in environmental waters by conventional techniques combines enrichment and counting, so that precision depends on reducing the errors of both techniques as much as possible.

For the detection of soft β-emitting radionuclides such as tritium or carbon-14, liquid scintillation counting or gas-filled counting has been used in many laboratories. The liquid scintillation counting process indicates a somewhat high background and lower efficiency, while the gas-filled counting method has a higher efficiency. Background reduction in gas proportional counting has been efficiently achieved through the use of coaxially enveloping counters surrounding the sample counter with anticoincidence circuits. Sample preparation for liquid scintillation counting takes only a few minutes, compared to many hours for the gas proportional counting method.

The enrichment of tritium is usually determined by the tritium separation (fractionation) factor during electrolysis, and by measuring the initial and final amounts of water. However, many workers have reported that the value of the separation factor of tritium depends on the electrode material, the type of electrolytic enrichment cell, the current density, the mode by which water is fed into the electrolytic cell, and the temperature of the electrolytic cell. In 1991, a reliable method was proposed for estimating tritium concentrations in water, based on a reliable correlation between the water electrolytic enrichment of deuterium and tritium.[45] The constancy of the ratio, k, during the electrolysis, $k = \alpha(\beta - 1)/\beta(\alpha - 1)$, was verified experimentally, where α and β are the separation factors of deuterium and tritium, respectively. The value of k is far more reproducible than the values of $\beta/\alpha(= 2.1)$[46] and $\log\beta/\log\alpha(= 1.337)$.[47] When the value of k was first measured experimentally, the initial tritium content of sample water, $(\text{T/H})_0$, could be estimated by the formula

$$\left(\frac{\text{T}}{\text{H}}\right)_0 = \left(\frac{\text{T}}{\text{H}}\right)_\text{f} \left[\frac{(\text{D/H})_\text{f}}{(\text{D/H})_0}\right]^{-k} \tag{20}$$

where $(\text{T/H})_\text{f}$ and $(\text{D/H})_\text{f}$ are the tritium and deuterium contents after electrolysis, and $(\text{D/H})_0$ is the deuterium content before the electrolysis.

A sample of hydrogen gas from the atmosphere can be obtained by passed the crude He–Ne fraction in the air liquefaction plant over hot CuO, and by freezing out the water. The water sample is carefully sealed prior to analysis in order to avoid contamination with atmospheric moisture.

In the 1970s, Clark *et al.*[48] developed a method for analysis of environmental tritium by means of mass spectrometric measurements of ^{3}He, which was allowed to accumulate for suitable periods in degassed samples of water sealed in containers. Oliver *et al.*[49] measured the half-life of tritium using the accumulation rate of ^{3}He. The results yielded a mean tritium half-life of 12.38 ± 0.03 year. This value is consistent with the value of 12.43 ± 0.05 year recently recommended by Unterweger *et al.*,[50] based on the gas counting measurements of NBS standards over a time span of 18 years. Recent advance in a mass spectrometric facility for low-level tritium determination, represented by the ^{3}He growth method, shows that the ^{3}He detection limit of the system is close to $10^{-16}\,\text{cm}^3$ at STP ($0\,°\text{C}$, $1\,\text{atm} = 1.01 \times 10^5$ Pa), corresponding to a tritium level of 0.003 TU for a 500 g water sample stored for six months.[51]

3.4.2 *The Natural Distribution of Tritium*

Large-scale release of anthropogenic tritium to the atmosphere began in 1953 with thermonuclear explosion testing. During the 1960s, high concentrations of tritium were originally deposited. The tritium concentration in precipitation rapidly increased several hundredfold until 1963, but has since declined as a result on the moratorium on testing. The worldwide deposition of HTO through precipitation has been summarized on the basis of the data published by the IAEA. The results indicate that HTO concentration decreased significantly over the oceans. In 1979, studies of behavior of tritium in the environment were compiled by the IAEA.[52]

The three major chemical forms of atmospheric tritium are HTO, HT, and CH_3T. At present, approximately 99% of tritium atoms exist as HTO, and the remaining 1% is mostly HT with a significant fraction as CH_3T. The HTO species follows the water cycle in the atmosphere, having a residence time from a few days in the troposphere, to years in the stratosphere. The HT, on the other hand, is found well mixed globally, holding a consistent concentration in areas

away from nuclear industry, over the entire troposphere and in the lower stratosphere. Conversion from HT to HTO in the atmosphere occurs quite slowly.

A tritium content of approximately 2×10^4 TU in atmospheric methane was measured between 1960 and 1963.[33] The tritiated methane, CH_3T, in the atmosphere could be accounted for by a leakage equivalent to less than 1% of the maximum amount of tritium estimated to have been released anthropogenically.

Most of the interest in tritium has been focused on HTO. The tritium content of water has been extensively applied to meteorological and hydrological studies as a natural tracer. The natural distribution of HTO before thermonuclear tests was reported by Kaufman and Libby.[46] The measured values of tritium contents in precipitation, river and lake waters, and vintage wines were mostly under 10 TU. Tritium contents of vintage wines appear to agree with the time elapsed since the harvest, indicating that tritium abundances over the preceding 18 years were essentially at identical levels during that time. The stratospheric distribution of HTO is found to increase rapidly with height above the tropopause. An annual cycle is observed in which the lower stratosphere was depleted during the spring, and replenished during summer and fall by subsidence from higher levels of HTO, the so-called meteorological ‘spring leak’ from the stratosphere. Consequently, the tritium content of precipitation in spring and early summer is relatively higher than that of the annual average.

Cosmic radiation and H_2–H_2O exchange reactions in the upper atmosphere produce and maintain a small atmospheric HT inventory. However, at the present time the man-made one appears to be by far the largest part of the atmospheric HT. Since 1949, the tritium content of atmospheric hydrogen molecules has been measured after being extracted from the so-called ‘neon fraction’ obtained at liquid air plants. The values have increased from 10^4 TU in 1954[53] to 10^6 TU in the 1960s, in comparison with 10^3 TU in 1949.[36] Monitoring of HT in 1971 and 1972 showed that HT did not undergo seasonal fluctuations, observed in HTO, and variations were small around a mean of approximately 46 HT molecules per mg of air.[54]

Tritium in water vapor has also been utilized in the study of meteorology. Kigoshi and Yoneda[55] observed daily variations in the tritium content of atmospheric moisture (water vapor) collected in Tokyo. High tritium contents indicate the arrival of continental air masses from the north, and the low contents in tropical low-pressure air masses are nearly equal to that of surface ocean water.

Because of greatly contrasting low tritium levels before thermonuclear tests and because of the distinct peak tritium levels that occurred in the atmosphere during 1962–1965, tritium has been used as an environmental tracer in the studies on surface water budgets, groundwater age and flow velocities, groundwater recharge, and dispersion and diffusion in aquifers. A 1989 study detailed the distribution of tritium in a recharge area of a shallow unconfined sand aquifer near Sturgeon Falls, Ontario.[56] It concluded that tritium concentrations of more than 100 TU were measured in the groundwater recharged between 1957 and 1961, while concentrations of more than 200 TU occurred only in groundwater recharged between 1961 and 1967. Because tritium released into the atmosphere by thermonuclear tests has been mostly transferred into the ocean, and has decreased by radioactive decay, so the tritium content of precipitation has already declined. Consequently, the role of tritium as a natural tracer is about to cease.

4 ISOTOPE EFFECT OF HYDROGEN

4.1 General

Differences in chemical and physical properties arising from differences in the nuclear mass of an element are called isotope effects. The isotope effect is greatest for hydrogen among all the elements, principally owing to the largest differences in relative mass of the isotopes.

From the classical chemical aspect, isotopes of an element are expected to have same chemical properties. Therefore, it has been believed that the behaviors of isotopes of an element are essentially the same. However, a change in the mass of an atom in a molecule produces changes in vibrational, rotational, and translational motions of the molecule. In the diffusion of gases it has long been known that the velocity of molecules changes with the mass of the molecule, thus producing a physical isotope effect.

In quantum mechanics, vibrational and rotational states are quantized, resulting in the isotopic molecules having different discrete energy level. This difference in energy levels results in differences in the distribution of isotopic molecules between different states. The observed differences in the physical properties among H_2, D_2, and T_2, and among H_2O, D_2O, and T_2O, are examples of quantum mechanical effects and are shown in Tables 2 and 3.

Consider two molecular species in equilibrium, each of which has a different set of energy levels for each isotopic molecule. In the mixture of the isotopic molecules, each isotope distributes between the two molecular species according to the energy levels set for the isotope. This results in uneven distribution of hydrogen isotopes between the two phases. In practice, the contribution of the vibrational energy is dominant over rotational and translational energies in equilibrium isotope effects.

Isotope fractionation may occur either by equilibrium isotope exchange reactions or kinetic processes. Kinetic isotope effects are mainly dependent on the differences in reaction rates of isotopic molecules. The kinetic isotope effect for hydrogen compounds have reviewed by Westheimer.[57]

4.2 Isotopic Properties of Hydrogen and Water

Equilibrium isotope effects can be considered in terms of the effect of atomic mass on *Bond Energies*. The forces binding atoms are independent of changes in atomic mass owing to isotopic substitution. Therefore the potential energy curve remains unchanged. For a diatomic molecule in the harmonic oscillator approximation, the vibrational energy levels are given by

$$E = \left(n + \frac{1}{2}\right) h\nu \quad (21)$$

where n represents an integer number from zero, and h is Plank's constant. The lowest vibrational energy ($n = 0$), $(1/2)h\nu$, is well known as the vibrational *Zero Point Energy* that molecules possess even at a temperature of absolute zero. The vibrational frequency, ν, is given by

$$\nu = \frac{1}{2\pi}\left(\frac{k}{\mu}\right)^{1/2} \quad (22)$$

where k represents the force constant that is constant for isotope substitution, and μ is the reduced mass of the two nuclei. At lower temperatures, all of the molecules will be in their lowest vibrational levels, and thus isotopic substitution will affect all processes involving vibrational excitation.

When a lighter isotope is substituted by a heavier isotope, the value of μ becomes larger, and the vibrational frequency, ν, becomes smaller. Therefore the molecules substituted by deuterium and tritium have correspondingly smaller zero-point energies, as shown in Table 2. The schematic potential energy curve for hydrogen molecules is shown in Figure 2. The difference in zero-point energy between H_2 and HD is $3\,\text{kJ}\,\text{mol}^{-1}$ and that between H_2 and D_2 is $8\,\text{kJ}\,\text{mol}^{-1}$. This means that the binding of a lighter nucleus is weaker than that of a heavier nucleus. In general, during chemical reactions a molecule with a light isotope is more active than a molecule with a heavy isotope.

The 10% mass change in water by the replacement of protium by deuterium results in substantial changes in many commonly known properties of water. In Table 3, a number of physical properties of normal water, H_2O, and heavy water, D_2O, are compared. The viscosity of D_2O is 25% higher than that of H_2O at 25 °C, which is the most conspicuous difference between H_2O and D_2O.

The differences in many of the physical properties of liquid H_2O and D_2O can be qualitatively understood in terms of strength. The hydrogen bond between O and D is stronger than between O and H. In the IR spectra of H_2O and D_2O, peaks are observed at 700 and 500 cm^{-1}, respectively, and are assigned to the librational motion of H_2O and D_2O molecules. Librational motion is a kind of rotational motion associated with the hydrogen bonds. The smaller wave number for D_2O indicates that the strength of the hydrogen bond is stronger in D_2O than in H_2O.

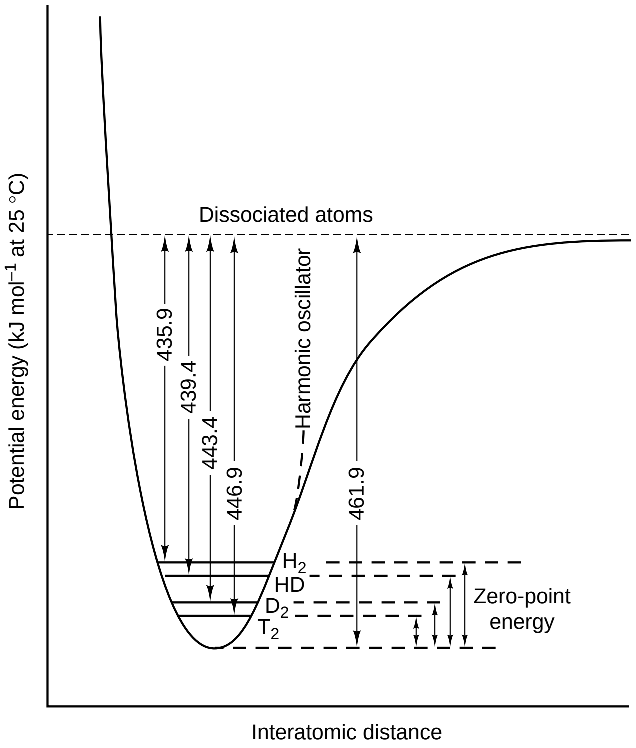

Figure 2 Schematic potential energy curve for the hydrogen molecules with scale at bottom of the curve exaggerated to show relation between $n = 0$ vibrational energy levels of the four isotopic forms of the molecules. Note that molecules containing a heavy isotope are more stable (have higher dissociation energies) than molecules with a light isotope. Isotope fractionations between molecules are explained by differences in their *zero-point energies*

In order to account for some of the differences in thermodynamic properties of H_2O and D_2O, theoretical studies have been applied. Swain and Bader[58] first calculated the differences in heat content, entropy, and free energy by treating the librational motion of each water molecule as a three-dimensional isotopic harmonic oscillator. Van Hook[59] demonstrated that the vapor pressure of H_2O and D_2O on liquid water and ice could be understood quantitatively within the framework of the theory of isotope effects in condensed systems. Nemethy and Scheraga[60] showed that in a model based on the 'flickering cluster' concept, the mean number of hydrogen bonds formed by each water molecule is about 5% larger in D_2O than in H_2O at 25 °C.

4.3 Relationship Between Fractionation Factor and Vapor Pressure

The fractionation factor α_{C-V} for the equilibration between a condensed phase and its saturated vapor is defined as

$$\alpha_{C-V} = \frac{(D/H)_C}{(D/H)_V} \quad (23)$$

where $(D/H)_C$ and $(D/H)_V$ are the D/H ratios of the condensed phase and vapor, respectively. The measurements of the D/H fractionation factor, α_{L-V}, between liquid water and vapor, have been performed by various workers.[61–63] In Figure 3, D/H fractionation factors are shown in the temperature range 10–40 °C. These results are obtained within the range of 0.5%. The results of Kakiuchi and Matsuo[61] are close to those of Majoube[62] at the high end of the temperature range, and are placed in the middle of those of Majoube[62] and Merlivat *et al.*[63] at the lower temperatures.

At temperatures higher than 100 °C, $\ln\alpha_{L-V}$ does not show a linear relationship with $1/T^2$ [63] however, the logarithm of the oxygen isotope fractionation factor, $\ln\alpha_{L-V}(^{18}O)$, does show a linear relationship with $1/T^2$, up to the critical temperature.

The D/H fractionation factors between ice and its vapor,α_{S-V}, were measured between −40 and 0 °C and expressed as the following relationship[64]

$$\log\alpha_{S-V} = -4.10\times 10^{-2} + \frac{7074}{T^2} \quad (24)$$

In a system containing condensed and gases phases, Bigeleisen[65] derived the relationship between the reduced partition function ratio (RPFR), f, and the measured

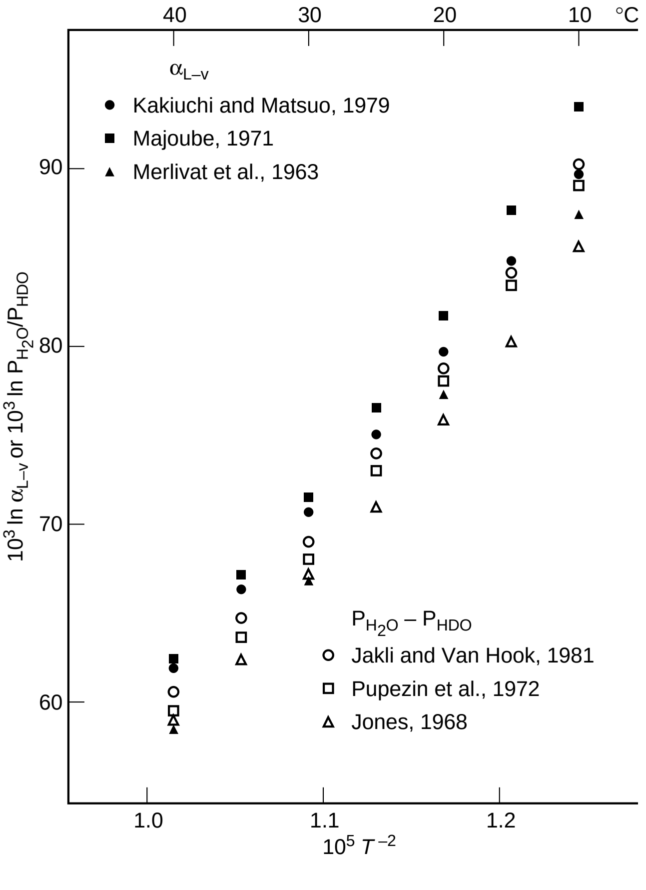

Figure 3 Comparison of the values of $\ln\alpha_{L-V}$ and $\ln(P_{H_2O}/P_{HDO})$ for pure water in the temperature range from 10 to 40 °C

fractionation factor in the infinite dilution limit, α_{C-V}, which refers to single isotopic enrichment (on distillation):

$$\ln\alpha_{C-V} = \ln\left(\frac{f_C}{f_V}\right) - \frac{(V' - V)^2}{(2\kappa' V' RT)} \quad (25)$$

where the primes (′) refer to the lighter isotopes, κ represents the isothermal compressibility, V represents the partial molar volume of the condensed phase, and R represents the gas constant. The second term is generally quite small and is often neglected. Thus, RPFRs are obtained directly from fractionation factors between gaseous and condensed phases in distillation experiments.

In experiments measuring the vapor pressure ratio of separated isotopes, P′/P, theoretical interest arises in the relationship between f and P′/P. Bigeleisen[66] introduced the following relationship:

$$\ln\left(\frac{f_C}{f_V}\right) = \ln\left(\frac{P'}{P}\right) - \left(\frac{1}{RT}\right)(P'V' - PV) + (B'P' - BP) \quad (26)$$

where P represents the vapor pressure and B represents the second virial coefficient in the pressure expansion form of the equation of state.

A relationship connecting ln(P′/P) and $\ln\alpha_{C-V}$ can now be written from equations (25) and (26) as follows:

$$\ln\alpha_{C-V} = \ln\left(\frac{P'}{P}\right) - \left(\frac{1}{RT}\right)(P'V' - PV) + (B'P' - BP) - \frac{(V' - V)^2}{(2\kappa' V' R\,T)} \quad (27)$$

We now turn our attention to the experimental results. The D/H fractionation factor between liquid and water vapor, α_{L-V}, and the vapor pressure ratio, (P_{H_2O}/P_{HDO}), are combined in equation (27). In order to compare the data, which were obtained by the measurement of the vapor pressure ratio, (P_{H_2O}/P_{D_2O}), between H_2O and D_2O, and by those of the D/H fractionation factor, the value of the HDO vapor pressure is estimated by the geometric mean. The $\ln(P_{H_2O}/P_{HDO})$ values calculated from the measured $\ln(P_{H_2O}/P_{D_2O})$ and $\ln\alpha_{L-V}$ values are shown in Figure 3. The values of $\ln\alpha_{L-V}$ are somewhat larger than those of $\ln(P_{H_2O}/P_{HDO})\{=(1/2)\ln(P_{H_2O}/P_{D_2O})\}$ in this temperature range.

4.4 Isotope Effect in Aqueous Solution

4.4.1 *Solvent Isotope Effects in Hydration*[67]

The term 'solvent isotope effect' is used in discussions of equilibrium processes in normal and heavy water for the isotope effect, which is attributed to isotopic substitution of the solvent. Solvent isotope effects may be due primary to differences in the structure constructed by the two isotopic water molecules.

The differences in the hydration of a solute in H_2O and D_2O have been extensively studied by measuring their thermodynamic properties, the change of free energy ($\Delta G^0{}_t$), enthalpy ($\Delta H^0{}_t$), and entropy ($\Delta S^0{}_t$) at the transfer of 1 mol of solute from a highly dilute solution in H_2O to the same concentration in D_2O under reversible conditions (mostly 25 °C and atmospheric pressure). Greyson[68] measured the electromotive force (emf) of electrochemical cells of several alkali halides containing heavy and normal water solutions. The cell potentials had been combined with available heat of solution data to determine the entropy of transfer of the salts between the isotopic solvents. The thermodynamic properties for the transfer from H_2O to D_2O and the solubilities of alkali halides at 25° in H_2O and D_2O are shown in Table 4.

The $\Delta G^0{}_t$ studies using electrochemical cells with dilute solutions or the solubility studies of alkali halide suggest that most salts have a higher standard free energy in D_2O than in H_2O between 0 and 100 °C; thus they are 'more soluble' in H_2O, as shown in Table 4. LiF is shown to have the highest driving force to go from H_2O to D_2O. The $\Delta H^0{}_t$ for alkali halides is correlated with the $\Delta S^0{}_t$. Alkali halide salts, except LiF, break more structure in D_2O than in H_2O, because there is more structure to break, thereby producing the positive $\Delta H^0{}_t$ and $\Delta S^0{}_t$. Judging from the values of thermodynamic properties of transfer, the orders of effects of alkali metal cations and halide anions on the structure of water were found to be $Cs^+ > K^+ > Na^+ > Li^+$, and $I^- > Br^- > Cl^- > F^-$, respectively.

4.4.2 *Solvent Vapor Pressure Isotope Effect*

The vapor pressure ratio measurements of separated isotopes are particularly useful because they directly measure the isotopic free energy ratios of the solvent. The solvent vapor pressure isotope effect between H_2O and D_2O is determined in terms of

$$\Delta \ln\left(\frac{P_{H_2O}}{P_{D_2O}}\right)^m = \ln\left(\frac{P_{H_2O}}{P_{D_2O}}\right)^0 - \ln\left(\frac{P_{H_2O}}{P_{D_2O}}\right)^m \qquad (28)$$

where the superscript 0 denotes pure water, while m represents the aquamolality, which corresponds to the molality of the solute in 55.51 mol of solvent. The values of $\Delta \ln(P_{H_2O}/P_{D_2O})^m$ for alkali chlorides and some salts were measured over a broad range in temperature and concentration by Pupezin *et al.*[69] and Jakli *et al.*[70] The measured values are positive except for the value obtained with 2 m LiCl, and become larger if salt is added to the both solvents. Changes in $\Delta \ln(P_{H_2O}/P_{D_2O})^m$ values with changing temperature for several concentrations of alkali chlorides mostly arise near 50 °C.

Jakli and Van Hook[71] also measured the values of $\Delta \ln(P_{H_2O}/P_{D_2O})^m$ in aqueous urea solutions. The values $\Delta \ln(P_{H_2O}/P_{D_2O})^m$ in urea solution are positive and increase with increasing molality of urea. There is little temperature dependence of $\Delta \ln(P_{H_2O}/P_{D_2O})^m$ in the temperature range 15–60 °C. The value of $\Delta \ln(P_{H_2O}/P_{D_2O})^m$ is significantly smaller than that for an alkali halide solution. Data of $\Delta \ln(P_{H_2O}/P_{D_2O})^m$ of some salts and urea at 25 °C are shown in Table 5.

4.4.3 *Fractionation Between Aqueous Solution and Water Vapor*

In order to explain the isotopic fractionation of hydrogen and oxygen isotopes between aqueous solution and water vapor or between aqueous solution and carbon dioxide,[72–77] the following model is proposed. In the aqueous solutions the presence of two different species of water molecules is assumed; one species represents the water molecules coordinated to the solute ions or molecules forming the hydration sphere, and another species represents the 'free' (or

Table 4 Free energy ($\Delta G^0{}_t$), enthalpy ($\Delta H^0{}_t$), and entropy ($\Delta S^0{}_t$) of transfer from H_2O to D_2O, and solubilities in H_2O and D_2O for alkali halides at 25 °C

'bulk') water molecules that are not involved in hydration, and is structurally similar to pure water. These two species of water molecules must be in energetically different states, resulting in D/H and $^{18}O/^{16}O$ fractionations between these two species. Addition of a solute to the aqueous phase changes the D/H and $^{18}O/^{16}O$ ratios in the 'free' water since newly formed hydration spheres selectively take hydrogen and oxygen isotopes. This in turn results in the change in the D/H and $^{18}O/^{16}O$ ratios in the water vapor or the $^{18}O/^{16}O$ ratio in the carbon dioxide in equilibrium with the 'free' water, which is considered to have an energy state similar to pure water.

The D/H fractionation factor, α_{sol-V}, between an aqueous solution and vapor is defined by the relation

$$\alpha_{sol-V} = \frac{(D/H)_{sol}}{(D/H)_V} \tag{29}$$

where $(D/H)_{sol}$ and $(D/H)_V$ are the D/H ratios of solution and vapor, respectively.

In order to compare the aqueous solution with pure water, Kakiuchi and Matsuo[75] defined β as

$$\beta = \frac{\alpha_{sol-V}}{\alpha_{pw-V}} = \frac{[(D/H)_{sol}/(D/H)_V{}^{sol}]}{[(D/H)_{pw}/(D/H)_V{}^{pw}]} \tag{30}$$

where α_{pw-V} represents the fractionation factor between pure water and vapor, and $(D/H)_V{}^{sol}$ and $(D/H)_V{}^{pw}$ are the D/H ratios of water vapor over the solution and pure water, respectively. When isotopically identical water is used as pure water and in aqueous solution, then $(D/H)_{sol}$ and $(D/H)_{pw}$ in equation (30) becomes the same. β indicates the ratio between the D/H ratio of vapor equilibrated with pure water and that of vapor equilibrated with an aqueous solution as follows

$$\beta = \frac{(D/H)_V{}^{pw}}{(D/H)_V{}^{sol}} \tag{31}$$

The negative values of $\ln\beta$ indicate that the D/H ratio of water vapor equilibrated with aqueous solutions is higher than that of water vapor equilibrated with pure water.

Kakiuchi[72] measured the D/H ratio of hydrogen gas in equilibrium with aqueous solution by means of catalytic exchange using a hydrophobic Pt catalyst. The aqueous solution−hydrogen gas equilibrium, α_{sol-g}, can be expressed as

$$\alpha_{sol-g} = \frac{(D/H)_{sol}}{(D/H)_g{}^{sol}} \tag{32}$$

where the subscript g indicates hydrogen gas. Similarly, with the solution-vapor equilibration method, β is also defined as

$$\beta = \frac{\alpha_{sol-g}}{\alpha_{pw-g}} = \frac{(D/H)_g{}^{pw}}{(D/H)_g{}^{sol}} \tag{33}$$

where, α_{pw-g} represents the fractionation factor between pure water and hydrogen gas, and $(D/H)_g{}^{sol}$ and $(D/H)_g{}^{pw}$ are the D/H ratios of hydrogen gas over the aqueous solution and pure water, respectively. Water vapor equilibrated with the aqueous solution is also equilibrated with the hydrogen gas on the catalyst at the same temperature. β is defined by equations (31) and (33), which are identical.

Table 5 presents the results of $\ln\beta$ determinations in relation to the concentration of some alkali halides[72–74] and urea[75] at 25 °C. Based on the assumption that the 'free' (or 'bulk') water in aqueous solutions is identical with pure water, the fractionation factor between the 'free' water molecules in solution and water vapor or between that and hydrogen gas, α_{f-V} or α_{f-g}, should be equal to that between pure water and water vapor or between that and hydrogen gas, α_{pw-V} or α_{pw-g}, respectively. Then the negative value of the $\ln\beta$ for alkali halide solutions indicates that the fractionation factor between hydrated water and the 'free' water in solution, α_{h-f},

is smaller than unity. This means that HDO is depleted in the hydration sphere of alkali halides. The observed $\ln\beta$ values show a linear relationship with concentration up to 6 m in various alkali halide solutions. Conversely, the $\ln\beta$ values obtained for urea solution are positive and do not show a linear relationship.

The temperature dependence of $\ln\beta$ in the aqueous sodium chloride solution in the temperature range from 10 to 95 °C using the solution–hydrogen gas equilibration method,[74] and from 50 to 100 °C using the solution-vapor method.[77] $\ln\beta$ values show a linear relationship with concentration at each temperature. Concentrations of 2, 4, and 6 molal change linearly with the reciprocal temperature squared.

The relationship between $\ln\beta$ and $\Delta\ln(P_{H_2O}/P_{D_2O})^m$ can be expressed as: $\ln\beta = -(1/2)\Delta\ln(P_{H_2O}/P_{D_2O})^m$, based on the assumptions that the mixing behavior of H_2O–HDO–D_2O is ideal, and that both equilibrium constants of the reaction, $H_2O + D_2O \rightleftharpoons 2HDO$, of the liquid and gas phases, are identical, even in aqueous solutions. Comparison of with natural D/H ratios, with $\Delta\ln(P_{H_2O}/P_{D_2O})^m$ values obtained by the vapor pressure measurements on separated isotopes at 25 °C (Table 5), shows the qualitative trends on concentration for alkali halide to be the same. However, the difference between the values of $-\ln\beta$ and those of $(1/2)\Delta\ln(P_{H_2O}/P_{D_2O})^m$ are remarkably large.

5 CHEMICAL PROPERTIES OF HYDROGEN

5.1 General

As the dissociation energy of a single H–H bond is high (436 kJ mol^{-1}), molecular hydrogen is stable and relatively inert at room temperature. It burns in air to form water and will react explosively with oxygen and halogens under certain conditions. At high temperature, hydrogen gas will reduce many oxides, either to lower oxides or to metal. In the presence of suitable catalysts, hydrogen reacts with N_2 to form NH_3. Hydrogen also forms hydrides with electropositive metals and nonmetals.

A number of reactions of hydrogen and organic molecules are catalyzed by transition metals. In the presence of suitable catalysts, usually groups 8–10 metals or their compounds, a great variety of both inorganic and organic substances can be reduced (*see* ***Heterogeneous Catalysis by Metals***). Heterogeneous *Hydrogenation* may be carried out in a gas phase or in solution, and a number of transition metal ions and complexes can react with hydrogen, transferring it to a substrate homogeneously in solution (*see* ***Hydrogenation & Isomerization of Alkenes***). Hydrogen recombination, which is one of the simplest chemical reactions, has generated wide interest, both theoretically and experimentally. Because of its electronic simplicity, hydrogen is a suitable subject for theoretical consideration of adsorbate-surface bonding. Hydrogen is important as a reactant in heterogeneously catalyzed process. In exchange reactions with organic molecules, hydrogen and deuterium have been extensively investigated in relation to catalysis.

Interesting issues in modern fundamental hydrogen chemistry include the possible appearance of unusual valence states of hydrogen under highly unusual thermobaric conditions. In particular, such unusual valence states may include the state of 'metallic' or 'metallized' hydrogen. The issue of metallic hydrogen as an individual phase was actively debated during the mid-1970 s. Data were obtained for the first time in 1989 by Mao *et al.*[78] as evidence for band overlap metallization of hydrogen above 200 GPa at 77 K. Measurements of absorption and Raman spectra provide evidence that electronic excitation in the visible region begin at 200 GPa. Strongly compressed solid hydrogen is reported to have a much greater electrical conductivity than that of other solid elements. It would be interesting to measure the electrical conductivity in 'metallic' hydrogen if that measurement were possible.

5.2 Atomic Hydrogen

Although the hydrogen molecules is the simplest stable form of hydrogen under ordinary conditions, atomic hydrogen can be formed from this species if sufficient energy is supplied:

$$H_2 \longrightarrow 2H \qquad \Delta H = 436\ \mathrm{kJmol^{-1}} \tag{34}$$

Under experimental conditions when hydrogen gas is heated the decomposition of the molecules to atoms begins at approximately 2000 °C. Values for the equilibrium constant of the dissociation of hydrogen molecule, $H_2 \rightleftharpoons 2H$, are given in Table 6. In addition, atomic hydrogen can be produced by electrical discharge, by irradiation with a mercury arc, or by

Table 6 Equilibrium constants for dissociation of a hydrogen molecule, $H_2 = 2H$, $K_p = P_H{}^2/P_{H_2}$

3000	2.78×10^{-2}
4000	2.768
5000	44.66

bombardment with electrons in the 10–20 eV energy range. A more convenient source of atomic hydrogen is available by passing a glow discharge through hydrogen gas at 100 Pa.

At pressures less than 1 Pa, hydrogen atoms are formed by heated wires of W, Pd, or Pt. Under such conditions, concentration hydrogen atoms up to 95% may be obtained using a discharge tube. The half-life of the H atom is about 1.0 s at 30 Pa, which allows it to be transported out of the discharge and its reactions examined. The presence of hydrogen atoms in such experiments is established by observation of the Balmer series of the H atom spectrum and the diminution in intensity of the H_2 molecules band spectrum. The very long half-life shows that only about 1 in 10^6 collisions between atoms leads to recombination.

The H atoms formed by the methods mentioned above are highly reactive and unite with many elements to give hydrides.[79] The reactions of H atoms in the gaseous phase and in solution have very extensively studied using kinetic methods because of the transient nature of this species.

As the recombination of H atoms is strongly catalyzed by many metals, recent work has used electrodeless discharges operating at microwave or radio frequencies. The high heat generated in the process of H atom recombination can be utilized as an atomic hydrogen torch, where hydrogen is dissociated in an arc and recombines on the surface of the metal to be melted. Temperatures of approximately 4000 °C are attained, capable of welding metals with very high melting points such as Ta or W.

If a metal such as Zn is dissolved in acid, hydrogen gas is produced, and thus the dissolving metal is a good reducing agent. Therefore hydrogen is being formed as a reduction product of the proton and it is not in itself the reducing agent. However, in practice, molecular hydrogen is a poor reducing agent, because of its kinetic stability. It is most likely that hydrogen atoms can be produced by proton reduction (i.e. by the process, $H^+ + e^- \rightarrow H$). Hydrogen atoms will usually unite with each other to produce molecular hydrogen, but can attack other species. Thus, in the reduction of an arsenic-containing compound to AsH_3, or an alkyl halide to an alkane by a metal couple (Al–Zn–Cu) in aqueous acid, atomic hydrogen may participate in the reaction.

5.3 Ionized Forms of Hydrogen

In this section, we will consider the *Proton* H^+, the hydride ion H^-, the hydrogen molecule ion $H_2{}^+$, and the triatomic two-electron species $H_3{}^+$.

The first ionization energy of H atom (1311 kJ mol^{-1}) is very high in comparison with that of many other elements, such as alkali metals. Removal of the 1s electron leaves a bare proton, which, having a radius of only about 1.5×10^{-3} pm, never exists in the condensed phase. However, when bonded to other species it is well known in solutions and in solids (e.g. H_3O^+, $NH_4{}^+$, etc.). The proton affinity of water and the solvation energy of the H^+ ion in water have been estimated from the thermodynamic cycle at 25 °C:

$$H^+(g) + H_2O(g) \longrightarrow H_3O^+(g) \qquad -\Delta H = 690\ \text{kJmol}^{-1} \qquad (35)$$

$$H^+(g) + xH_2O(aq) \longrightarrow H^+(aq) \qquad -\Delta H = 1090\ \text{kJmol}^{-1} \qquad (36)$$

It follows that the heat of solution of the H_3O^+ ion in water is 400 kJ mol^{-1}.

Compounds that furnish solvated H^+ ions in suitable polar solvents, such as water, are protonic acids. The nature of the H^+ ions in water, which should more correctly be called the hydroxonium ion, H_3O^+, is customarily referred to as 'the hydrogen ion'.

The hydrogen atom, like the alkali metals and halogens, has an affinity for the electron (*see Electron Affinity*). From the following reaction, heat is produced:

$$H(g) + e^- \longrightarrow H^-(g) \qquad -\Delta H = 72\ \text{kJmol}^{-1} \qquad (37)$$

This value is larger than the corresponding value for Li (57 kJ mol^{-1}) but substantially smaller than the value for F (333 kJ mol^{-1}). The hydride ion H^- has the same electron configuration as He, but is much less stable because the single positive charge on the proton must control the two electrons. The hydride ion is thus readily deformable, a characteristic feature of its structural chemistry.

The species $H_2{}^+$ and $H_3{}^+$ are important as model systems for *Chemical Bonding* theory. The hydrogen molecule ion, $H_2{}^+$, comprises two protons and one electron, and is extremely unstable even in a low-pressure gas discharge system. The energy of dissociation of an $H_2{}^+$ ion is smaller than that of an H_2 molecule (436 kJ mol^{-1}) and the internuclear distance of an $H_2{}^+$ ion is larger than that of an H_2 molecule (74.1 pm).

The triatomic hydrogen molecule ion $H_3{}^+$, was first detected in gas discharges and later fully characterized by mass spectrometry; its relative atomic mass, 3.027, clearly distinguishes itself from tritium, 3.016. The 'observed' triangular three-center two-electron structure is more stable than the hypothetical linear structure.

5.4 Reactions of Molecular Hydrogen

5.4.1 General

Molecular hydrogen is not reactive at ordinary temperatures. However, at higher temperature, hydrogen gas combines with most elements, either directly or with the aid of a catalyst. Some of the more important reactions are shown in Figure 4. The resultant hydrides are described simply in Section 5.5.

Only a few compounds are reduced by H_2 at room temperature. An aqueous solution of palladium chloride is readily reduced:

$$PdCl_2(aq) + H_2 \longrightarrow Pd(s) + 2HCl(aq) \qquad (38)$$

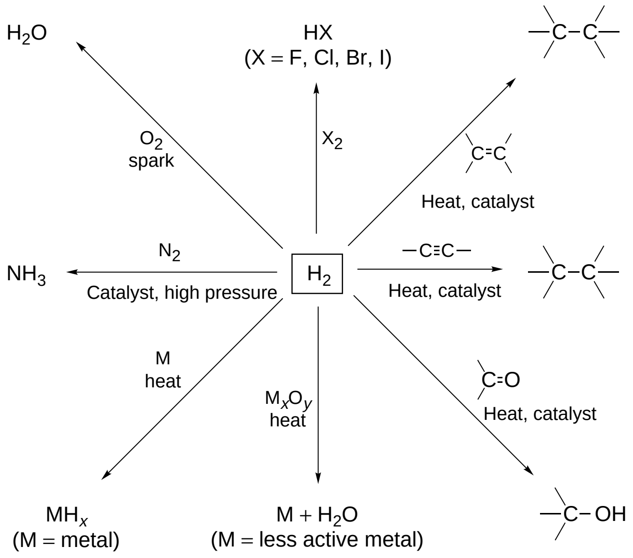

Figure 4 Major reactions of molecular hydrogen

This reaction, using a 1% solution of $PdCl_2$, acts as a sensitive test for the presence of hydrogen and may be used quantitatively.

Inorganic reactions and experimental method for hydrogen are thoroughly described in the literature.[80]

5.4.2 *Reactions of Hydrogen with Halogens*

Mixtures of hydrogen gas and halogens combine vigorously. The reactions are initiated by the dissociation of the halogen molecules in presence of heat, light, or other agents. All of the reactions are exothermic (*see* ***Chlorine, Bromine, Iodine, & Astatine: Inorganic Chemistry*** and ***Fluorine: Inorganic Chemistry***).

Even at the temperature of liquid nitrogen, 77 K, hydrogen react violently with fluorine:

$$H_2 + F_2 \longrightarrow 2HF \quad (39)$$

The combination is highly efficient owing to the strength of the H–F bond. The stability of the H–F bond and its high heat of formation give the combination of H_2 and F_2 the highest specific impulse available to the science of rocket propulsion.

Hydrogen and chlorine combine to form HCl:

$$H_2 + Cl_2 \longrightarrow 2HCl \quad (40)$$

Enclosed mixtures of H_2 and Cl_2 undergo rapid combination at 20 °C if exposed to light. The thermal combination of H_2 and Cl_2 is carried out in the absence of a catalyst, although charcoal is a catalyst.[81] Without a catalyst, the elements combine slowly at 100 °C and more rapidly at 200 °C. In the presence of a catalyst, rapid combination occurs at 20 °C or below.

Direct combination of H_2 and Br_2 is the most economical method for the preparation of pure HBr:

$$H_2 + Br_2 \longrightarrow 2HBr \quad (41)$$

This reaction is more difficult to achieve than those involving F_2 or Cl_2 are. In the absence of a catalyst, the reaction occurs slowly at 250 °C, but rapidly at 500 °C. The reaction is most readily brought about in the presence of a carbon catalyst at a temperature above 150 °C. In contrast to Cl_2, there is no reaction at 20 °C indirect sunlight. At 200 °C, sunlight causes rapid combination, forming HBr.

The formation of HI from its elements is the least favorable, in terms of energy, of the hydrogen–halogen combination reactions (excluding At):

$$H_2 + I_2 \longrightarrow 2HI \quad (42)$$

In the absence of a catalyst, the combination of H_2 and I_2 occurs only above 500 °C, although at these temperatures HI undergoes extensive thermal decomposition, producing an equilibrium mixture. This reaction, therefore, is always brought about by the presence of a catalyst.

5.4.3 *Reactions of Hydrogen with Major Elements*

Molecular hydrogen reacts with oxygen to form water (*see* ***Oxygen: Inorganic Chemistry***):

$$2H_2 + O_2 \longrightarrow 2H_2O \quad (43)$$

This reaction is exothermic. The heat required to produce gaseous H_2O and liquid H_2O in this reaction at 25 °C and 1 atm is 242 and 286 kJ mol^{-1}, respectively. This reaction proceeds spontaneously at temperatures above 500 °C. At temperatures lower than 500 °C this reaction occurs in the presence of a suitable catalyst, such as Pt or Pd, or if activated by an electric spark or a flame. The combustion of hydrogen in oxygen produces flame temperatures as high as 2800 °C, a technique utilized in oxyhydrogen welding torches.

The direct reduction of sulfur by hydrogen to produce hydrogen sulfide does not take place readily at room temperature, but does take place at 250 °C:

$$H_2 + S \longrightarrow H_2S \quad (44)$$

A catalyst is usually requires in the formation of H_2S. Metal sulfides are the most common catalysts used in the laboratory or in large-scale production of H_2S. The catalytic activity of metal sulfides is linked to the metal–sulfur bond strength.

Large quantities of ammonia are produced from the exothermic reaction of gases H_2 and N_2:

$$N_2 + 3H_2 \rightleftharpoons 2NH_3 \qquad -\Delta H = 92\,\text{kJmol}^{-1} \quad (45)$$

The equilibrium favors NH_3 formation at low temperature and high pressure. In order to achieve acceptable reaction rates and conversion to NH_3, the reaction is carried out over an Fe or Fe_2O_3 catalyst at 500 °C and ca. 10^5 Pa.

Under ordinary conditions, carbon does not react with H_2 at an appreciable rate. At high temperatures and in the presence of catalysts, the following reaction occurs:

$$\mathrm{C(graphite)} + 2\mathrm{H_2} \longrightarrow \mathrm{CH_4} \tag{46}$$

Powdered graphite impregnated with Ni, or C in the presence of Fe–Cr sponge, reacts at 500–1000 °C to form CH_4, along with small quantities of other hydrocarbons.[82]

5.4.4 *Reduction of Metal Compounds*

The reduction of metal oxides (M_xO_y) by hydrogen gas is metallurgically valuable. Water is produced in this reaction:

$$\left(\frac{1}{y}\right)\mathrm{M}_x\mathrm{O}_y + \mathrm{H_2} \rightleftharpoons \left(\frac{x}{y}\right)\mathrm{M} + \mathrm{H_2O} \tag{47}$$

The reduction of metal sulfates by H_2 also produces water; for example, $MgSO_4$ at approximately 750 °C and $CaSO_4$ at approximately 900 °C. But the reactions proceed in different ways because the thermodynamically stable products are MgO and CaS:

$$\mathrm{MgSO_4} + 4\mathrm{H_2} \longrightarrow \mathrm{MgO} + \mathrm{H_2S} + 3\mathrm{H_2O} \tag{48}$$

$$\mathrm{CaSO_4} + 4\mathrm{H_2} \longrightarrow \mathrm{CaS} + 4\mathrm{H_2O} \tag{49}$$

5.4.5 *Miscellaneous Reactions*

The reduction of SO_2 by H_2, according to the equation

$$\mathrm{SO_2} + 3\mathrm{H_2} \longrightarrow 2\mathrm{H_2O} + \mathrm{H_2S} \tag{50}$$

is important in sulfur chemistry (*see* ***Sulfur: Inorganic Chemistry***). Inorganic nitrogen compounds react with H_2, yielding products containing N–H. Germanium nitride reacts with H_2 at 600 °C (*see* ***Nitrogen: Inorganic Chemistry***):

$$\mathrm{Ge_3N_2} + 3\mathrm{H_2} \longrightarrow 3\mathrm{Ge} + 2\mathrm{NH_3} \tag{51}$$

Unsaturated organic compounds such as alkynes, alkenes, ketones, oximes, nitriles, and imines, are readily reduced by H_2 using a catalyst; for example:

$$\mathrm{C_2H_2} + 2\mathrm{H_2} \longrightarrow \mathrm{C_2H_6} \tag{52}$$

$$\mathrm{C_2H_4} + \mathrm{H_2} \longrightarrow \mathrm{C_2H_6} \tag{53}$$

$$\mathrm{C_6H_6} + 3\mathrm{H_2} \longrightarrow \mathrm{C_6H_{12}} \tag{54}$$

$$\mathrm{(CH_3)_2CO} + \mathrm{H_2} \longrightarrow \mathrm{(CH_3)_2CHOH} \tag{55}$$

Hydrogenations using heterogeneous catalysts usually require thermal condition above room temperature and H_2 pressures higher than 10^3 Pa. Homogeneous catalysts are often more selective with individual reactions and make the reactions possible at lower temperatures and H_2 pressures.

5.5 Hydrides

Hydrogen combines a variety of elements to form hydrides, compounds with widely differing properties.[83] Figure 5

Figure 5 A classification of the hydrides. The starred elements are the transition elements for which complex molecules or ions containing M–H bonds are known. (Ref. 84. Reproduced by permission of Wiley Inc.)

represents an approximate classification of the various hydrides.[84]

Elements with very low electronegativeties of approximately 1.0 (*see Electronegativity*), form compounds in which the hydrogen appears as an anion, H^-. These compounds have many of the properties associated with ionic substances and are sometimes called ionic or saline hydrides. Ionic hydrides, formed with alkali (M^+H^-) and alkaline earth ($M'^{2+}H_2{}^{2-}$) metals, are colorless crystalline solids that either melt or decompose at temperatures above 600 °C. All of the hydrides can be formed by direct combination of the elements at elevated temperatures:

$$2M + H_2 \longrightarrow 2MH \quad (56)$$

$$M' + H_2 \longrightarrow M'H_2 \quad (57)$$

For lithium and sodium the hydrides can also be prepared by heating the corresponding nitride in a stream of hydrogen:

$$2M_3N + 3H_2 \longrightarrow 6MH + N_2 \quad (58)$$

Elements with electronegativities of approximately 2.0 or greater form hydrogen compounds with covalent bonds. These substances are generally volatile and are often referred to as covalent hydrides. The covalent hydrides fall into two distinct classes. The first are the compounds of the carbon, nitrogen, oxygen, and fluorine groups, which have normal electron-pair bonds between the element and hydrogen. The second are compounds exemplified by the simplest boron hydride, B_2H_6, which do not have enough valance electrons to form electron-pair bonds to all of the hydrogen and therefore are termed ‘electron deficient’ (*see* ***Boron Hydrides***). Into this category fall the hydrides of Be, B, Al, and Ga.

The transition metal hydrides are formed by the elements with intermediate electronegativities (*see* ***Hydride Complexes of the Transition Metals***; ***Hydrides: Solid State Transition Metal Complexes***). The fundamental difference between the ionic hydrides and the transition metal hydrides is clearly illustrated by their differentially corresponding absorption of hydrogen.

5.6 Interaction of Hydrogen with Metals

5.6.1 Hydrogen Absorption

The metals, which form ionic hydrides, show extended temperature ranges in which hydrogen absorption does not occur until favorable conditions for the formation of the hydride are reached. At this point the expected stoichiometric amount of hydrogen is absorbed. In contrast, some of the metals that form transition metal hydrides are capable of absorbing a considerable amount of hydrogen.

The nature of the hydrogen atoms bound in the transition metal hydrides is not clearly understood. Some of these substances are good reducing agents, suggesting the presence of hydridic or atomic hydrogen. Rapid diffusion of hydrogen in metals such as Pd indicates that unbound hydrogen atoms may be present. The constitution of these systems may vary with composition. For example, up to a composition of $PdH_{0.5}$ the palladium–hydrogen system has properties associated with conduction, but at higher concentrations of hydrogen it becomes a semiconductor. In the same range of stoichiometries the paramagnetisum decreases from a value for a pure metal to a minimum value at a composition corresponding to $PdH_{0.6}$.

Formation of a binary hydride is an exothermic process, excluding some cases such as Ni and Cu where it is endothermic, and also Cr where it becomes endothermic at higher temperature. For other metals, which dissolve hydrogen without hydride formation, such as Fe, Co, Mo, Ag, and Pt, the process is endothermic; that is, hydrogen uptake increases with increasing temperature. This may complicate the interpretation of thermal desorption spectra, since some hydrogen may enter the bulk rather than appear in the gas phase. Very large quantities of hydrogen can be absorbed in Pd, Ti, Zr, V, Ta, and U hydrides. In the endothermic systems, however, the H to metal atom ratio is generally very small at elevated temperatures. Finally, with metals such as W, Re, Os, and Ir, no solubility is detectable by macroscopic techniques, although this does not exclude the possibility that significant amounts may be dissolved on the scale of surface process.

5.6.2 Hydrogen Adsorption

Single-crystal hydrogen adsorption results are available to data only for atomic hydrogen, that is, the H_2 molecule has to be split by external means, such as a gas discharge or by a hot wire as mentioned in Section 5.2. The large surface area of powders allows adsorption studies by means of volumetric measurements. In contrast, single crystals exhibit only a few square millimeters of surface, and adsorbed hydrogen has been detected to date only through changes of surface conductivity and work function. Studies show that adsorption processes and surface reactions of single crystals depend on the crystallographic orientation of the crystal surface. For powders, the orientation of the adsorbing face is not yet known (*see* ***Surfaces***).

Hydrogen adsorption has been extensively studied on metals and metal oxides. In particular, detailed explanations have been given for the interactions of hydrogen with metals Mo, W, Ni, Pd, and Pt,[85] and with the metal oxides ZnO and TiO_2.[86]

Knowledge of the adsorption of hydrogen on silicon and germanium surfaces is important in order to obtain information on interfacial phenomenon of semiconductors.[87] The adsorption of hydrogen on Si (111) surfaces is one of the best understood systems, although the exact nature of the clean surfaces is not well understood.

6 PHYSICAL PROPERTIES OF HYDROGEN

6.1 General

There has been a tremendous upsurge in research and development studies of hydrogen: determinations of its properties at temperatures ranging from 0 to 10^6 K, and at pressures ranging from 10 to 4×10^{10} Pa. In space programs, hydrogen is widely used as a rocket fuel and it is well known for generating energy by nuclear fusion.

Major physical properties of atomic hydrogen and molecular hydrogen of natural composition are listed in Tables 1 and 2. The basic physical properties of hydrogen have been measured with high precision. The hydrogen molecule, owing to its simple nature, has been used extensively as a model for detailed calculations, often accompanied by a wide range of measurements of suitable properties. For example, values for ortho- and para-hydrogen are discussed later in Section 6.3. Hydrogen is very sparingly soluble in water: at STP (0 °C, 1 atm = 1.01×10^5 Pa) only 2.14 volumes of hydrogen dissolve in 100 volumes of water.[88] Its solubility in liquid hydrocarbons such as hexane, cyclohexane, and benzene is a linear function of pressure up to 1.5×10^7 Pa. The solubility of hydrogen in liquid ammonia increases with increasing temperature,[89] in contrast to the solubility of usual gases, which decrease with increasing temperature. The solubilities of hydrogen in water and liquid ammonia are shown in Table 7. The thermal conductivity of hydrogen is approximately seven times that of air; this property is useful when analyzing for the presence hydrogen in other gases.

Solid hydrogen has been studied extensively. Molecular hydrogen usually freezes in the hexagonal close-packed form, with $a_0 = 376.1$ pm and $c_0 = 610.5$ pm for H_2,[90] and $a_0 = 365$ pm and $c_0 = 583$ pm for D_2,[91] as determined by X-ray diffraction. It has been shown, however, that the formation of molecular hydrogen can be modified into a cubic close-packed geometry in the presence of gold foil with a cube texture at 4.2 K. D_2 and para-H_2 behave similarly.[91]

Table 7 Solubilities of hydrogen in water and liquid ammonia[a]

Water					
t(°C)	1 atm	50 atm	100 atm	500 atm	1000 atm
0	0.0214	1.068	2.130	9.838	18.001

100	–	15.67	140.6	388.2

[a] cm^3 of H_2 (reduced to 0 °C and 1 atm) g^{-1} (H_2O or liq NH_3).

High-temperature hydrogen plasmas are used in experiments to produce energy by thermonuclear fusion of hydrogen to helium; this is the same reaction by which the energy of the Sun and other stars is generated.

6.2 Hydrogen Spectroscopy

The observation and interpretation of the spectrum of atomic hydrogen played a vital part in the development of quantum chemistry. Studies of the spectrum of the hydrogen atom are presented in the literature.[92] The laser technique has contributed to recent advances in the analysis of the spectrum.[93] The fine detail in the spectrum can only be distinguished by light that is highly monochromatic or confined to a narrow range of wavelengths. Lasers are a source of such light, used in the exploration of the hydrogen spectrum.

The spectroscopy and dynamics of superexcited molecules, including the hydrogen atom and molecule, are reviewed in the literature.[94] Synchrotron radiation has been used in the study of photodissociation of a highly excited H_2 molecules into two excited H atoms.[95]

6.3 Ortho- and Para-hydrogen

All diatomic molecules for which the constituent nuclei have spin exhibit the phenomenon of spin isomerism. The nuclear spins can be parallel (the ortho isomer) or opposed (the para isomer). For most diatomic molecules, which might be expected to exhibit, spin isomerism the energy separation of the rotational states is small compared to kT, even at low temperatures. However, in the case of hydrogen molecules, which have the smallest moment of inertia of any diatomic molecules, the energy difference between the rotational energy levels is relatively large and only the lowest states are populated at room temperature.

The ortho-para ratio is determined by the statistical calculation of the availability of states given by the partition function. Calculated ortho–para equilibria for H_2, D_2, and T_2 are shown in Figure 6 at the temperature range from 0 to 300 K.[96–98] When the two nuclear spins are parallel, the resultant nuclear spin quantum number is 1 (i.e. $1/2 + 1/2$) and the state is threefold degenerate. When the two spins are opposed, however, the resultant nuclear spin is zero and the state is nondegenerate. Therefore para-H_2 has the lower energy and this state is favored at lower temperatures. The equilibrium concentration of H_2 approaches three parts ortho to one part para at room temperature.[96] As the nuclear spin quantum number of the deuteron is 1 rather than 1/2 for the proton (see Table 1), the D_2 system is described by Bose-Einstein

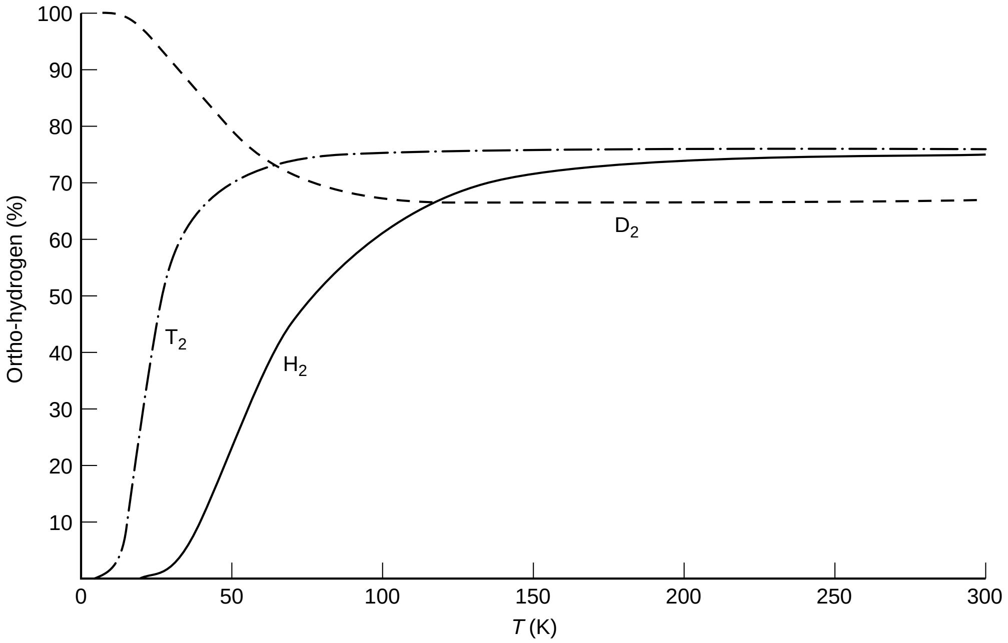

Figure 6 Ortho–para equiblia for H_2, D_2, and T_2 from 0 to 300 K

statistics rather than the more familiar Fermi-Dirac statistics. For this reason the stable low-temperature form is ortho-D_2 and at high temperatures the equilibrium concentration approaches two parts ortho to one part para, as shown in Figure 6.[97] Tritium molecules, T_2, of which the nuclear spin is 1/2, resemble H_2 molecules in their ortho–para relationship.[98]

As the ortho–para conversion involves the forbidden triplet-singlet transition in the nuclear spin state, spontaneous transformation is very slow. Thus, samples of hydrogen that have been cooled exhibit the proportion of the two forms corresponding to the equilibrium composition at room temperature. The conversion of the ortho molecules to para molecules and vice versa requires the simultaneous breaking of both the spin and orbital symmetries, and the equilibrium ratio is therefore established slowly.

The rate constant for the ortho–para conversion in the solid H_2 is 1.9%/h.[99] This value is expected to be different when confined to a restrict geometry owing to interactions with the walls, the changes in the phonon spectrum, and the reduced number of nearest neighbors. The orientational ordering of ortho-H_2 in zeolite as well as the supercooling of the liquid–solid transition has been studied using NMR techniques.[100] Two distinct conversion rates were observed over short and long timespans. An apparently bimolecular conversion rate of 0.43%/h (one-fourth of the bulk value) dominates during the first 500 h, after which the rate increases to 2.2%/h.

The conversion is catalyzed by a number of surface-active or paramagnetic species such as Pd, Pt, or active Fe_2O_3. The presence of both ortho- and para-hydrogen molecules is seen in experiments as an alternation in the intensities of successive rotational lines in the fine structure of the electronic band spectrum of hydrogen molecules. The dual presence also explains the temperature dependence of the heat capacity of hydrogen gas.

According to the quantum theories, it is predicted that molecular hydrogen has a nonstatistical ortho–para composition at low temperature. The calculated values of the ortho-para ratio are found to be sensitive towards the actual model and approximation being used. Therefore measurements of the ortho–para ratio could provide much needed information to improve our understanding of the recombination processes. Although the importance of measuring the ortho–para composition was recognized in the 1970s, with many experimental studies of hydrogen recombination having been reported,[101] a truly convincing measurement is yet to be reported. One of the obstacles towards measuring the composition is that the recombination produces molecules in vibrationally excited states and the analysis of the ortho-para composition is typically carried out after the molecules have relaxed back to the vibrational ground state. Nonstatistical ortho-para ratios in hydrogen recombinations at temperatures below 1 K have been observed, and no ortho-para conversion during the vibrational relaxation process was demonstrated.[102]

6.4 Hydrogen in Semiconductors

In semiconductor science (*see* ***Semiconductor Interfaces***), hydrogen has long been used as an inert gas for crystal growth, or as a component in gases for the various forms of chemical vapor deposition (SiH_4, AsH_3, $Ga(CH_3)_3$, etc.).

Despite its omnipresence and chemical reactivity, hydrogen as an impurity has until recently received limited attention.

Under certain conditions, hydrogen can have a large influence on the electronic properties of a semiconducting material. This was first realized in the research of amorphous silicon in the 1970s. At that time, evaporation of pure Si as the principal deposition method was replaced by plasma-enhanced chemical vapor deposition of silane. Because of the relatively low temperatures needed to obtain amorphous rather than polycrystalline silicon, several atomic per cent of hydrogen remained trapped in the amorphous silicon matrix, mostly in the form of Si–H. An immediate consequence of the presence of hydrogen in silicon is a pronounced reduction of structural defect via Si–H bond formation. This passivation of deep electronic defects is a prerequisite for almost all-technical applications of hydrogenated amorphous silicon (a-Si:H). There has been a significant amount of research dealing with hydrogen in amorphous silicon and its influence on electronic properties.

Experimental and theoretical studies on hydrogen in crystalline semiconductors have been compiled in the literature.[103]

6.5 Hydrogen Energy

In the space exploration program, large quantities of liquid hydrogen have been used both as a fuel for generating electric power in fuel cells, and as a rocket fuel with oxygen or fluorine as the oxidizer.

Active searches for alternative forms of energy have been prompted by the growing recognition that reserves of coal and oil are finite and that nuclear power cannot supply all our energy requirements. Hydrogen has been considered as a source of fusion energy and/or clean energy.

High-temperature hydrogen plasmas, in addition to being a key component in energy projects of the nuclear fusion reaction using deuterium and/or tritium, have also been studied as agents for chemical reactions.

Since the energy crisis in 1973, a number of laboratories have undertaken intensive research projects with the aim of developing methods for hydrogen production by utilizing solar energy. Because of its physical and chemical properties, hydrogen is accepted as a nearly ideal energy carrier for the future. It can be produced from water by various techniques and has advantages over electricity because it can be stored. On combustion, hydrogen reforms to water (closed cycle), so produces little pollution. The photoelectrochemical and photocatalytic methods for hydrogen production are of special benefit, because solar energy is free and practically inexhaustible. However, the supply of energy on the surface of the Earth is not so enormous in comparison with the amount of energy consumed by mankind. Progress in this field is featured in a review article.[104]

In 1989, the phenomenon of cold fusion was first reported during electrolysis of heavy water by Fleischmann *et al.*[105] These workers observed the generation of neutrons and tritium from electrochemically compressed D^+ in a Pd cathode. Their study has stimulated a variety of calorimetric and nuclear measurements. However, the occurrence of the phenomena is sporadic and appears unreproducible on a consistent basis. Therefore a pessimistic view of cold fusion must be taken with respect to the possibility of future energy production.

Glossary

Anti-Markovnikov addition: the addition of HX across a C=C bond such that the hydrogen is added to the carbon bound to the lesser number of hydrogen atoms (cf. Markovnikov addition below)
Diffusion control: this occurs when the rate of diffusion of a reactant to the site of the reaction is significantly slower than the rate of reaction
Homogeneous hydrogenation: a hydrogenation reaction in which the substrate, hydrogen, and catalyst are all dissolved in the same solution. These systems can be distinguished from the traditional heterogeneous systems by their ability to hydrogenate insoluble polymeric substrates
Markovnikov addition: the addition of HX across a C=C bond such that the hydrogen is added to the carbon bound to the greater number of hydrogen atoms (cf. anti-Markovnikov addition above)
Metallocycle: a chain of carbon atoms bound at each end to the same metal ion to form a cyclic compound
Radical: a species containing an unpaired electron (e.g. $CH_3\bullet$, Fe^{3+})
Radical scavenger: a compound, often a relatively stable radical, that reacts preferentially with the radicals generated in the system. This reaction is also known as trapping
Sigmatropic rearrangement: a concerted reaction in which an initially σ-bonded group migrates within a π-bonded framework (e.g. an alkene or alkadiene) and reforms its sigma bond elsewhere [1,3]-Sigmatropic rearrangement: a reaction of the type YC–C=C → C=C–CY [3,3]-Sigmatropic rearrangement: a reaction of the type C=C–CY–C–C=CX → YC=C–C–CX–C=C

1 INTRODUCTION

Alkene complexes of late transition metals have been known for over a century. Transition metal hydrido complexes were first characterized nearly 60 years ago. These two types of complex hold the keys to two important catalytic processes: alkene isomerization and hydrogenation. Many complexes catalyze both processes and the catalytic reactions of some of the more active complexes have long been known.[1–3]

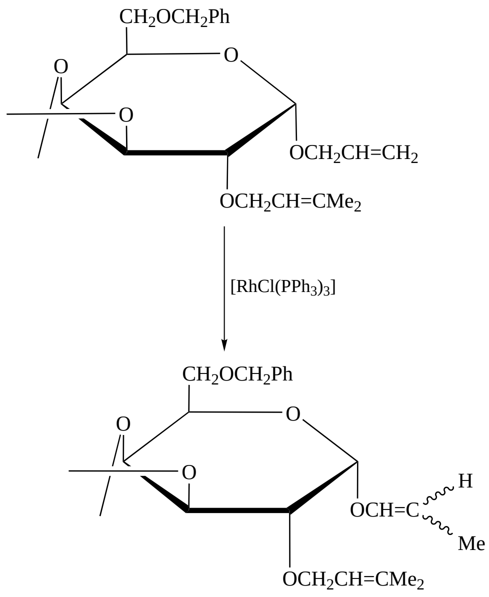
Except in radical reactions, the transition metal complex must coordinate with unsaturated organic compounds in order to bring about their transformations. However, since alkenes, and in particular substituted alkenes, do not readily displace other ligands from transition metal complexes, the catalytically active complexes are usually coordinatively unsaturated. Transition metal complexes normally only catalyze the formation of organic molecules of greater thermodynamic stability. There are, therefore, no thermodynamic problems in converting alkenes or alkynes to alkanes. However, once equilibrium has been achieved, alkene isomerizations will usually give mixtures of products, with the thermodynamically most stable predominating.

Three fundamental types of isomerization may be distinguished. The first is double-bond migration, as in the isomerization of pent-1-ene to (Z)-pent-2-ene. The second involves skeletal rearrangements, such as the conversion of bicyclo[3.1.0]hex-2-ene derivatives to the corresponding cyclohexadienes. The third, and possibly most useful type, is the catalysis of group migrations, particularly in the Cope- and Claisen rearrangements.

There are two principal mechanisms by which double-bond migration may occur. The first, the η^3-allylic mechanism, is more often proposed than encountered. In this, the alkene interacts with the transition metal and forms an η^3-allyl hydrido complex. The hydride is then transferred back to the η^3-allyl to complete a 1,3 hydride shift. This occurs in the $[PdCl_2(PhCN)_2]$ system. In the second, which is much more common, a hydrido complex (e.g. $[NiH\{P(OEt)_3\}_4]$) reacts with an alkene to form an alkyl complex. The alkyl complex then reverts to an isomeric alkene and the hydrido complex by undergoing a β-hydride abstraction reaction.[4] Reactions of the latter type are frequently responsible for by-product formation in homogeneous catalytic hydrogenation, deuteriation, Hydroformylation, or Hydrosilation. This type of rearrangement is one of the few cases where synthetic use has been made of catalytic isomerization by transition metal complexes. The double-bond migrations that occur in acyclic alkenes are usually regarded as unmitigated nuisances since they ultimately convert commercially desirable terminal alkenes to internal (E)-alkenes of low reactivity and value. However, the conversion of allyl protecting groups to prop-2-enyl groups by catalytic isomerization facilitates their hydrolytic removal in carbohydrate chemistry. The reaction shown in equation (1) demonstrates that allyl groups are selectively isomerized. However, side reactions make the yields of prop-2-enyl esters slightly less than optimum.[5]

Skeletal rearrangements can be more precisely defined as rearrangements resulting from either decyclization or annulation reactions that do not involve migration of ring

substituents. These rearrangements arise from interactions between strained, cyclic organic compounds and the dz^2 orbital of a square-planar transition metal complex. A metallocycle is formed by oxidative addition of the organic species. Extrusion of a metal complex from this may result in ring expansion of polycyclic substrates or acyclic alkene production as a result of decyclization. The least common rearrangement involves transannular reactions of large cycloalkenes to form bi- or polycyclic products.



(1)

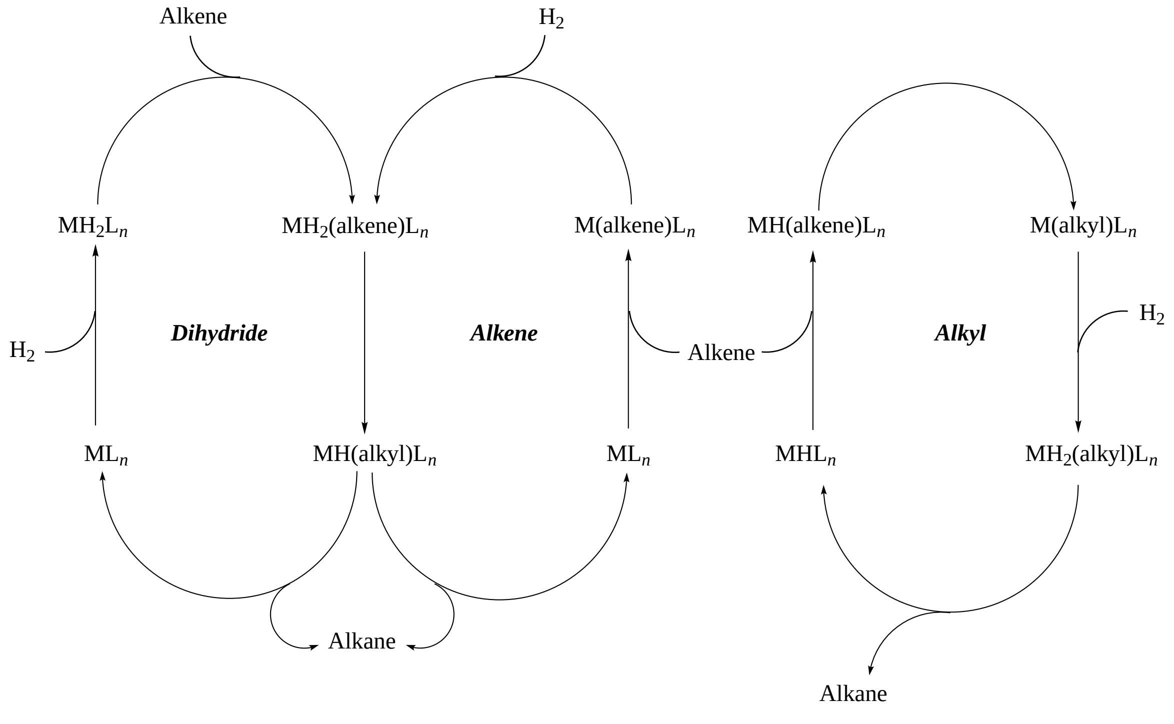
The Cope- and Claisen rearrangements are also catalyzed by square-planar transition metal complexes. Palladium complexes have been responsible for spectacular increases in the rates of Cope rearrangements by factors of up to 10^8. Certain other sigmatropic rearrangements are also catalyzed by transition metal complexes.

Three major mechanisms of catalytic hydrogenation are known.[6] These are differentiated by the order in which the two reactants are activated and are further distinguished, and named, by the reagent activating molecular hydrogen (Scheme 1).

The two most important mechanisms involve the reaction of an alkene with dihydrido complexes or, the reverse of this, the reaction of dihydrogen with an alkene complex. The third process, known as the *alkyl route*, is of limited applicability and may give rise to substantial quantities of by-products.

The main advantage of catalysis by transition metal complexes is that the reactions may be carried out in solution (i.e. the reactions are homogeneous) and they therefore depend neither upon the state of subdivision nor the surface properties of the heterogeneous metal catalyst. The greater selectivity of the homogeneous catalysts can also be used to advantage when other functional groups are present in the substrate. Normally, homogeneous catalysts are selective towards the least sterically hindered C=C bond and do not catalyze the hydrogenation of other multiple interatomic bonds.

It is also possible to hydrogenate alkenes by transferring hydrogen from another organic compound (transfer hydrogenation). Many transition metal complexes, particularly those



Scheme 1

of ruthenium,[2] catalyze this stoichiometrically simple reaction (equation 2). The mechanism of the reaction is complicated because of the need to activate the reactants in the correct order.

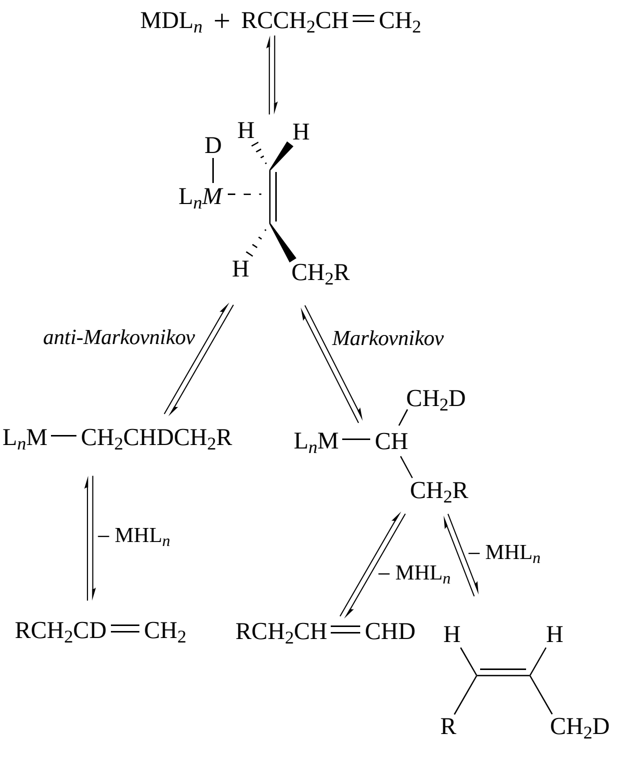
$$RCH{=}CH_2 + Me_2CHOH \xrightarrow{ML_n} RCH_2CH_3 + Me_2CO \qquad (2)$$

2 ISOMERIZATION

2.1 Isotope Exchange and Double-bond Migration

Monohydrido transition metal complexes are the most active catalysts in double-bond migration reactions. These complexes form alkyl complexes when allowed to react with alkenes. The relatively long lifetimes of alkyl complexes in these systems allows them to undergo β-hydride abstraction reactions before they can react with the other reagents present. The mechanism of the reaction is shown in Scheme 2.

Anti-Markovnikov addition of hydrogen to the alkene forms a 1-alkyl complex from the alk-1-ene substrate. This alkyl complex can either react with other reagents or revert to the original alkene and hydrido complex. If the reaction is carried out using a deuterio complex as shown in Scheme 2, then there is a 50% chance of isotopic exchange occurring upon reversion.



Scheme 2

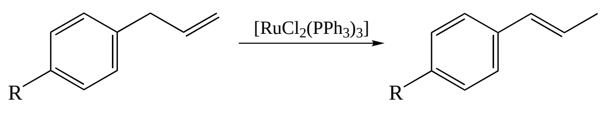
Markovnikov addition of hydrogen to the alk-1-ene forms a 2-alkyl complex. Thermodynamically it is less likely that this 2-alkyl complex will revert to the original alk-1-ene than be converted to an alk-2-ene as a result of competing β-hydride abstraction reactions.

An alternative explanation is that reforming the alk-1-ene involves breaking a primary C–H bond, which requires more energy than breaking a secondary C–H bond, to form the (Z)-alk-2-ene. If the isomerization reaction is allowed to continue, eventually, by repetition of the catalytic cycle shown in Scheme 2, the alk-1-ene will be further converted into a mixture of alk-2-enes and alk-3-enes. The equilibrium is only slowly achieved because the low-binding constants of internal alkenes make it difficult for them to enter the catalytic cycle.

Isomerization in the absence of a hydrido complex or added hydrogen is frequently and incorrectly assigned an η^3-allylic mechanism. This facile assignment overlooks the possibility of hydrido complexes being formed from reactions with alcohols or other solvents or reagents during the reaction.

Several isomerizations brought about by $[RhCl(PPh_3)_3]$ fall into this category. Hydrolysis of added $SnCl_2{\cdot}2H_2O$ forms HCl, which adds to the catalyst forming the pentacoordinate monohydride $[RhHCl_2(PPh_3)_2]$, which can bring about the isomerization of polyunsaturated carboxylic acids and their esters. The isomerization can be inhibited by the addition of lithium carbonate, which, by removing the HCl formed, prevents the formation of the hydrido complex. Deuteride formation from alkan(^{2}H)ol solvents and the subsequent incorporation of deuterium into the ester has also been observed.

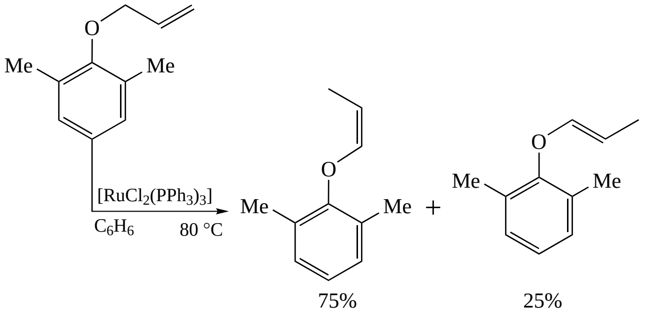
Another way in which hydrido complexes can be formed is by Orthometalation. It has been demonstrated that $[RuCl_2(PPh_3)_3]$ is particularly susceptible to this reaction. The hydrido complex $[RuHCl\{(2\text{-}C_6H_4)PPh_2\}(PPh_3)_2]$ may well catalyze the many isomerizations brought about by the ruthenium catalyst. Indeed, the ruthenium complex is a more active catalyst than many other transition metal complexes in the isomerization of allyl groups. It usually isomerizes allyl groups to (E)-prop-2-enyl substituents, but allyl 2,6-dimethylphenyl ether forms mainly the (Z)-product (equations 3 and 4).



(3)

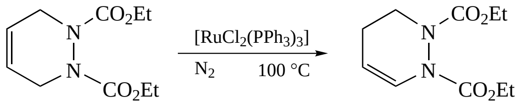
Peroxides may either be deliberately added or be present in alkenes that have been exposed to the air. The low concentrations of these species are of the same order as those of the catalytic complexes and can convert the catalysts to more active species. Mixtures of peroxides, 4-vinylcyclohexene, and $[RuCl_2(PPh_3)_3]$ form the complex $[RuCl_2(PPh_3)_2(CO)(C_8H_{12})]$. The carbonyl complex is the

true catalyst since it can isomerize pure 4-vinylcyclohexene.



(4)

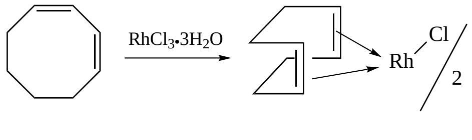
Genuine η^3-allylic mechanisms give different product distributions from β–hydride abstraction mechanisms, particularly in the case of isotopically labeled substrates. One of the few unambiguous demonstrations of the η^3-allylic mechanism occurs in the $[RuCl_2(PPh_3)_3]$ catalyzed isomerization of a dihydropyridazine derivative (equation 5). Both polyhydrido ruthenium complexes and $[RuHCl(PPh_3)_3]$ were inferior catalysts for the reaction, and the addition of ethanol to the reaction mixture reduced the yield by a factor of 25. All these observations lead to the conclusion that hydrido complexes, and by implication the β-hydride mechanism, were not involved.[7] It has also been proposed that the isomerization shown in equation (4), which is catalyzed by a wide variety of transition metal complexes including several nonhydridic species, occurs by an η^3-allylic mechanism because substituents on the allyl group hinder the rearrangement.[8]



(5)

Double-bond migration also occurs in dienes. Again the isomerization gives rise to more stable products usually containing conjugated double bonds. Possibly one of the most simple reactions is the $(Z) \rightarrow (E)$ conversion of penta-1,3-diene by $[Fe(CO)_5]$.[9]

However, the usual course of events in the isomerization of cycloalkadienes is to achieve conjugation where coordination is impossible. Thus cyclohexa-1,4-diene is isomerized to cyclohexa-1,3-diene by $[RuCl(PPh_3)_3]$. Nevertheless, $RhCl_3{\cdot}3H_2O$ isomerizes cycloocta-1,3-diene, the most stable isomer, to a chelated cycloocta-1,5-diene complex (equation 6). Since no intermediate cycloocta-1,4-diene can be observed in the reaction, it was presumed to proceed via an η^3-intermediate.[10]



(6)

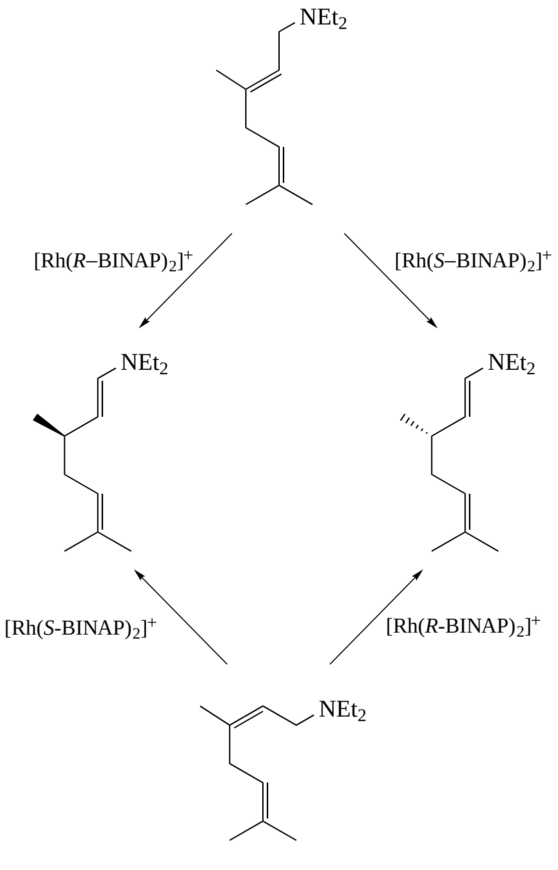
The chiral, cationic complexes $[Rh(BINAP)_2]^+$ catalyze the conversions of N,N-diethylaminoterpenes in good optical yields (Scheme 3).[11]

2.2 Decyclization and Annulation Reactions

Cyclopropane compounds are the most strained carbocyclic species and should, therefore, be the most susceptible to decyclization reactions.

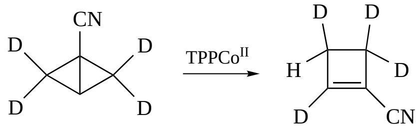
Vinylcyclopropane is converted to $(3E)$-penta-1,3-diene and 2-methylbuta-1,3-diene by catalytic quantities of $[RhCl(CO)_2]_2$. Its homolog, 2-cyclopropylpropene, is similarly converted to $(3E)$-2-methylpenta-1,3-diene and 2,3-dimethylbuta-1,3-diene. Although the same catalyst converts either (E)- or (Z)-1-methyl-2-phenylcyclopropane to identical mixtures of 1-phenyl-2-methylpropene and 1-phenylbut-2-ene, the reactions proceed at different rates. It has been proposed that ring opening and rhodium coordination to C-1 occurs first, followed by hydride migration to form the products.

Fused cyclopropane rings can also be opened. The main product from the reaction between $[RhCl(cod)]_2$ and (Z)-bicyclo[4.1.0]hept-3-ene is 1-methylcyclohexa-1,3-diene.[11] An allylic radical mechanism has been proposed to account



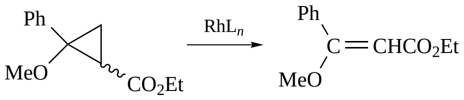
Scheme 3

for the isomerization of 1-cyanobicyclo[1.1.0]butane in the presence of tetraphenylporphyrincobalt(II). The decyclization of the tetradeutero substrate is shown in equation (7), and demonstrates how deuterium migration may occur.



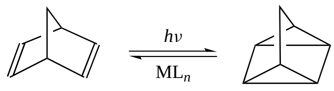
(7)

Trisubstituted cyclopropanes are also catalytically converted to alkenes (equation 8). Rhodium(II) ethanoate or $[RhCl(CO)_2]_2$ catalyze the reaction, but both catalysts form twice as much (E)- as (Z)-isomer.

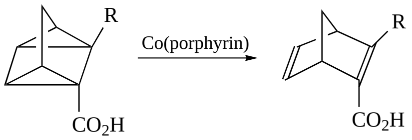


(8)

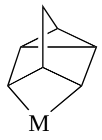
Quadricyclane effectively contains two cyclopropyl rings and it can be converted to bicyclo[2.2.1]hepta-2,5-diene when treated with numerous transition metal complexes (equation 9). The reaction is of current interest as an energy storage system since bicyclo[2.2.1]hepta-2,5-diene can be photolyzed to quadricyclane.[12] The most likely mechanism for the decyclization reaction is initial interaction between the strained cyclopropyl rings and the transition metals' d_{z^2} orbitals followed by formation of the metallocycle (**1**). The isomerizations of heavily substituted quadricyclanes (equation 10) are slow.[13]



(9)

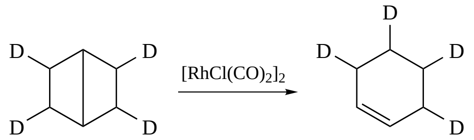


(10)

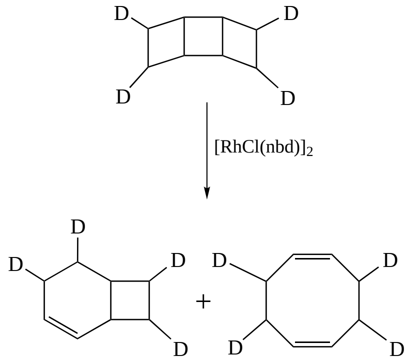


(**1**)

Isolated cyclobutane rings are too stable to undergo catalytic decyclizations. However, bicyclo[2.2.0]hexane and its tetradeutero isotopomer are converted to cyclohexene (equation 11) by catalytic quantities of $[RhCl(CO)_2]_2$. The complex is inserted across the bridge and an intermediate acyl complex can be detected. Unless the reaction is carried out at 5 °C it is not possible to isolate an acyl intermediate in the isomerization of tricyclo[4.2.0.0^{2,5}]octane when the carbonylrhodium(I) complex is used stoichiometrically. The reaction, shown in equation (12), is catalyzed by $[RhCl(nbd)]_2$.



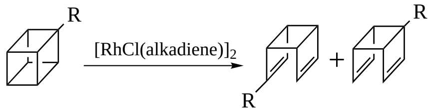
(11)



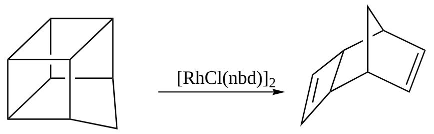
(12)

Fused cyclobutene rings are easily opened. Hexamethyl(Dewar)benzene (HMDB) is thermolyzed to hexamethylbenzene at 100–140 °C, but $[RhCl(HMDB)]_2$ catalyzes the conversion at <70 °C. Since the catalyst itself is stable at 100 °C, it has been suggested that the catalyst is cleaved by excess substrate and that the rate-determining step is the elimination of hexamethylbenzene from $[RhCl(HMDB)_2]$.

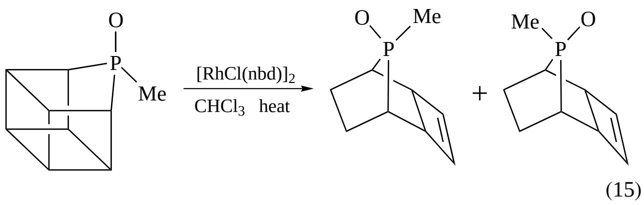
Cubanes are partially decyclized to tricyclooctadienes when allowed to react with catalytic quantities of $[RhCl(LL)]_2$ complexes (LL = cod, nbd). Monosubstituted cubanes form two products, as shown in equation (13). Homocubanes (equation 14) react similarly. If methyloxyphosphahomocubane is decomposed, two isomeric products are obtained (equation 15). *Endo*- and *exo* isomers are obtained from the catalytic isomerization of 9,10-dimethoxycarbonyl bishomocubane (equation 16). Sundry palladium(II) complexes, $AgNO_3$, or $PdCl_2$ form significant quantities of (**2**).



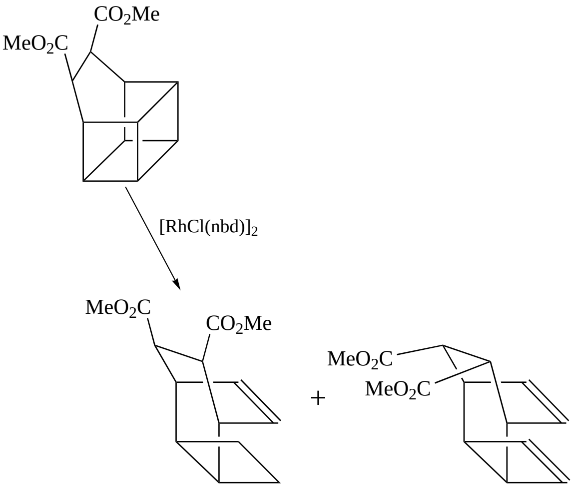
(13)



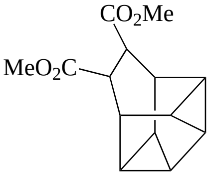
(14)



(15)

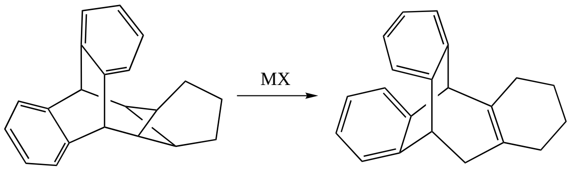


(16)

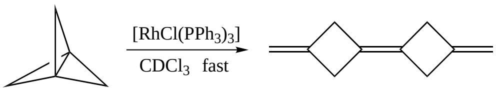


(**2**)

Ring expansion reactions of the type shown in equations (17) and (18), in which a more equitable distribution of carbon atoms between two rings of a polycyclic hydrocarbon is produced, provide the link between the decyclization reactions above and the annulation reactions considered later. It would seem that the greater the strain in the reactant, the larger the number of potential catalysts. The complexes of seven different metals catalyze the reaction shown in equation (17). Of the possible catalysts, only the silver (I) salts bring about any by-product formation.[14] The isomerization of [1.1.1]propellane (equation 18) is catalyzed by $[RhCl(PPh_3)_3]$.[15]



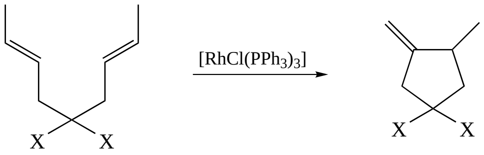
(17)



(18)

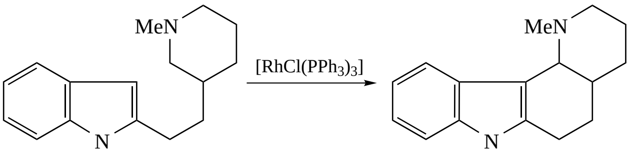
It seems unlikely, on the basis of deuterium-labeling experiments, that a metallocycle is involved in the ring expansion of (1-methylcyclopropyl)methanol catalyzed by $[RhCl(CO)_2]_2$. Further, if the reaction is carried out in the presence of carbon monoxide, no carbonyl group is incorporated in the organic product.

The formation of a cyclic compound from purely alicyclic reagents is relatively rare but it has been achieved in the case of certain diallylic compounds (equation 19). The same catalyst also brings about the conversion of *N*-methyltrihydropyridine compounds to fused ring systems containing *N*-methylperhydroquinoline rings (equation 20).



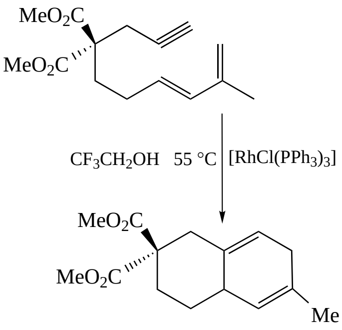
(19)

(X = CO_2Me, CO_2Et, COPh, $^1/_2$(5,5-cyclohexa-1,3-dienyl))

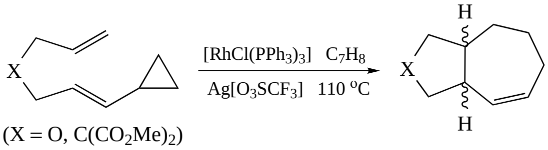


(20)

Suitable α, ω-enynes can be cyclized when allowed to react with catalytic quantities of $[RhCl(PPh_3)_3]$. Alken-2-ynes do not react and the yield is greatly diminished in the case of alk-2-enyne substrates. However, substitution of the alkene bond does not appear to inhibit the dicyclization of dienynes or the cyclization of alkynenones.[16] The dienyne's reaction, shown in equation (21), is catalyzed more effectively by rhodium(I) complexes containing tertiary phosphite ligands. Under similar conditions, trienes can also be cyclized.[17] The cyclopropyl ring can serve as an alkene bond precursor in cyclizations (equation 22).[18]



(21)



(22)

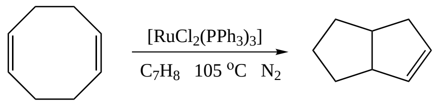
(X = O, $C(CO_2Me)_2$)

The cyclization of pent-4-enals and related compounds to cyclopentanones is catalyzed by $[RhCl(PPh_3)_3]$ in a reaction that involves oxidative addition of the –CHO group to the rhodium(I) catalyst. This reaction has much in common with the decarbonylation that most aldehydes undergo in the presence of this catalyst (*see* ***Decarbonylation Catalysis***).

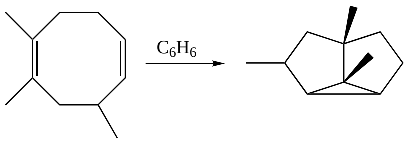
More commonly, side chains can be incorporated in existing rings. Thus 2-propenylazirines can be converted to

pyrroles and pyridines when treated with catalytic quantities of $[Pd(PPh_3)_4]$. The mechanism of the reaction involves an η^3-allylic species that can give rise to either product.[19]

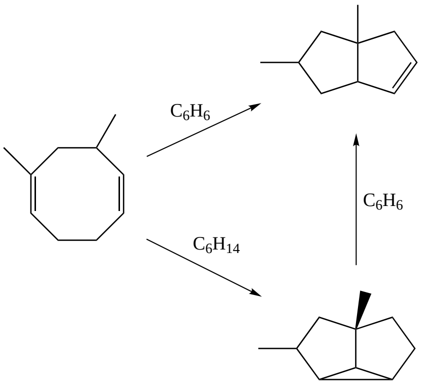
The least common type of isomerization involves transannular reactions of large rings. Cycloocta-1,5-diene forms varying quantities of bicyclo[3.3.0]oct-2-ene when allowed to react with either $[RuCl_2(PPh_3)_3]$ or $[NiBr_2(PPh_3)_2]$ (equation 23). A hydridonickel complex derived from nickel(II) carboxylates and $AlCl_2Et$ gives the best yield. The various dimethylcycloocta-1,5-dienes form methylated bicyclo[3.3.0]oct-2-enes when allowed to react with the nickel catalyst in benzene, but tricyclooctanes are initially formed if the reactions are carried out in hexane (equations 24–26).[20]



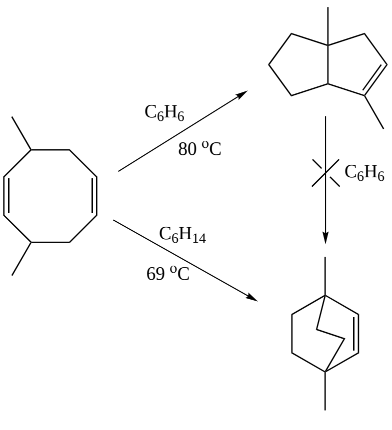
(23)



(24)



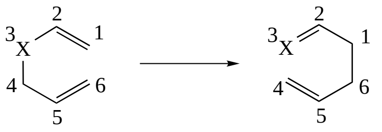
(25)



(26)

2.3 Group Migrations

The most important reactions involving skeletal changes together with substituent group migration are the Cope- and Claisen rearrangements. These are both classified as [3,3]-sigmatropic rearrangements. The two reactions are very similar in nature, as can be seen from equation (27). They are catalyzed by various transition metal complexes and other inorganic species, but can also occur as uncatalyzed thermal rearrangements.



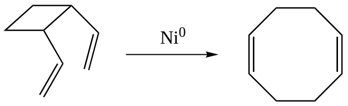
(27)

(Cope X = CH_2; Claisen X = O, N, S)

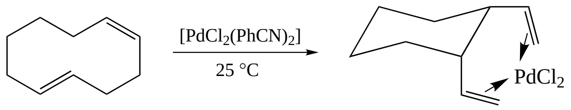
In particular, palladium(II) complexes are capable of greatly increasing the rates of these rearrangements. The selectivity observed in those catalyzed reactions where more than one product can be obtained may differ from that prevailing in the thermal reactions.

The catalyst need not necessarily be a d^8 square-planar complex, since the potential of the catalyzed rearrangement was first revealed by nickel(0) complexes or mercury(II) trifluoroacetate, both d^{10} species. The pioneering work in this area has been the subject of two reviews.[21,22]

The Cope rearrangement takes place with hydrocarbon substrates. Nickel(0) and palladium(II) species were first demonstrated to show opposite effects in the rearrangement, the nickel(0) catalyst being responsible for ring expansion (equation 28) and the palladium(II) complex for ring contraction (equation 29). The reaction shown in equation (29) is catalyzed less effectively by $H_2[PtCl_4]$.



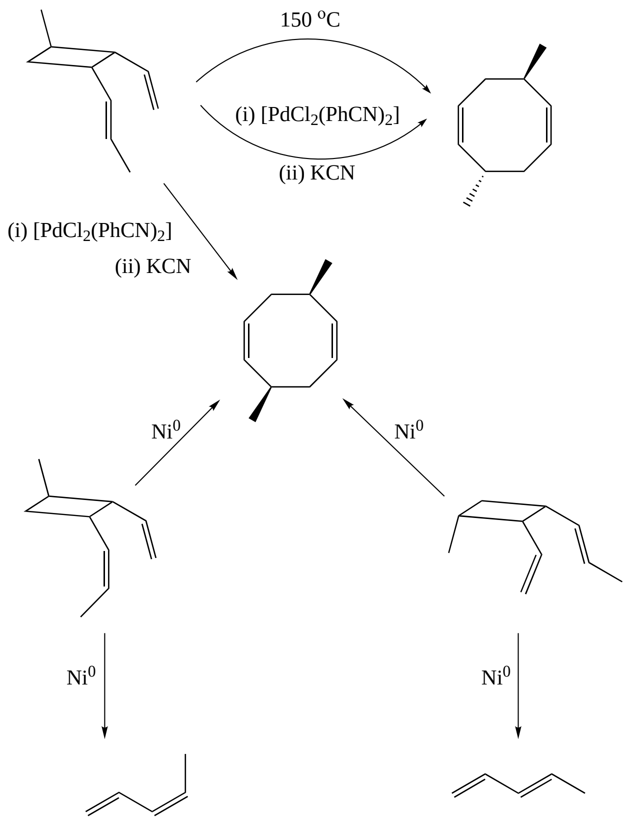
(28)



(29)

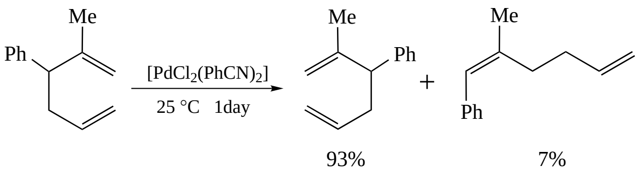
It was later demonstrated that both Ni^0 and Pd^{II} species catalyzed the conversion of 1-methyl-2-vinyl-3-prop-2-enylcyclobutanes to (*E*)-3,7-di-ethylcycloocta-1,5-diene. However, as shown in Scheme 4, $[PdCl_2(PhCN)_2]$ forms an equal quantity of the (*Z*)-isomer, the sole product of the thermal rearrangement. A side reaction in the Ni^0-catalyzed reaction clearly demonstrates the scission of the C–C bond required in the rearrangement, by producing penta-1,3-diene in low yield.

A major practical disadvantage of the palladium-catalyzed rearrangement is the need to disgorge the $PdCl_2$ residue from the product diene by treating it with KCN. Fortunately, as the reaction shown in equation (30) demonstrates, more crowded substrates do not give products containing palladium. The selectivity of this reaction is an improvement over the



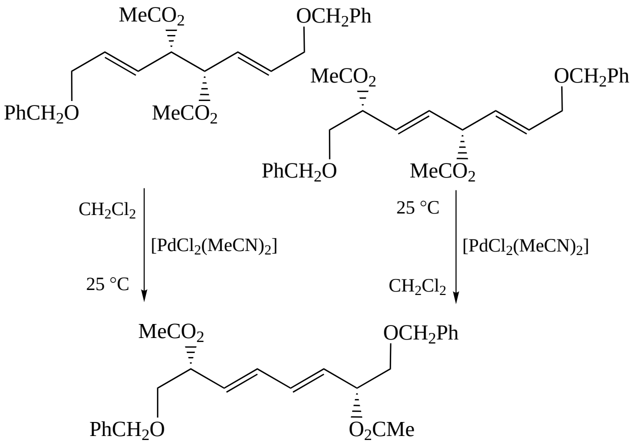
Scheme 4

thermal rearrangement, which, carried out at 180 °C for 13 h, produces the (E)-isomer in 75% yield. Other reactants of this type are isomerized similarly. The retention of configuration during the migrations shown in equation (31) is of great potential importance.[23] Transfer of chirality also occurs in the $[PdCl_2(PhCN)_2]$-catalyzed [1,3]-sigmatropic rearrangements of steroidal allylic side chains. The stereoselectivity shown in equations (32) and (33) arises from the steroid shielding one side of the double bond and requiring the palladium complex to attack from the other.[24]

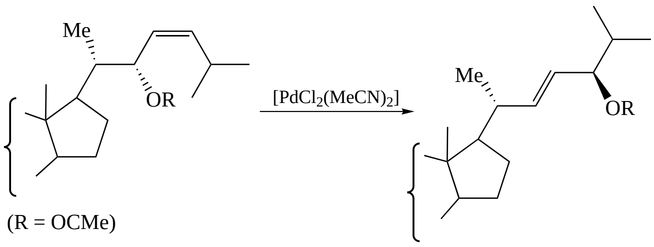


(30)

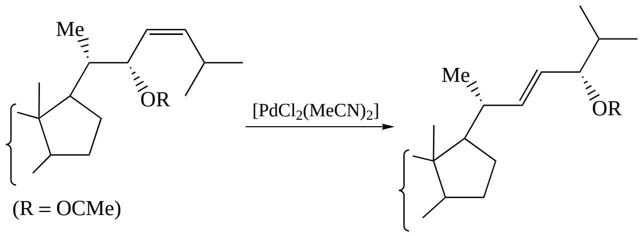
Unfortunately, more heavily substituted hexadienes than those shown in equation (30) do not undergo the rearrangement, presumably because they have very low binding constants with catalytic palladium(II) species. Nevertheless, the Claisen rearrangement of allyl vinyl ethers can only take place provided palladium coordination to the vinyl group is prevented by alkyl substituents.[25]



(31)



(32)

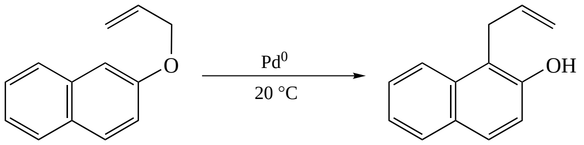


(33)

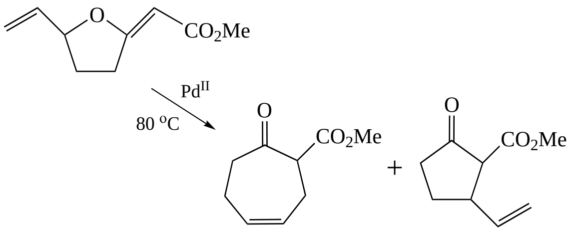
Potentially, the Claisen rearrangement is of greater synthetic utility merely because it is not confined to hydrocarbon substrates. However, no palladium-catalyzed thio-Claisen rearrangements have been observed, possibly owing to sulfur poisoning the catalysts. Nevertheless, thioimidates have been rearranged in the presence of catalytic quantities of $[PdCl_2(PhCN)_2]$.

Although rhodium(I) and ruthenium(II) complexes have been widely used to isomerize allyl ethers to prop-2-enyl ethers (see Sect. 2.1), an ill-defined $[Pt(PPh_3)_n]$ complex brings about the Claisen rearrangement of the naphthyl ether, shown in equation (34). The cleavage of the allyl group required in the reaction was believed to yield allylplatinum cations and aryloxy anions. An interesting variant of the reaction is shown in equation (35). The products are formed in approximately equal yields and the cyclopentanone results from a [1,3]-rearrangement. At 140 °C, $M_2[PtCl_6]$ (M = H, Na) brings about the rearrangement of 2-allyloxypyridine (equation 36). The thermal rearrangement gave low yields of

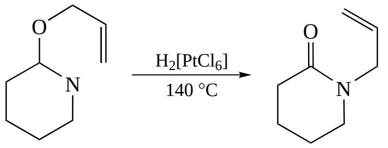
several products.



(34)



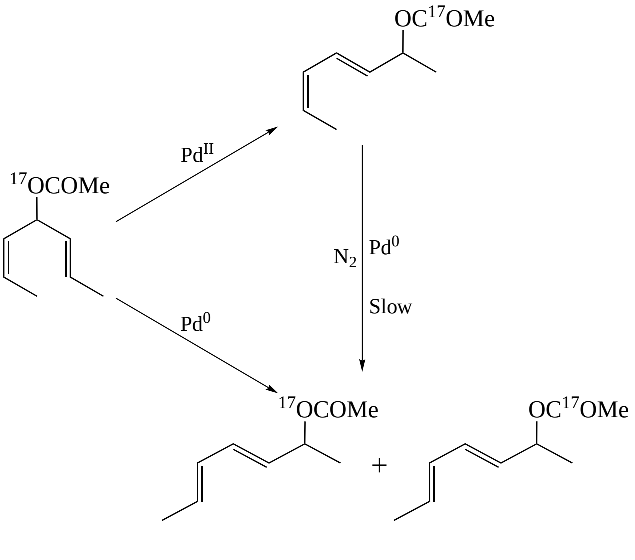
(35)



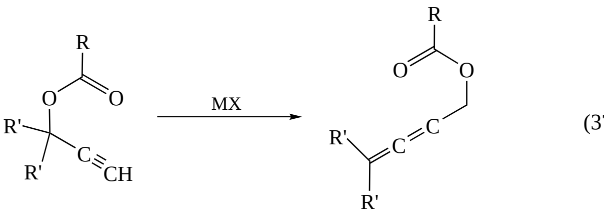
(36)

Palladium(II) complexes also catalyzed the rearrangements of allylic esters. However, as illustrated in Scheme 5, when palladium(0) complexes are used the stereochemical course of the rearrangement is different. It should be noted that the palladium(II)-catalyzed rearrangement occurs preferentially at the (E)-disubstituted double bonds. Again, the selectivity of the palladium(II) complex arises from it forming σ-bonded intermediates.[26]

Alkynyl esters are isomerized by silver(I) or copper(I) compounds in another [3,3]-sigmatropic rearrangement although the reaction is not of wide synthetic application. Copper(I) chloride requires harsher conditions than $AgBF_4$ to effect the transformation shown in equation (37).



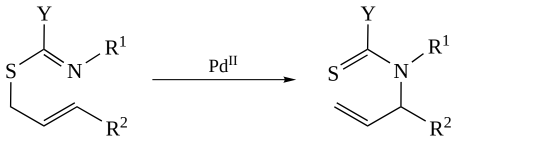
Scheme 5



(37)

($MX = AgBF_4$, $R = 4\text{-}C_6H_4NO_2$, R' = Et; MX = CuCl, R = R' = Me)

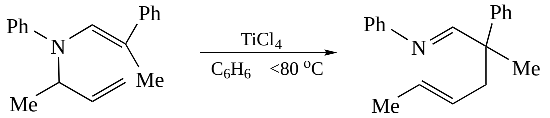
Palladium(II) complexes appear to be the only metal complexes capable of catalyzing the rearrangements of sulfur–nitrogen or sulfur–oxygen substrates. A very similar reaction takes place with both *S*-allyl thioimidates and *S*-allyl iminothiocarbonates (equation 38). In the latter case, low yields are obtained if there is no substituent on the allyl group (i.e. $R^2 = H$).



(38)

(Y = Ph, $R^1 = R^2 = Me$; Y = OR, $R^1 = H$, R^2 = H, Me, Ph, Bz)

Although most catalysts for the various rearrangements are complexes of the late transition metals, $TiCl_4$ catalyzes the amino-Claisen rearrangement shown in equation (39). In this case, the thermal rearrangement gives identical product yields.



(39)

3 HYDROGENATION OF ALKENES

3.1 Introduction

The ability of finely divided late transition metals to catalyze the heterogeneous hydrogenation of alkenes to alkanes has long been known and there are many industrial and laboratory applications of this reaction. However, the knowledge of the mechanism does not fully reflect the extensive efforts made in studying the reaction. The heterogeneity of the reaction debars many of today's powerful instrumental techniques commonly used to investigate reaction mechanisms. Additionally, it is apparent that there are several side reactions occurring during heterogeneous hydrogenation. Isomerization and isotope exchange in particular make study of the hydrogenation reaction difficult.

Homogeneous catalysts do not suffer from these disadvantages and are much more amenable to study. However, not every late transition metal complex can function as a homogeneous hydrogenation catalyst. In order to exhibit catalytic activity, the complex must possess certain properties. First, the complex must not be reduced to the metal by hydrogen. The earliest attempts to bring about the homogeneous hydrogenation of alkenes, by mixing a transition metal complex, hydrogen, and alkene, were unsuccessful because the systems soon became heterogeneous as the result of metal formation.

Second, the catalytic complex must form a labile-alkene complex. If no alkene complex is formed then the metal complex cannot transfer hydrogen to the alkene. A very stable alkene complex is also disadvantageous since an essential property of catalytic species is their lability.

A third factor, often overlooked but of great practical importance, is sufficient solubility of the catalyst in organic solvents, since alkenes and the majority of their derivatives are insoluble in water. This requirement disqualifies most classical complexes from acting as hydrogenation catalysts.

These requirements are fulfilled by certain tertiary phosphine complexes of the late transition metals, such as $[RhCl(PPh_3)_3]$, $[RuCl_2(PPh_3)_3]$, and $[RhH(CO)(PPh_3)_3]$. Steric crowding induces one of the large triphenylphosphine ligands to dissociate and its place in the coordination sphere can be occupied by an alkene ligand. Dissociation of an acido ligand can also provide a vacant coordination site for alkene coordination. The loss of the perchlorato ligand from $[Rh(OClO_3)(CO)(PPh_3)_2]$ when dissolved in unsaturated dinitriles allows hydrogenation of the solvents to occur.[27]

It will also be noticed that all the above catalysts contain second transition series metals. Generally, the slower reactions of the third transition series elements are not normally conducive to catalytic efficiency, although some very active iridium catalysts are now known. First transition series metals seldom form stable, lower oxidation state tertiary phosphine complexes.

Although all homogeneous hydrogenation catalysts have the above properties in common, four different mechanisms of catalytic hydrogenation have been identified to date. The radical mechanism does not necessarily involve metal–carbon bonds and thus differs from the remaining three mechanisms. The latter mechanisms take their names from the way the catalyst activates dihydrogen. In the first, the catalytic complex activates dihydrogen and participates in the dihydride route. The alkene complex performs this task in the second and hydrogenation is said to occur via the alkene route. Monohydrido catalysts usually follow the alkyl route in which the alkyl intermediate activates dihydrogen. All these mechanisms will be discussed in more detail below. It is often difficult to determine the mechanisms of the reactions, particularly in the case of the dihydride and alkene routes, which share a common intermediate. Many workers have disregarded James' observation that the form of the rate equation is independent of the mechanism.[28] Indeed, the rate equation is similar to that found in Michaelis–Menten enzyme reactions.

3.2 Activation of Reactants

It was quickly realized that both the hydrogenation of alkenes and the reduction of the complex to the metal were brought about by hydrido species. It was therefore essential that the catalysts should be resistant to the autoreduction reaction. At the time of this discovery, many stable hydrido complexes containing π-acid ligands, such as tertiary phosphines, were being isolated, so the search for homogeneous catalysts concentrated on these.

Unfortunately, many of these complexes do not react with hydrogen and therefore cannot act as hydrogenation catalysts. The complexes that did react with hydrogen were usually low oxidation state complexes. The tertiary phosphine ligands also stabilized these low oxidation states and could often be used as the reducing agents in their formation from higher-valent metal salts.

It is now believed that dihydrogen initially adds to many transition metal complexes in the form of a σ-complex. The bond between the hydrogen atoms is broken upon addition to the transition metal complex and homogeneous hydrogenation catalysts can equilibrate mixtures of ortho- and parahydrogen.

The principal modes of conversion to hydrido complexes,[29] oxidative addition, homolysis, and heterolysis, are shown in equations (40–42), respectively. Oxidative addition of hydrogen to a transition metal complex at some stage in the catalytic cycle is essential to its activity. This requires that the metal has two accessible oxidation states corresponding to d^n and d^{n-2} electronic configurations or d^n and d^{n-1} for dinuclear oxidative addition. Hence, only those metals whose complexes meet this criterion may act as catalysts.

$$[Rh^{I}Cl(PPh_3)_3] + H_2 \longrightarrow [Rh^{III}H_2Cl(PPh_3)_3] \quad (40)$$

$$[Ru^{II}Cl_2(PPh_3)_3] + H_2 + NEt_3 \longrightarrow [Ru^{II}HCl(PPh_3)_3] + [NHEt_3]Cl \quad (41)$$

$$[Co(CO)_8] + H_2 \rightleftharpoons 2[CoH(CO)_4] \quad (42)$$

Alkene activation is synonymous with coordination. Alkenes normally have low-binding constants, and they do not readily displace other ligands from the coordination sphere. It has been found that the sterically driven dissociation of bulky tertiary phosphine ligands to form coordinatively unsaturated complexes allows alkenes to enter the coordination sphere. Alkenes with large substituents or the less favorable trans stereochemistry at the double bond bind less well. This can be used to advantage, since hydrogenation of the more sterically favored double bond will occur. The electronically favored double bond is preferentially hydrogenated in heterogeneous catalysis.

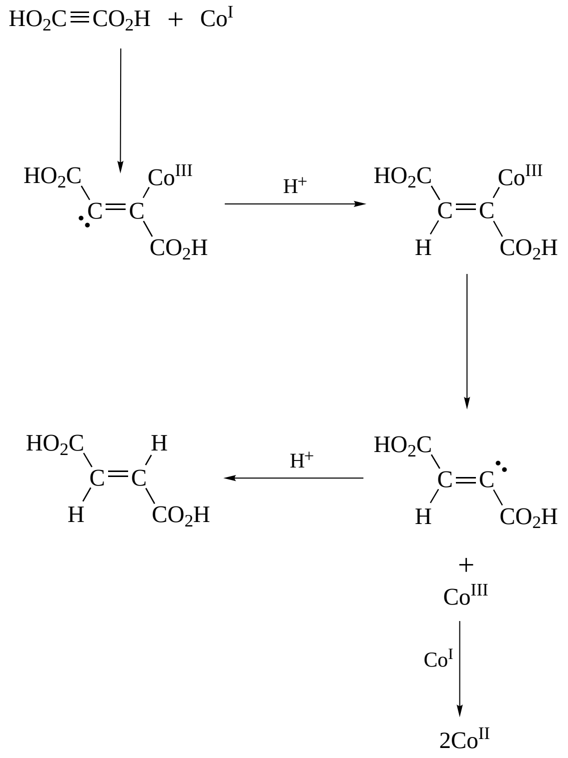
Paradoxically, alkenes with high-binding constants are often unsuitable substrates in homogeneous catalytic hydrogenation. This is particularly the case with chelating alkadienes, which occupy two coordination sites and thereby form complexes unable to activate dihydrogen. This may arise either from the alkadiene complex being coordinatively saturated or, because of the π-acidity of the alkadiene ligand, it may have electronic origins. Sometimes this increased π-acidity may be beneficial in preventing reduction of the metal. For example, in the $PdCl_2$-catalyzed reduction of methyl sorbate, palladium is not precipitated until all the diene has been reduced. Even when diene complexes do bind H_2, the inability of the diene to undergo face rotation can prevent them achieving the coplanar M(C=C)H arrangement required for insertion.

3.3 Radical Hydrogenation of Alkenes

This is the least common and least important mechanism of alkene hydrogenation. There have been very few unambiguous demonstrations of this mechanism. Experiments purporting to show that hydrogenation has been inhibited by the addition of a radical scavenger have frequently ignored the fact that these scavengers are often excellent ligands that poison the catalysts used by occupying a coordination site required in one of the more common mechanisms discussed in Sections 3.4–3.6.

In the hydrogenation of α-cyclopropylstyrene by various monohydridocarbonyl complexes, a radical mechanism has been proposed to account for the opening of the cyclopropyl ring in one of the competing reactions. The organic radicals can be trapped by [Co^{II}(dmgH)(PBu_3)], but more conventional radical scavengers react preferentially with the hydrido complexes present.[30]

A second example of an undoubted radical mechanism occurs during the vitamin B_{12s} reduction of either (E)- or (Z)-butendioic acid in aqueous solution. However, the point is better illustrated by the reduction of butyndioic acid[31] to (E)-butendioic acid by two molecules of vitamin B_{12s}. This cobalt (I) species is oxidized to vitamin B_{12r} which contains cobalt (II). The course of the reaction is shown in Scheme 6. The formation of the (E)-alkene is strongly indicative of a radical process since more conventional homogeneous catalysts invariably form (Z) products (see below).



Scheme 6

3.4 The Dihydride Route

By contrast with the radical systems, this mechanism is the most common and most studied. It is also historically important for giving the first practical demonstration of catalytic homogeneous hydrogenation of alkenes.

The most important catalyst in this class is Wilkinson's Catalyst, chlorotris(triphenylphosphine)rhodium(I).[1] The catalytic cycle of this complex is shown in Scheme 7. The basic catalytic cycle is very simple, but parasitic side reactions make its study more difficult.

The key component of the catalytic cycle is the intermediate $RhCl(PPh_3)_2$. This highly reactive, 14-electron species can undergo three possible reactions. The least productive of these is dimerization to $[RhCl(PPh_3)_2]_2$. The dimer is catalytically inactive, but can be formed near the end of batch hydrogenations when the concentrations of the remaining alkene and hydrogen are low. The monomer may also react reversibly with the alkene present to form a 16-electron alkene complex, [$RhCl(PPh_3)_2$(alkene)]. Theoretically, there is no reason why this alkene complex should not undergo oxidative addition of dihydrogen to form the rhodium(III) intermediate, [$RhH_2Cl(PPh_3)_2$(alkene)]. However, it will be shown below that this is very unlikely. Consequently the only productive path that the tricoordinate species can follow is the oxidative addition of dihydrogen to form [RhH_2Cl-$(PPh_3)_2$]. The fluxional, dihydridorhodium(III) complex, being coordinatively unsaturated, takes up a molecule of alkene to form [$RhH_2Cl(PPh_3)_2$(alkene)] in what appears to be the rate-determining step of the catalytic cycle. Molecular modeling has shown that only those species in which the alkene is coordinated cis- to two cis-hydrido ligands can undergo successive hydrido ligand transfer to the alkene.[32] An alkyl complex is first formed and reductive elimination of the alkane takes place once the second hydrido ligand is transferred.

The actual course of events is more complicated than the simple resumé of the catalytic cycle given above. First, there is the competition between alkene and dihydrogen for the

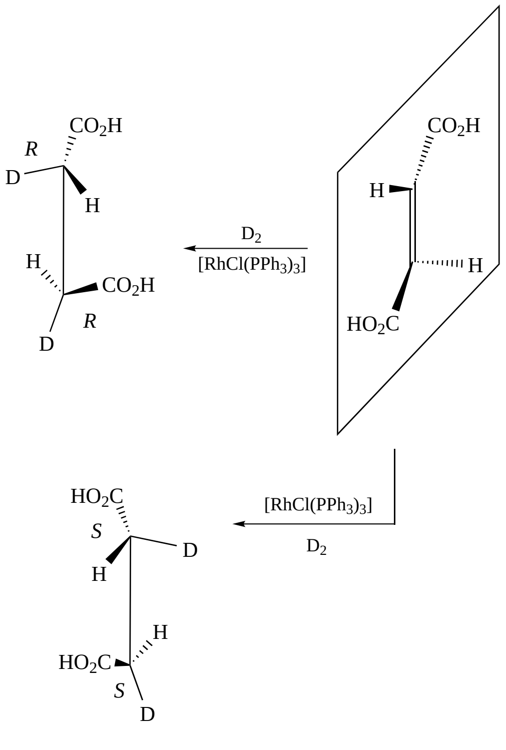
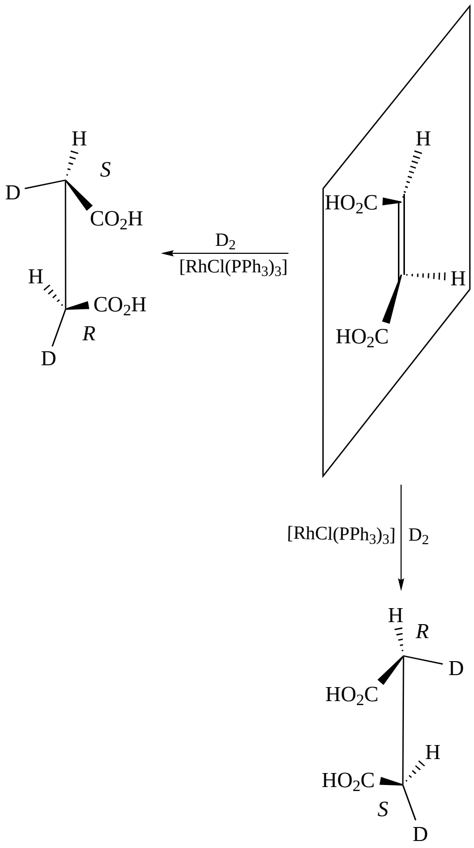
Scheme 7

intermediate $RhCl(PPh_3)_2$. It can be demonstrated that there are two reasons why the catalytic cycle proceeds slowly. The rate of alkane formation may be slow because of the alkene's unfavorable geometry, or because the concentration of the dihydrido species is low. The first possibility is exemplified by the difficulty of coordinating (*E*)-1,2-diphenylethene to rhodium. The second occurs when the alkene has a very high binding constant. Ethylene reacts rapidly with the preformed dihydrido complex to form ethane, but, under the competitive conditions of the catalytic cycle, the reaction soon ceases. It is not possible to form ethane by adding dihydrogen to the ethylene complex $[RhCl(PPh_3)_2(C_2H_4)]$ in equilibrium with dissolved ethylene. Effectively ethylene poisons its own reduction just as it does in heterogeneous systems employing copper metal catalysts. This is because the ethylene complex is incapable of activating dihydrogen. The attack of ethylene upon $[RhH_2Cl(PPh_3)_2]$ shows that the common intermediate $[RhH_2Cl(PPh_3)_2(C_2H_4)]$ can be formed and that transfer of hydrogen to ethylene can occur. The poisoning of the system by ethylene can also be demonstrated by adding ethylene during the reduction of cyclohexene. The addition of ethylene stops the reaction, whereas the addition of (*E*)-1,2-diphenylethylene (which coordinates to rhodium only with difficulty) has no effect upon the rate of formation of cyclohexane.

The stereochemistry of the addition has been shown to be cis. This can be demonstrated by the deuteration of (*E*)- or (*Z*)-butendioic acids to form (*R*,*R*)- and (*S*,*S*)-2,3-dideuterobutandioic acid or (*R*,*S*)-2,3-dideuterobutandioic acid, respectively (equations 43 and 44). The deuteration of other (*E*)-alkenes to *threo*-alkanes and (*Z*)-alkenes to *erythro* products also demonstrates that cis addition occurs.

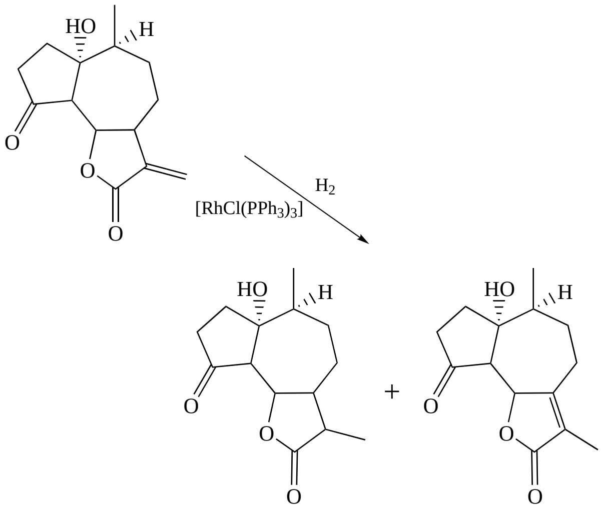


(43)



(44)

It was once thought that the exclusively cis addition was a consequence of the simultaneous addition of both hydrogen atoms. However, it has since been demonstrated that the hydrido ligands are transferred successively to the alkene and that a relatively long-lived intermediate alkyl complex is formed. The best evidence for the participation of the alkyl complex comes from hydroisomerization side reactions (equation 45), and the scrambled addition of deuterium to medium-sized cycloalkenes.[33]



(45)

If more than two deuterium atoms are added to cyclooctene, then isotope exchange must have taken place, and if more than four atoms of deuterium are added, then double-bond migration must also have occurred. The incorporation of excess deuterium can readily be explained by the participation of intermediate alkyl complexes that undergo β−hydride abstraction reactions.

Normally [RhCl(PPh$_3$)$_3$] is a very good deuteration catalyst, giving little scrambled or polydeuteration. It is far superior to heterogeneous catalysts in this respect and has been used to tritiate alkenes at the double bond.

Alk-1-ene substrates can form either 1-alkyl or 2-alkyl complexes, the latter as a result of Markovnikov addition. The 2-alkyl complexes are less stable than the 1-alkyl complexes because they are more sterically hindered. As a consequence, they undergo β-hydride abstraction reactions more readily and are more likely to give polydeuterated products. Changing the chloro ligand for the larger iodo ligand ensures that alk-1-enes are more likely to form 1-alkyl intermediates and form dideuteroalkenes. However, when cyclic or internal alkenes, which must form secondary alkyl intermediates, undergo deuteration, the chloro complex should be used to lessen the steric hindrance in the intermediate alkyl complex.

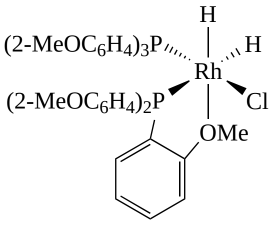
The stability of the intermediate alkyl also depends upon the neutral ligands present. Its stability can be increased by using P(4-C$_6$H$_4$F)$_3$ ligands in place of triphenylphosphine. These reduce the electron density on rhodium and make β-hydride abstraction reactions less likely to occur.

Another of the major advantages of homogeneous catalytic hydrogenation is the facility to hydrogenate molecules containing other multiple interatomic bonds exclusively at the site of the C=C bond. Heterogeneous catalysts usually hydrogenate all the multiple bonds present. They are thus unsuitable for the catalytic hydrogenation of alkenals, nitroalkenes, or unsaturated nitriles.

The accessibility and effectiveness of [RhCl(PPh$_3$)$_3$] has done little to encourage the employment of other dihydride route catalysts except for directed and enantioselective hydrogenation and reactions with very hindered substrates where [RhCl(PPh$_3$)$_3$] is not successful and cationic iridium- and rhodium catalysts are used. Replacement of the chloro ligand by a heavier halide increases the rate of hydrogenation. Homologous complexes can be prepared from [RhCl(C$_2$H$_4$)$_2$]$_2$ and triarylphosphines. Those ligands containing electron-donating substituents increase the rate of hydrogenation, while the converse is true for those neutral ligands containing electron-withdrawing groups.

The stereochemistry of the neutral ligand also affects the properties of the catalyst. Although [RhCl{P(2-C$_6$H$_4$OMe)$_3$}$_3$] initially reduces alkenes rapidly, the reaction ceases before all the alkene has been consumed because of the formation of the coordinatively saturated complex (**3**).

Nevertheless, replacing triarylphosphines by trialkylphosphines destroys the catalytic properties of the complex, since



(**3**)

the resulting [RhH$_2$Cl(PR$_3$)$_3$] complex is coordinatively saturated and cannot activate the alkene. The greater stability of dihydridoiridium(III) complexes means that [IrCl(PPh$_3$)$_3$] fails to show the activity of its rhodium analog.

Biologically important substrates can be hydrogenated in aqueous solution by using sulfonated triarylphosphine ligands that confer water solubility upon the catalyst.[34] However, it was later reported that rhodium metal was formed from these complexes in the presence of hydrogen. It was claimed that the role of the ligands is merely to prevent aggregation of the rhodium colloid produced.[35]

Several *cis*-dihydridoruthenium(II) complexes of general formula [RuH$_2$L$_4$] have been claimed to follow the dihydride route merely because of their stoichiometry. Since these complexes are coordinatively saturated, they must lose the neutral ligand trans to a hydrido ligand to allow alkene coordination to take place. This would then allow the formation of an alkyl complex since the alkene would be coordinated cis to the second hydride. Since both alkene isomerization and H/D exchange can be observed in the system, the alkyl complex must have a long lifetime.[36]

More active catalytic systems in which a significant degree of hydroisomerization is observed are those employing [IrH$_5$(PR$_3$)$_2$] (which may be lower-valent iridium species containing σ-bound H$_2$) or [(cod)IrL$_2$]BF$_4$ complexes. The hydroisomerization may arise from the minimal steric constraints present, which allow 2-alkyl intermediates to be formed. The low-steric demands imposed by the catalyst have been exploited in the hydrogenation of the substituted alkenes 1-methylcyclohexene and 2,3-dimethylbut-2-ene. The hydrogenations of these substrates are very slow when other homogeneous catalysts are employed.[37]

3.5 The Alkene Route

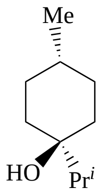
The first catalysts to be shown to follow the alkene route were the cationic [Rh(PPh$_3$)$_2$(diene)]ClO$_4$ complexes.[38] These complexes, unlike their neutral [RhCl(PPh$_3$)(diene)] counterparts, can activate dihydrogen in solution. However, the diene complexes are converted into the true catalysts when allowed to react with hydrogen. The diene is converted to alkene in a stoichiometric reaction that must follow the alkene route. The highly coordinatively unsaturated [Rh(PPh$_3$)$_2$(solvent)$_2$]$^+$ complex can then react with either

alkene or dihydrogen and follow the alkene or dihydride route, respectively. There is considerable evidence for the belief that both hydrogenation routes may be followed simultaneously. The alkene route is shown in Scheme 8.

The predominant route depends upon the nature of the substrate. Nonchelating substrates probably follow the dihydride route, but dienes or alkenes containing a substituent group capable of chelating to rhodium may follow the alkene route.

The iridium complex $[Ir(cod)PCy_3(py)]PF_6$ is a remarkably active and selective hydrogenation catalyst for the reduction of terpinen-4-ol. The trisubstituted alkene bond is very rapidly reduced and the addition of hydrogen occurs to the more shielded face of the alkene to form (**4**) at least 1000 times more rapidly than its stereoisomer, the weakly preferred product in heterogeneous catalysis. The tricyclohexylphosphineiridium(I) catalyst is also more active than $[Ir(cod)(PPh_3)_2]^+$ or the rhodium analog of the latter.[39] High selectivity has also been observed with other cyclohexenol substrates.[40]

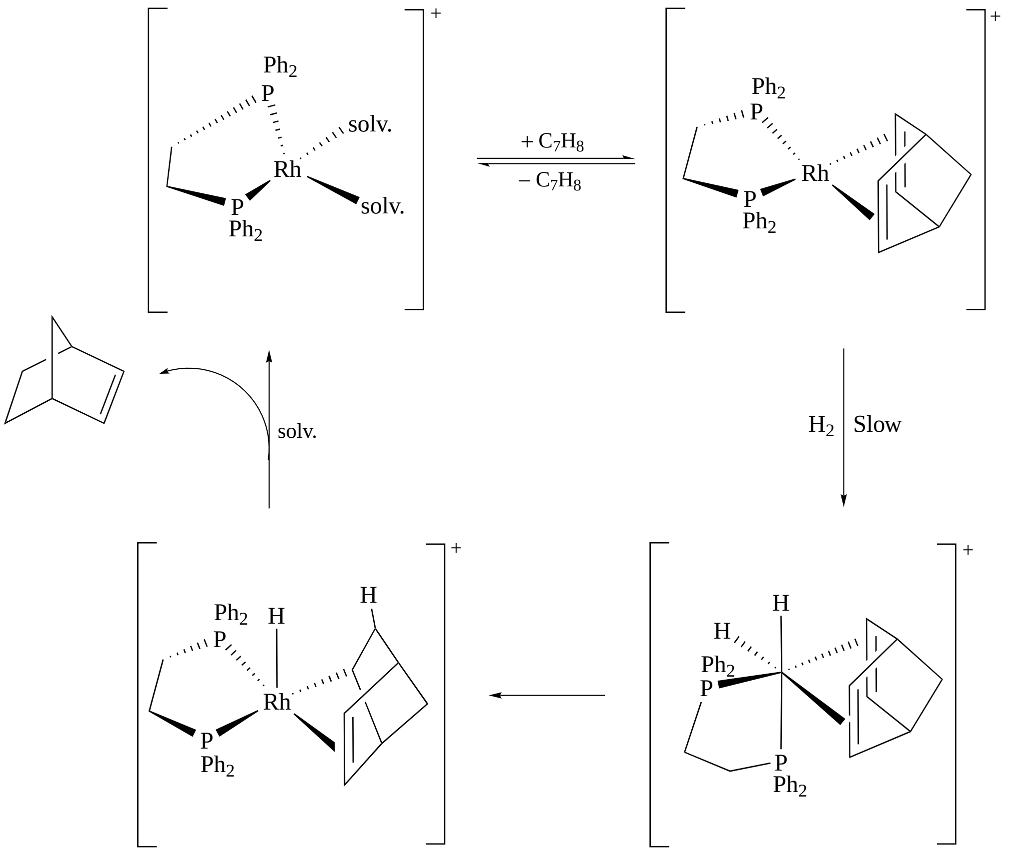
The two tertiary phosphine ligands may be replaced by a chelating ditertiary phosphine. The greatest application of the alkene route comes in asymmetric synthesis when chiral, ditertiary phosphine ligands are used. This topic is discussed more fully in (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***).



(**4**)

3.6 The Alkyl Route

Chlorohydridotris(triphenylphosphine)ruthenium(II) was the first complex in which homogeneous hydrogenation of alkenes was shown to follow the alkyl route.[41] It can be prepared from dihydrogen and $[RuCl_2(PPh_3)_3]$ in the presence of base (equation 41). Most other alkyl route catalysts are also monohydrido complexes. They are usually specific for terminal alkenes. The behavior of several *exo*-*nido*-dicarbaborane complexes of rhodium has been reviewed.[42]

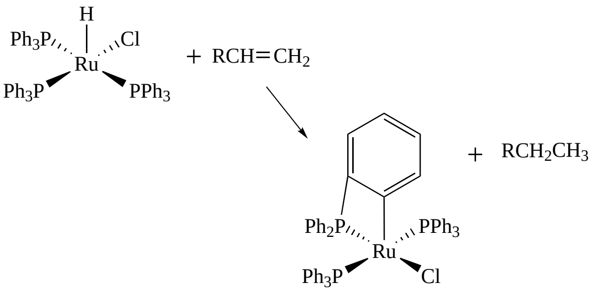


Scheme 8

During deuteration reactions, considerable isotope exchange and a little isomerization are observed. All these properties are characteristic of a catalytic cycle involving a relatively long lived alkyl complex.

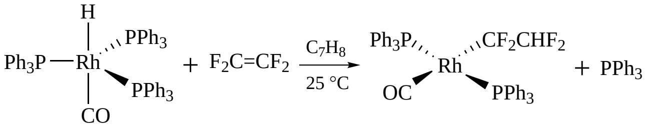
In the catalytic cycle shown in Scheme 9, the rate-determining step is the oxidative addition of dihydrogen to the 1-alkyl complex. σ-Bond metathesis is an alternative pathway for hydrogenolysis of the metal alkyl. Any 2-alkyl complexes that may be formed by the Markovnikov addition of the hydrido ligand to the alkene are unstable and are very likely to decompose before the slow oxidative addition of dihydrogen and the transfer of a second hydrido ligand can occur. Their instability has steric origins, and consequently this type of catalyst exhibits high selectivity towards terminal alkenes since internal alkenes must form unstable secondary alkyl complexes.

The ruthenium complex is such an exceedingly active catalyst that, at higher catalyst concentrations, orthometalation of the catalyst by the alkene present may occur if local hydrogen starvation is encountered. (equation 46).

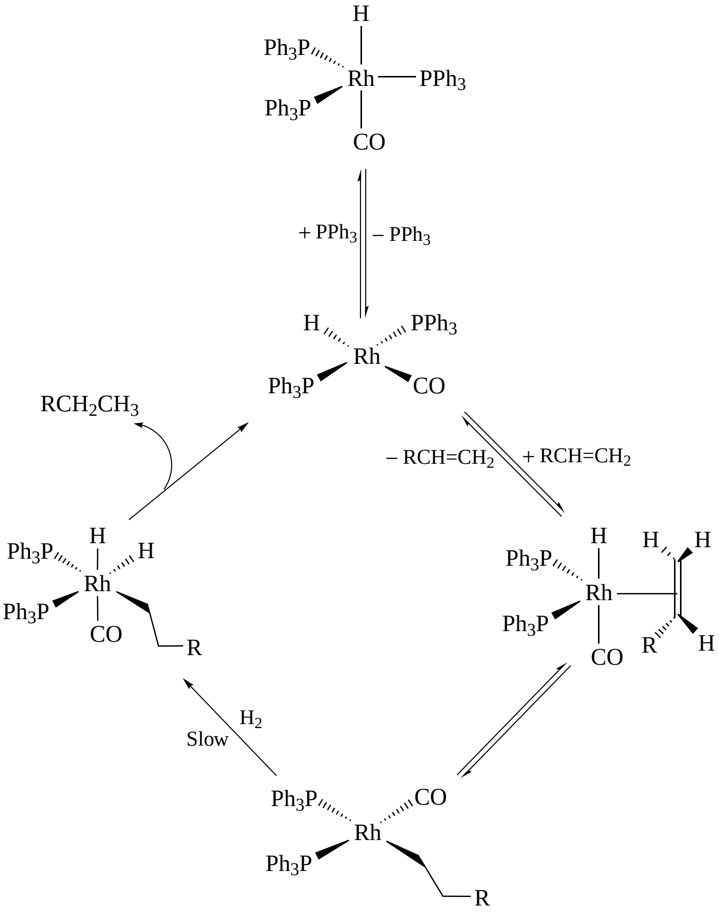


(46)

Accordingly the less active, but more amenable, complex $[RhH(CO)(PPh_3)_3]$ is usually selected to exemplify hydrogenation by the alkyl route.[3] One of the great advantages of this system has been the isolation of several intermediates in the catalytic cycle from stoichiometric reactions. The two principal reactions are shown in equations (47) and (48).

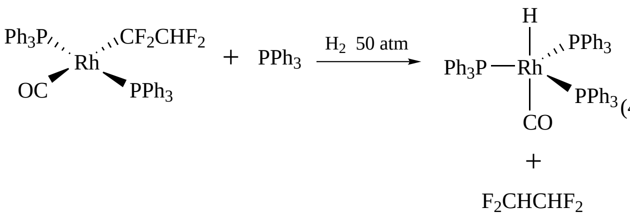


(47)



Scheme 9

It was noted above that the crowded alkyl complex was the source of the regioselectivity exhibited by this class of catalyst. However, at lower catalyst concentrations or higher hydrogen pressures the catalyst is much less selective. In the latter case, the higher concentration of hydrogen results in a 2-alkyl complex being hydrogenated before decomposition. In the former case, a second triphenylphosphine ligand can be lost and the relaxation of steric constraints allows more stable, possibly solvated, [Rh(CO)(2-alkyl)(PPh_3)] complexes to be formed.



(48)

For example, at 50 °C and under 10 atm pressure, cyclohexene can be hydrogenated to cyclohexane. The reaction proceeds if the catalyst concentration is less than 0.75 mM, and shows an inverse dependence upon catalyst concentration down to 0.25 mM. This behavior indicates the importance of triphenylphosphine dissociation. Removing one PCy_3 ligand by acidification from the similar ruthenium catalyst [RuHCl(CO)(PCy_3)$_2$] brings about a decrease in selectivity and an increase in hydrogenation rates. This catalyst also brings about hydroisomerization since the pentacoordinate intermediate [RuCl(alkyl)(CO)(PCy_3)$_2$] must lose a PCy_3 ligand before activating H_2.[43]

Two acetatoruthenium catalysts have been shown to form alkyl complexes when allowed to react with alkene and hydrogen. However, a second molecule of hydrogen is not responsible for converting the alkyl complex to alkene. Instead, the alkyl complexes are decomposed by a proton from the carboxylic acid solvents.[44]

3.7 Alkyne Hydrogenation

Alkyne hydrogenation remains a largely forgotten area of homogeneous catalytic hydrogenation. There are clear commercial benefits to be obtained in the conversion of alkynes to alkenes; however, homogeneous catalysts are not usually sufficiently selective towards the alkene intermediate.

There seems no reason why any of the mechanisms discussed in Sections 3.4–3.6 cannot function in the conversion of alkynes to alkenes. The alkene route of hydrogenation is frequently encountered because alkynes complex more strongly to transition metals than alkenes and their complexes are formed preferentially in competition with the oxidative addition of dihydrogen. Internal alkynes coordinate to bis(arylimino)acenaphthene complexes of palladium and the tricoordinate species activate molecular hydrogen. Transfer of both atoms of hydrogen forms a Z–alkene complex that is decomposed by a second molecule of internal alkyne to restart the catalytic cycle.[45]

Unfortunately, several complexes, capable of catalyzing the hydrogenation of alkenes by the dihydride route, fail to hydrogenate alkynes since they form alkyne complexes that are incapable of activating dihydrogen. Hex-2-yne coordinates to [RhH_2(nbd)($PPhMe_2$)]$^+$ cations more readily than hex-1-yne and is more selectively reduced to Z-hex-2-ene as a consequence.[38]

Some catalysts suffer a different type of alkyne poisoning. Chlorotris(triphenylphosphine)rhodium(I) is an effective terminal alkyne polymerization catalyst.[1] When this complex is used in the reduction of these alkynes, it gradually loses its activity because of the competing polymerization reaction. Even initially the rate of alkyne hydrogenation is much slower than that of the corresponding alkene because of the greater binding constant of the former substrate.

Addition of alkyne to [RuHCl(PPh_3)$_3$] brings about a color change, presumably due to formation of a vinyl complex. These undergo hydrogenolysis and form alkenes. Normally the alkenes are reduced more rapidly than the alkyne and the selectivity of the method is low. However, although some internal alkynes are hydrogenated to alkanes, sterolic acid is reduced to oleic acid. The formation of the (Z)-alkenoic acid shows that the addition of hydrogen to the alkene is cis.

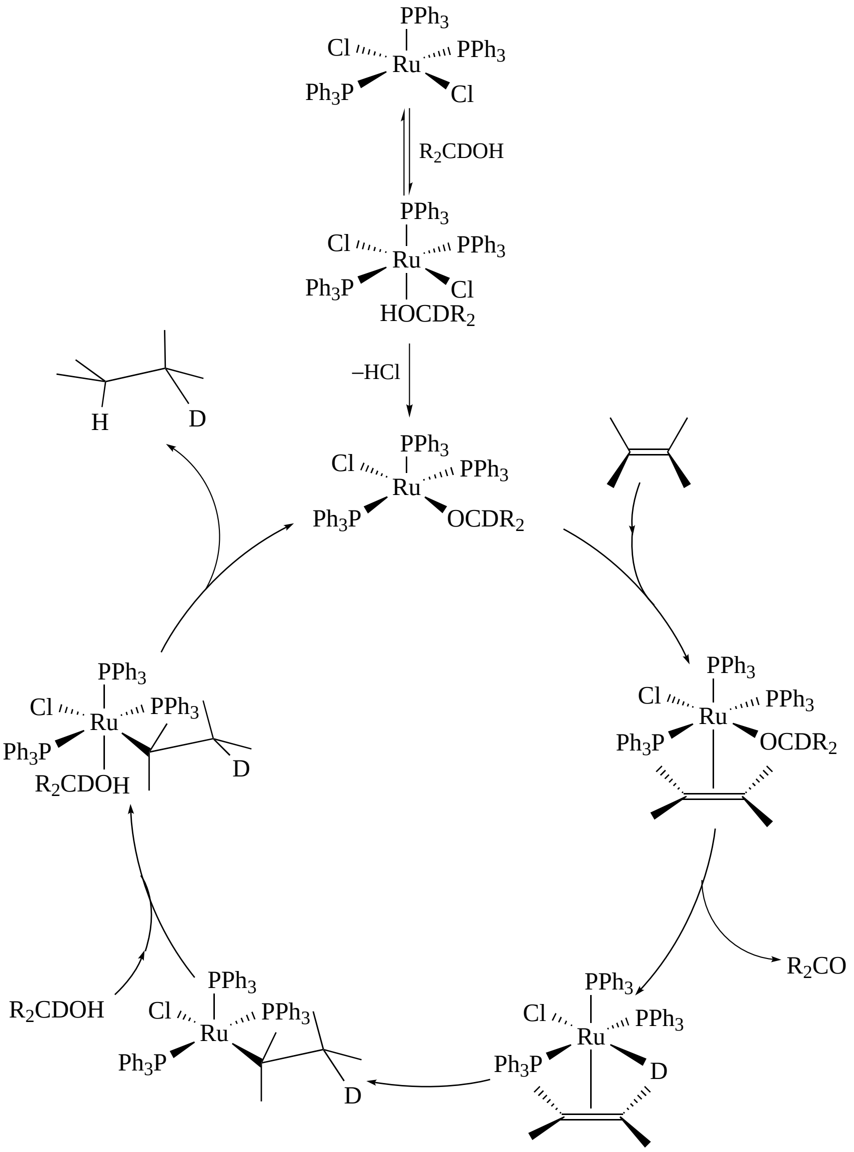
Most catalysts also bring about the cis addition of hydrogen to alkynes. For example, [RhCl(PPh_3)$_3$] catalyzes the initial formation of (Z)-but-2-enoic acid from but-2-ynoic acid.

3.8 Transfer Hydrogenation

Dihydrogen is not used as a reactant in transfer-hydrogenation reactions. Instead, the hydrogen required for alkene reduction is abstracted from an organic molecule. Secondary alcohols have proved to be the most generally useful hydrogen sources.

The mechanism of transfer hydrogenation is complicated because of the need to activate the reagents in the correct order. Since several of the more successful transfer-hydrogenation catalysts are monohydride complexes, deuterium-labeling experiments to ascertain the source and destination of the transferred hydrogen are subject to some uncertainty. This complication arises from the simultaneous isotope exchange reactions that occur.

The catalytic cycle involving [$RuCl_2$(PPh_3)$_3$], one of the more active transfer-hydrogenation catalysts, is shown in Scheme 10.[2] The catalyst first forms an alkoxido complex, with elimination of HCl, when allowed to react with the secondary alcohol. This pentacoordinate complex forms an 18-electron species by coordinating a molecule of alkene. The alkoxido ligand transfers its α-deuterium atom to the metal, after which the ketone oxidation product of the secondary alcohol is eliminated. The steps are believed to occur in



Scheme 10

this order since the presence of a chiral alkoxido ligand is required to account for the selectivity shown in the reactions of prochiral alkenes when chiral secondary alcohols are used as the hydrogen source.

In Scheme 10, transfer of the deuterium marker to the alkene forms a 2-deutero-1-alkyl complex. To complete the catalytic cycle, this complex coordinates a second molecule of the labeled alcohol. The hydroxyl proton of this is transferred to the alkyl ligand and reductive elimination of the monodeuteroalkane ensues. The alkoxido complex resulting can then activate a further molecule of alkene in the next revolution of the catalytic cycle.

The results of several stoichiometric reactions of labeled compounds have led to the proposals put forward in the catalytic cycle.

Transfer hydrogenation is usually carried out under harsher conditions than would be required to add molecular hydrogen across the same alkene bond.

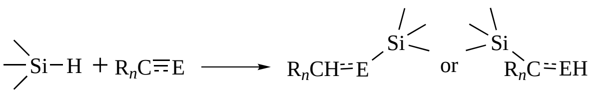
Glossary

Coordination catalysis: a catalytic process which takes place in the coordination sphere of a metal complex
Dehydrosilylation: a condensation reaction between a hydrosilane and another hydride, E−H, with formation of an Si−E bond and hydrogen
Hydroelementation: a reaction in which an element–hydrogen bond adds across an unsaturated molecule

1 INTRODUCTION

The term hydrosilation (or hydrosilylation) refers to the addition of a molecule containing a Si–H bond across the multiple bond of a substrate, usually an alkene, alkyne, or carbonyl compound (equation 1).[1–4] The reaction can be promoted by UV-light, radiation (γ- and X rays), radical initiators, Lewis acids, nucleophiles, or, most importantly, transition metal catalysts. Hydrosilation is related to the important processes of hydrogenation (*see Hydrogenation*) and hydroboration (*see Hydroboration*), all of which belong to the general reaction class of hydroelementation.



(1)

The first example of a hydrosilation reaction was the peroxide catalyzed addition of trichlorosilane across 1-octene, reported by Sommer in 1947.[5] The discovery of the transition metal catalyzed variant of the reaction by Speier[6] in 1957 initiated a broad interest in the reaction. This interest has grown further even in recent years. With increasing importance of organosilanes in organic synthesis and especially material science, the value of Si–C bonding reactions was very well recognized. The finding that essentially every known metal in some ligand framework can catalyze the hydrosilation reaction brought about very different chemo- and regioselectivities. As conversion and yields are usually very good, the reaction enjoys a wide acceptance in academic and industrial[7] environments.

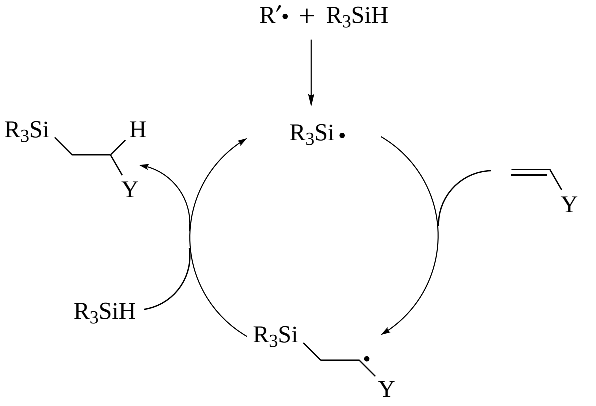
2 RADICAL AND OTHER NONTRANSITION METAL CATALYZED HYDROSILATION

As the Si–H bond is relatively weak (ca. 300–400 kJmol^{-1}) silyl radicals can be easily generated. Using a radical initiator such as azobisisobutyronitrile (AIBN) or organic peroxides the hydrosilation process can take place as a radical chain reaction (Scheme 1).[8,9]

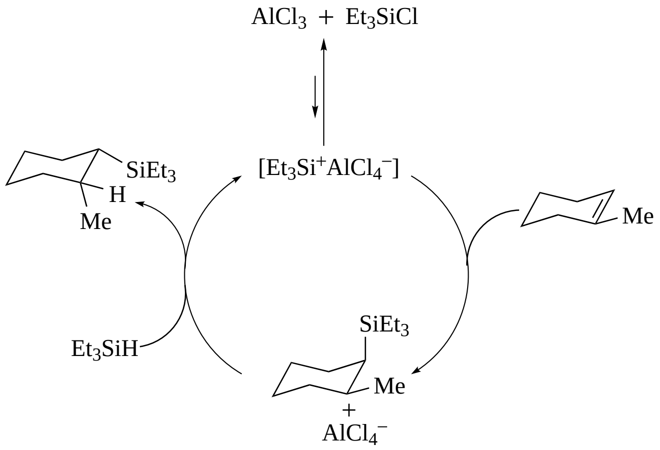
The addition of the tris(trimethylsilyl)silyl radical to alkenes and alkynes was found to be highly stereoselective (*see Stereoselectivity*) and constitutes an interesting method in organic synthesis.[10] Compared to the transition metal (*see Transition Metals*) catalyzed process the radical reaction is often plagued by severe disadvantages. Radical reactions are frequently less selective and tend to give side-products such as telomers, which are formed by the reaction of an intermediate radical with another unsaturated substrate rather than with a hydrosilane. A large excess of the silane component can occasionally suppress this unwanted side reaction. In cases of higher substituted alkenes as substrates, however, hydrosilation using radical conditions can be useful. Transition metal catalysts frequently cannot be used with tri- and tetrasubstituted alkenes.

Aluminum trichloride catalyzed hydrosilation provides an interesting alternative to the free radical process. The addition of the silane was found to occur regioselectively at trisubstituted alkenes in a *trans*-fashion.[11] Mechanistically it was concluded that the reaction proceeds via the addition of a silylenium cation to the multiple bond, generating the more stable (more substituted) carbocation, which abstracts a hydride from another molecule of hydrosilane (Scheme 2).[12]

A similar *trans*-selectivity was also found for the aluminum trichloride catalyzed hydrosilation of alkynes. Z-Vinylsilanes can be obtained by this method as the exclusive products.[13]



Scheme 1 Radical chain hydrosilation reaction

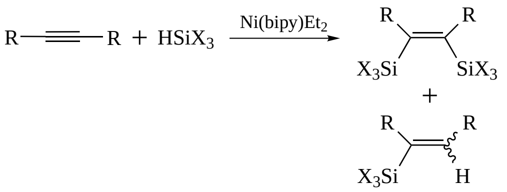


Scheme 2 Aluminum chloride catalyzed hydrosilation reaction

3 CATALYSIS (*See Catalysis*) BY TRANSITION METAL COMPOUNDS

Most hydrosilation reactions are catalyzed by transition metal compounds. Among the known catalyst systems, hexachloroplatinic acid ($H_2PtCl_6{\cdot}6H_2O$) in isopropanol (Speier's catalyst)[14] still holds paramount position. The usefulness of this system is illustrated by its high rates and the fact that cases with substrate/catalyst ratios of 10^8 are known to work on industrial scale.[14] Besides Speier's catalyst, the Karstedt catalyst system, which is obtained by treatment of hexachloroplatinic acid with vinylsiloxane, enjoys widespread popularity.[15] Besides these two, a whole array of other Pt catalysts has been investigated. It is assumed that Pt(II) species are the most effective catalysts.[4] A controversy over the active catalytic species in Speier's catalyst being actually metallic platinum seems to have been resolved in favor of a homogeneous mechanism.[16] Nevertheless, platinum metal on heterogeneous support materials is an active hydrosilation catalyst also.

Among metals other than platinum, rhodium is probably the most important with respect to hydrosilation catalysis. Mainly Rh(I) compounds, with Wilkinson's complex $(Ph_3P)_3RhCl$ (*see Wilkinson's Catalyst*) being the most investigated, have been found to be active catalysts. While the use of Rh-catalysts seems not to be advantageous in the case of alkene hydrosilation, it offers interesting selectivities in the hydrosilation reactions of alkynes and carbonyl compounds (*vide infra*). Nickel compounds, although in general less active, have been found to react very selectively in certain cases. The hydrosilation/dehydrosilation of alkynes gives 1,2-bissilylalkenes along with the normal hydrosilated products (equation 2).[17]



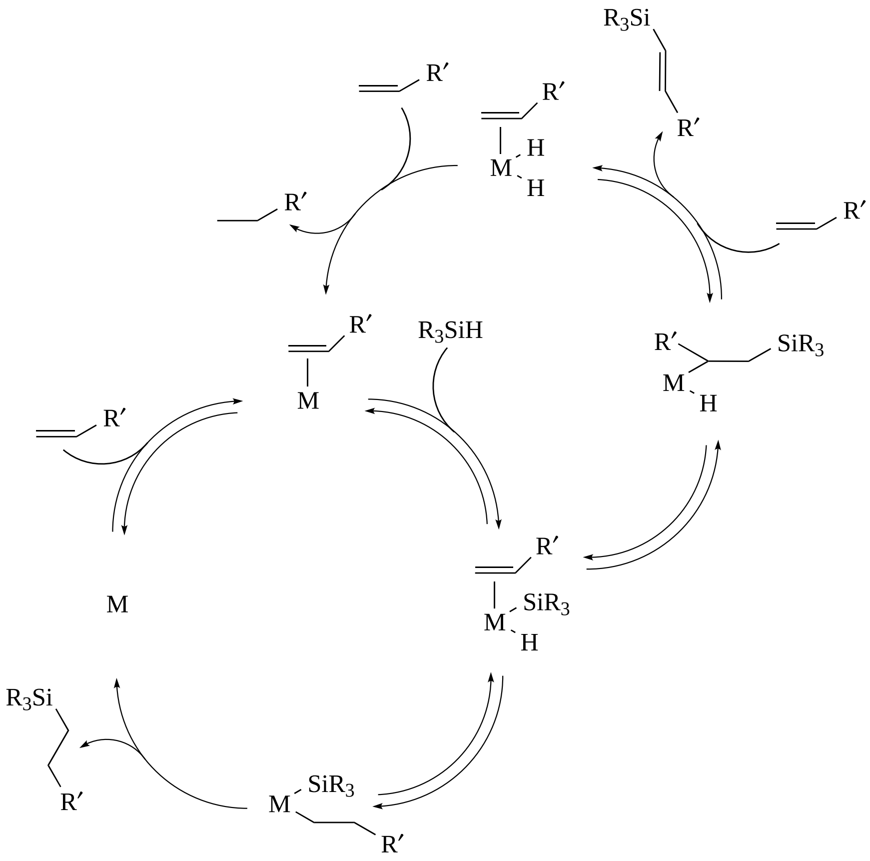
(2)

Nickel and palladium compounds have also been found to exhibit an interesting reactivity pattern in the hydrosilation of diynes (vide infra).

Other late transition metals used in special cases of hydrosilation include cobalt, iron, ruthenium (vide infra for reactions with alkynes), osmium, chromium, molybdenum, tungsten and copper.[4] Metallocenes (*see Metallocene Complexes*) of early transition metals and lanthanides have also been found to catalyze the hydrosilation of a number of unsaturated compounds including alkenes and esters (vide infra).

4 MECHANISMS OF METAL COMPLEX CATALYZED HYDROSILATION

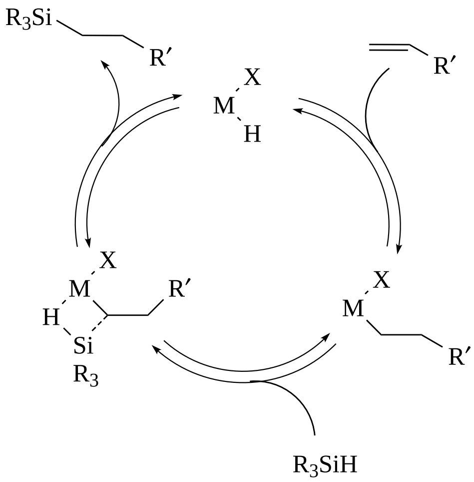
Chalk and Harrod provided the first mechanistic explanation for the transition metal catalyzed hydrosilation as early as in 1965.[18] Their mechanism was derived from studies with Speier's catalyst and provided a general scheme, which could be used also for other transition metals. The catalytic cycle consists of an initial oxidative addition (*see Oxidative Addition*) of the Si–H bond, followed by coordination of the unsaturated molecule, a subsequent migratory insertion (*see Insertion*) into the metal-hydride bond and eventually a reductive elimination (*see Reductive Elimination*) (Scheme 3 lower cycle). The scheme provides an explanation for the observed Z-geometry in the hydrosilation of alkynes, which is a consequence of the *syn*-addition mechanism. The observation of silated alkenes as by-products in the hydrosilation of alkenes along with the lack of well-established stoichiometric examples of reductive elimination of alkylsilanes from alkyl silyl metal complexes



Scheme 3 The Chalk–Harrod mechanism for hydrosilation and a modified version

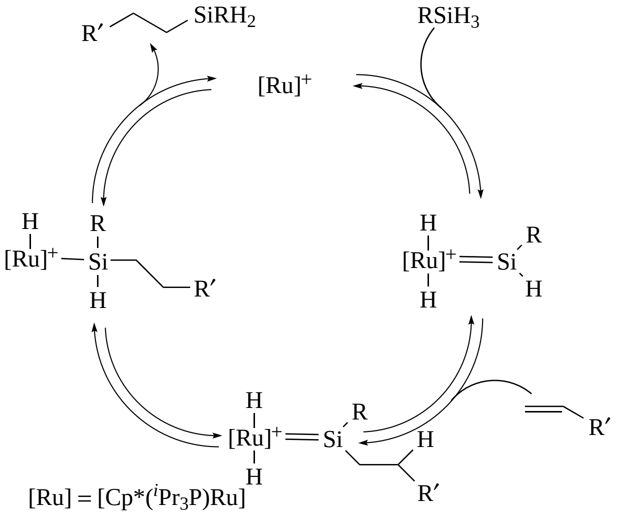
promoted the formulation of a modified Chalk–Harrod mechanism (Scheme 3 upper cycle).[19] The modification brings about the migratory insertion of the alkene into the metal-silyl bond. While a final reductive elimination of the thus formed β-silylalkyl metal hydride leads to the formation of the same hydrosilation product as in the original mechanistic proposal, a β-hydride elimination of this intermediate yields a silated alkene. The resulting metal dihydride is subsequentially functioning as a hydrogenation catalyst of alkenes present.

More recent studies have shown that a number of other mechanisms are operative in the hydrosilation process for different metals. Mechanistic proposals for early metals, lanthanides and actinides have been elaborated on. These involve a Chalk–Harrod like initial migratory insertion into a metal-hydride bond, followed by a σ-bond metathesis step (Scheme 4).[20] An alternative mechanism, however, was proposed for Group 4 metallocene catalysis, which involves a coordinated olefin, which undergoes σ-bond metathesis with the hydrosilane.[21]



Scheme 4 Early metal hydrosilation mechanism involving σ-bond metathesis

Most recently an example of a ruthenium catalyzed selective addition of primary silanes to alkenes was shown to involve ruthenium silylenes as intermediates (Scheme 5).[22] A remarkable feature of this mechanism is, that the insertion of the alkene does not occur either into a metal-hydride or metal-silyl bond but directly into the Si–H bond of an activated silylene. The mechanism therefore resembles a hydroboration reaction and as a consequence displays anti-Markownikow selectivity.



Scheme 5 Ruthenium silylene catalyzed hydrosilation of primary silanes[22]

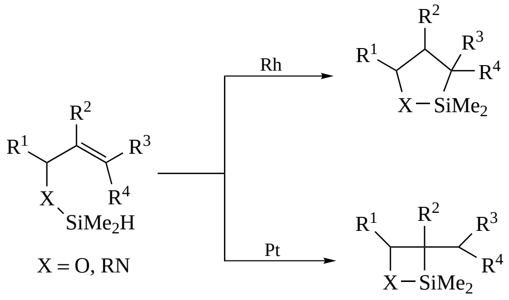
5 SUBSTRATE TYPES

5.1 Alkenes

Alkenes are most easily hydrosilated by Speier's catalyst. The reaction of trichlorosilane with 1-alkenes usually gives terminal silanes in high yields. 2-Silylalkanes, as products of an initial double bond isomerization, are rarely encountered. Internal alkenes, however, give the expected internally silated product only as minor components as well as the 1-silylalkane. Interestingly, this alkene isomerization is not encountered when dimethylchlorosilane is used as the silating agent.[23] The importance of the right catalyst and ligand framework is illustrated in the reaction of trichlorosilane with styrene. This gives a mixture of α- and β-silyl isomers (35:65)[24] when catalyzed with $H_2PtCl_6{\cdot}6H_2O$. The addition of triphenylphosphane or pyridine to the same catalyst gives 92–95% of the β-isomer.[25] The α-isomer can be obtained almost exclusively employing either $[CpNi(CO)]_2$[26] or $NiCl_2{\cdot}2PPh_3{\cdot}CuCl$.[24]

The hydrosilation reaction is highly compatible with a number of functional groups including ether, epoxide, acetal, ketone, ester, nitrile, amine, amide, nitro, carbamate, isocyanate, phosphate, sulfide, sulfone, and others.[4] As a consequence, it is a very attractive reaction for the construction of complex organic molecules. Sometimes allylic displacement is observed as a side reaction, especially in the reaction of allyl halides.[27]

Intramolecular hydrosilation was found to be a useful method for 1,2- or 1,3-chirality transfer. The hydrosilyl moiety is easily attached to a heteroatom such as oxygen or nitrogen and subsequently an intramolecular hydrosilation can be achieved. Depending on the substituents on the substrate and the catalyst used, either four- or five-membered rings can be obtained. Subsequent Tamao oxidation can be used to transform the Si–C bond into an alcohol (equation 3).[28,29]



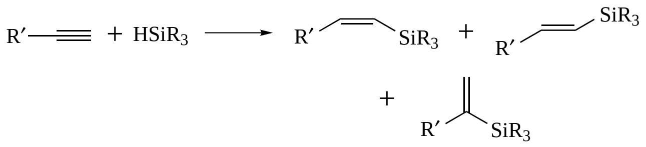
(3)

5.2 Alkynes

Alkynes can be advantageously hydrosilated to give vinylsilanes. The reaction with the triple bond is much faster than with an olefin, therefore a subsequent hydrosilation step to the disilylalkane is usually not encountered. This different reactivity can be exploited in the hydrosilation of vinylacetylene, where 1-silyl-1,3-butadiene is formed chemoselectively (equation 4).[30]

(4)

The hydrosilation of 1-alkynes can give either Z- or E-isomers (*see (E) & (Z) Isomers*) of the linear vinylsilane or the Markownikow product (equation 5). Reaction of 1-hexyne with trichlorosilane under platinum catalysis conditions gives a mixture of 1- and 2-silyl-1-hexene (78:22).[31] From the E-stereochemistry of the 1-silyl isomer, a *syn*-addition mechanism can be assumed.



(5)

When employing Rh-COD catalysts, the choice of solvent and cocatalyst allows very good selectivities for either Z- or E-vinylsilanes (Table 1).[32]

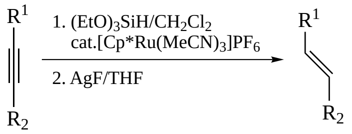
A mechanistic rationale for the apparent *trans*-addition in some of these processes is shown in Scheme 6. Initial insertion of the alkyne into the metal-silyl bond yields an intermediate with an unfavorable interaction between the metal and the silyl group. Coordination of the vinyl part to the metal gives formally a metallacyclopropene.

Table 1 Hydrosilation of 1-hexyne with triethylsilane in the presence of rhodium catalysts[32]

Catalyst	Solvent (%)	Z (%)	E (%)	iso (%)
$[Rh(COD)Cl]_2$	DMF	97	1	2
$[Rh(COD)Cl]_2$	EtOH	94	4	2
$[Rh(COD)Cl]_2$	MeCN	36	33	31
$[Rh(COD)Cl]_2/2PPh_3$	MeCN	2	97	1
$[Rh(COD)_2]BF_4/2PPh_3$	MeCN	2	95	3
$[Rh(COD)_2]BF_4/2PPh_3$	EtOH	5	95	0
$[Rh(COD)_2]BF_4/2PPh_3$	Acetone	1	99	0

A consequence of this coordination mode is that the hybridization (*see Hybridization*) at the silyl bearing carbon changes from sp^2 to sp^3. In the course of de-coordination, the change back to sp^2 hybridization gives the sterically less hindered metal vinyl complex with E-geometry of the metal and the silyl group.[33,34] Final reductive elimination eventually yields the thermodynamically less stable Z-alkene.

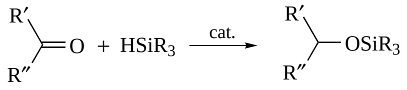
Use of the cationic $CpRu(MeCN)_3PF_6$ catalyst allows very selective formation of the Markownikow product.[35] The same catalyst has also been applied with triethoxysilane and a desilylating agent (CuI/TBAF, AgF) as a method to convert internal alkynes to E-alkenes (equation 6).[36,37]



(6)

5.3 Carbonyl Compounds

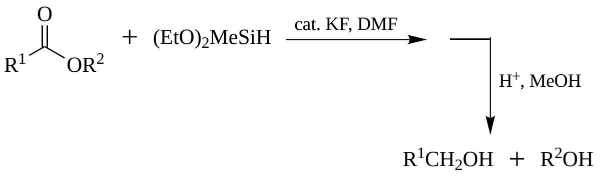
The discovery of facile hydrosilation of carbonyl compounds employing Wilkinson's complex[38] $RhCl_3(PPh_3)_3$ initiated a broad interest in this synthetically useful reaction (equation 7).



(7)

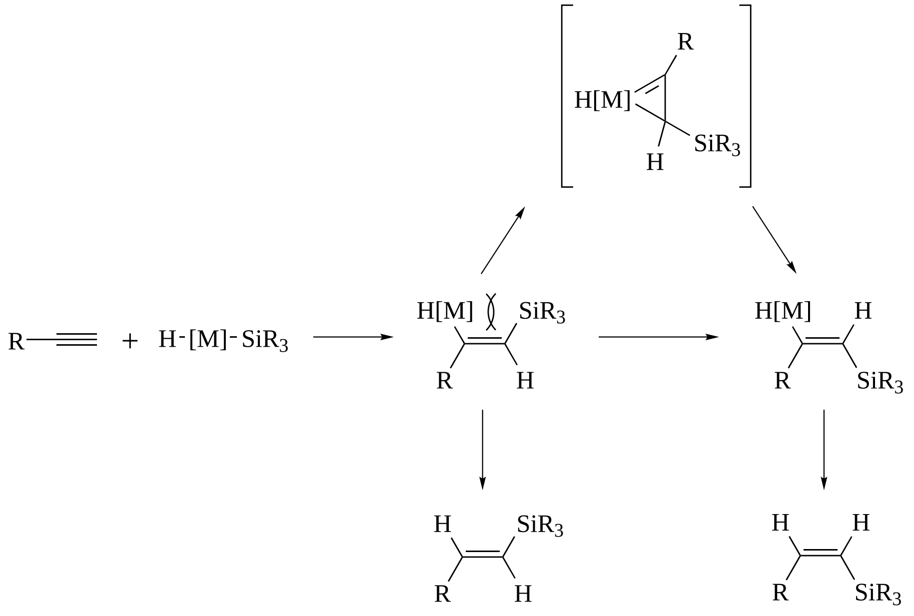
For aldehydes and ketones $RhCl_3(PPh_3)_3$ serves as an excellent catalyst.[39]

Some alkali metal and trialkylammonium salts also work as efficient catalysts for the reduction of aldehydes, ketones and esters with monohydrosilanes.[40,41] Among those salts CsF was found most effective. Esters are reduced to the alcohols (equation 8).



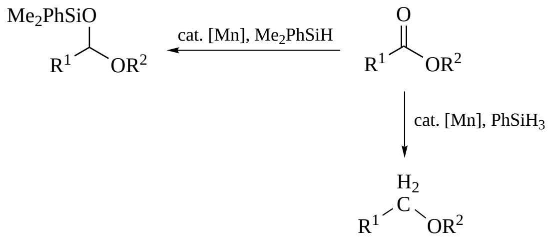
(8)

Transition metal catalyzed reduction of esters either to the silyl acetal ($R^1CH(OSiR)OR^2$) or complete reduction to the respective ethers could be accomplished using a manganese catalyst $[(Ph_3P)(CO)_4MnCOCH_3]$ and either a tertiary or a



Scheme 6 Explanation for the formation of Z-vinylsilanes

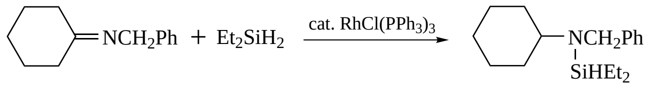
primary silane (equation 9).[42]



(9)

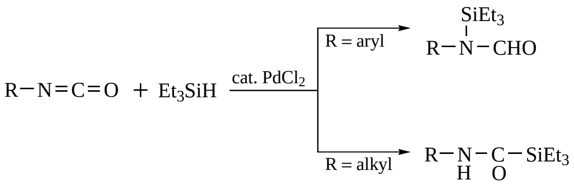
5.4 Unsaturated Nitrogen Containing Substrates

Substrates containing carbon nitrogen multiple bonds have received somewhat less attention. Nevertheless, imines can be converted to N-silylamines, again with $RhCl_3(PPh_3)_3$ being one of the most effective catalysts (equation 10).[2]



(10)

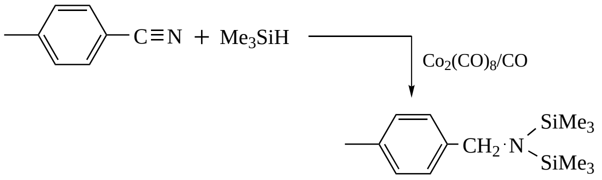
Oximes can also be reduced to N-silylamines under similar conditions.[43] The $PdCl_2$ catalyzed reaction of isocyanates with triethylsilane depends on the structure (R = alkyl or aryl) of the isocyanate. Either N- or C-silylformamides can be obtained (equation 11).[44]



(11)

Carbodiimides can be converted to N-silylformamidines at elevated temperatures with $PdCl_2$ or with $RhCl_3(PPh_3)_3$ catalysts.[45]

The hydrosilation of aromatic nitriles is promoted by $Co_2(CO)_8$ to give N,N-bis(silyl)benzylamines (equation 12).[46] Aliphatic nitriles require higher temperatures. α,β-Unsaturated nitriles with substituents in α- and/or β-positions give N,N-bis(silyl)enamines as major products.[47]



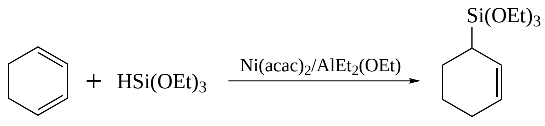
(12)

5.5 Conjugated Compounds

The hydrosilation of 1,3-dienes with Speier's catalyst often gives product mixtures of 1,2 and 1,4-addition, with the latter usually being the main product.[48] In contrast to this, the palladium-catalyzed reaction with trichlorosilane gives the 1,4-addition product exclusively. If trimethylsilane is used, an adduct with two equivalents of diene can be obtained with an excellent yield (equation 13).[49,50]

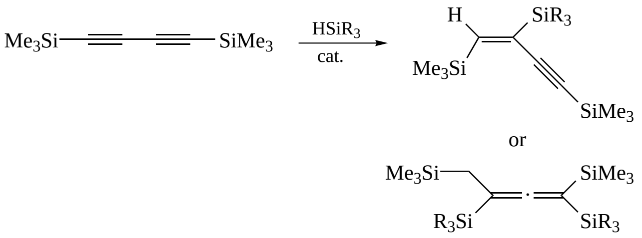
(13)

Cyclic dienes are hydrosilated by 1,4-addition using Pd[51] or Ni[52] catalysts (equation 14).



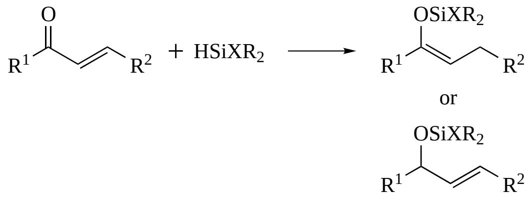
(14)

The hydrosilation of 1,4-bis(trimethylsilyl)-1,3-butadiyne gives either enynes as the product of monohydrosilation or allenes as deriving from di-hydrosilation (equation 15).[53]

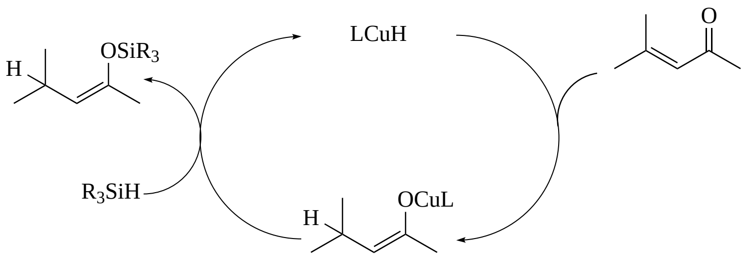


(15)

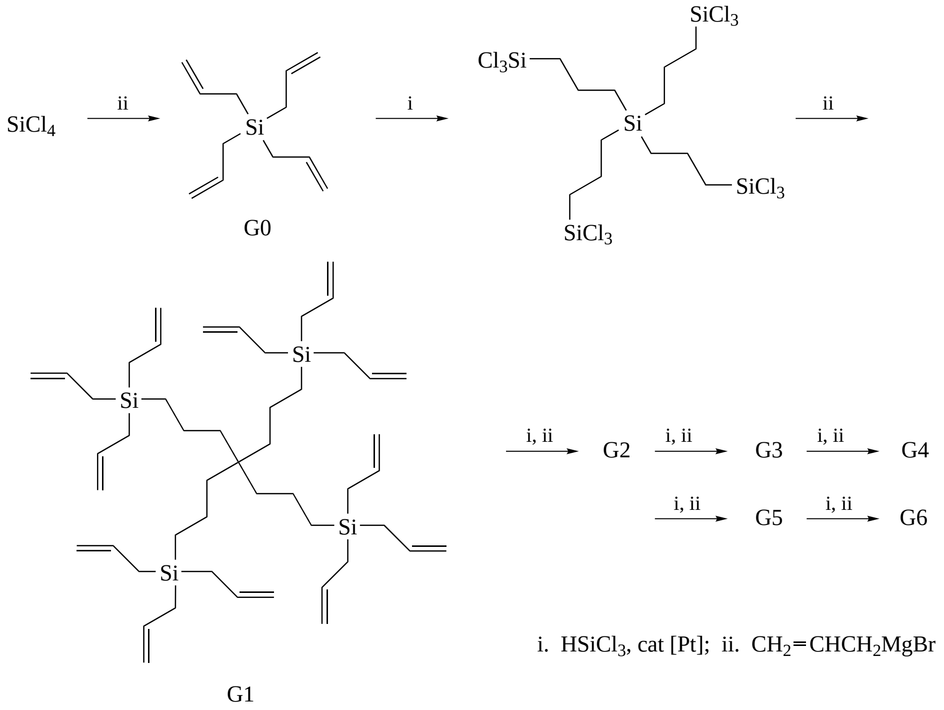
α,β-Unsaturated carbonyl compounds can be hydrosilated either in 1,2- or 1,4-addition to give either silyl enol ethers or silyl allyl ethers. Using Wilkinson's catalyst, it was found that the regioselectivity (*see Regioselectivity*) of this reaction was mainly governed by the silane used. While monohydrosilanes promote 1,4-addition, the 1,2-addition process is observed with di- and trihydrosilanes (equation 16).[54]



(16)



Scheme 7 Copper promoted formal enolate addition of hydrosilane



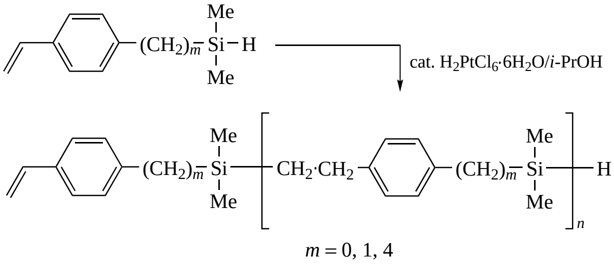
Scheme 8 Dendrimer synthesis employing hydrosilation/allylation chemistry

The use of copper catalysts in the presence of silanes provides another possibility to achieve 1,4-addition selectively.[55,56] The active species is likely to be a copper hydride, which reacts to give a copper enolate, which undergoes a σ-bond metathesis step with the hydrosilane (Scheme 7).[57]

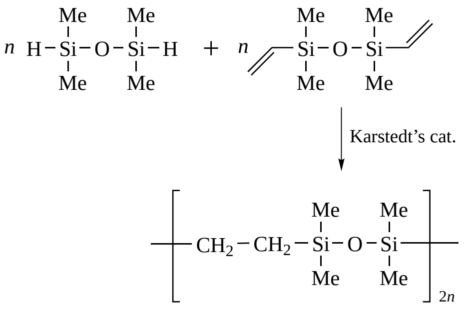
5.6 Dendrimers, Polymers (*See Polymer*) and Other Macromolecules

The high degree of completion and selectivity and the high yields make the hydrosilation reaction an ideal candidate for the buildup of dendrimeric structures. The combination with allylation, vinylation, and alkynylation reactions provides very efficient syntheses of carbosilane dendrimers (Scheme 8).[58]

Numerous examples are known in which hydrosilation reactions are used to prepare monomers for polymerization experiments. The reaction itself can also be used for a polymerization process. This can be accomplished as the hydrosilation of alkenes either using a single-source precursor (equation 17)[59] or a two-component mixture (equation 18).[60]

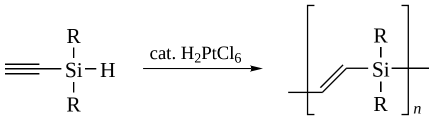


(17)



(18)

Also silylacetylenes undergo self-polymerization under hydrosilation conditions to give high molecular weight polymers (equation 19).[61]

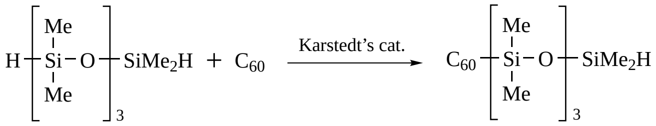


(19)

The functionalization of polymers is another useful feature of the hydrosilation reaction. The introduction of highly fluorinated alkyl chains by the hydrosilation of Si–H groups of the polymer with fluorinated alkenes is a typical example.[62]

Poly(phenylsilanes) obtained by the dehydrocoupling polymerization of phenylsilane undergo AIBN initiated free radical hydrosilation with alkenes, ketones and aldehydes.[63] Cross-linking and branching of polymers can also be easily accomplished using hydrosilation.

Treatment of C_{60} with poly(hydrosiloxane) in the presence of Karstedt's catalyst proceeds to give C_{60}-polysiloxanes (equation 20).[64]



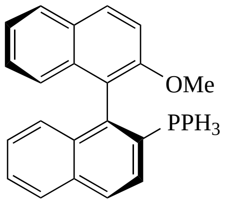
(20)

6 ENANTIOSELECTIVE CATALYTIC HYDROSILATION

During the process of hydrosilation two prochiral sp^2 hybridized atoms are converted to potentially chiral (*see Chiral*) sp^3 atoms. This opens up the possibility for asymmetric catalysis. The use of prochiral silanes of the type $RR'SiH_2$ also allows for the generation of chiral silanes.

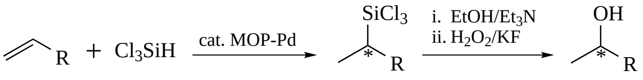
6.1 Enantioselective (*See Enantioselectivity*) Hydrosilation of Alkenes

The asymmetric hydrosilation of prochiral alkenes has been a challenging subject, which eventually experienced a breakthrough with the introduction of a palladium catalyst, which employs the MOP-ligand (**1**).[65]



(**1**)

Using this system, 1-alkenes can be hydrosilated with excellent enantioselectivities (e.e. 91–97%). Subsequent Tamao oxidation to the respective secondary alcohol occurs under retention of configuration (equation 21).



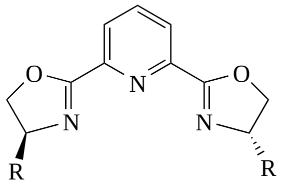
(21)

Also norbornene and related systems,[66] as well as dihydrofuranes,[67] have been hydrosilated with good enantioselectivities with similar MOP ligands. Intramolecular rhodium catalyzed asymmetric hydrosilations have been achieved with good enantioselectivities, for example with *meso*- or other allylsilylethers.[68,69]

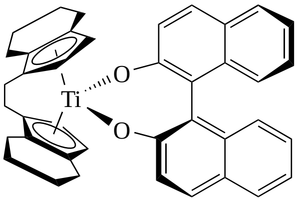
6.2 Enantioselective Hydrosilation of Ketones and Other Carbonyl Compounds

Asymmetric hydrosilation of prochiral ketones constitutes a formal reduction of the ketone to the secondary alcohol. Initial studies were driven by the apparent similarity of the hydrosilation with hydrogenation. Accordingly similar ligands such as DIOP, Chiraphos and BINAP related compounds (*see* ***P-donor Ligands***) were used. A breakthrough was achieved using bis(oxazolinyl)pyridine (**2**) ligands and Rh(III) catalysts.[70] A chiral titanocene catalyst (*R*,*R*)-(EBTHI)$Ti(OR)_2$ (**3**) was also found to give good to excellent enantioselectivities.[71]

The synthesis of optically active amines by hydrosilation of imines was achieved in excellent e.e.s using a related catalyst system: (*R*,*R*)-(EBTHI)TiH. This is conveniently generated



(**2**)



(**3**)

from (R,R)-(EBTHI)TiF_2 by reduction with $PhSiH_3$.[72] Hydrosilation of prochiral imine N-oxides (nitrones) through the use of a Ru-binap catalyst system gives the respective hydroxylamines in high enantiomeric purity.[73] The attachment of a phosphinyl moiety to an imine nitrogen provides excellent asymmetric induction in the reduction to the amine when using a copper-hydride catalyst and a chiral phosphine.[74]

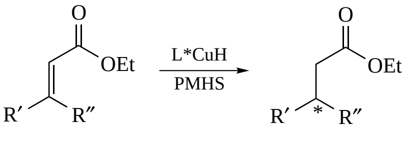
6.3 Enantioselective Hydrosilation of Conjugated Systems

Palladium-catalyzed asymmetric hydrosilation of cyclic and linear 1,3-dienes proceeds as 1,4-addition with moderate to good enantioselectivities.[75] α-Ketoesters such as pyruvates can be hydrosilated with Rh(I)-(+)-DIOP catalysts to yield lactates with much better optical purity than simpler ketones (equation 22).[76] This effect is likely to be caused by a ligand function of the ester moiety in the transition state.

$$\mathrm{MeCOCOOPr}^n \xrightarrow[]{\alpha\text{-NpPhSiH}_2,\ (-)\text{-DIOP-Rh(I)}} \xrightarrow{\mathrm{H^+/MeOH}} \mathrm{Me\overset{*}{C}H(OH)COOPr}^n \quad (22)$$

85% e.e.

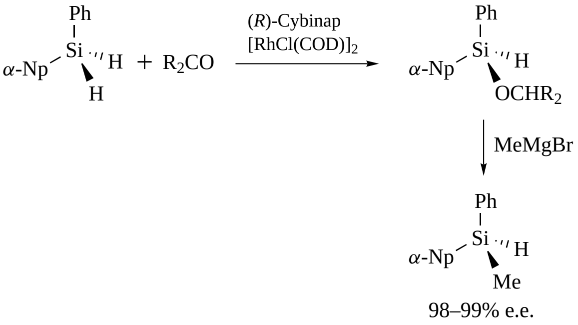
Asymmetric reduction of α, β-unsaturated esters, lactones or lactames can be effected with copper-hydride catalysts and chiral phosphanes such as various BINAP related compounds in excellent yields and enantioselectivities (equation 23).[77,78] As the hydrosilane component, polymethylhydrosiloxane (PMHS) is frequently used for this reaction.



(23)

6.4 Asymmetric Synthesis of Chiral Silanes

The use of prochiral secondary silanes in the asymmetric hydrosilation can give an optically pure silylether, which can be alkylated with a Grignard reagent with retention of the configuration (equation 24).[79]

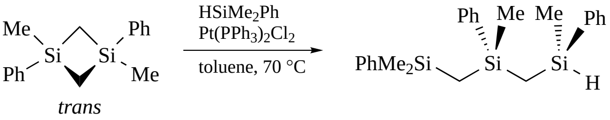


(24)

7 RELATED REACTIONS OF SILANES

The main side reaction of the hydrosilation reaction is the dehydrogenating silation reaction. Under certain conditions this reaction can be the main or even the exclusive reaction. The reaction can occur, not only with alkenes, but also with almost all known substrates. It achieves vinylsilanes from alkenes,[80] silylalkynes from alkynes,[81] and silyl enol ethers from ketones.[82]

Strained silacarbocycles exhibit a similar reactivity as an unsaturated molecule. Therefore the addition of a hydrosilane to a Si–C σ-bond can be accomplished giving rise to the stereospecific formation of trisilanes (equation 25).[83]



(25)

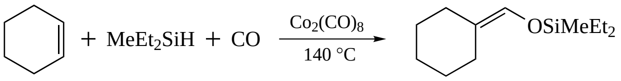
The dehydrogenating polymerization of hydrosilanes was found to be catalyzed by Group 4 metallocene alkyl and silyl derivatives (equation 26).[84] For zirconocene and hafnocene catalysts, the reaction was found to proceed via σ-bond metathesis steps.[85]

$$n\mathrm{PhSiH_3} \xrightarrow[-(n-1)\mathrm{H_2}]{\text{cat. } \mathrm{Cp_2TiMe_2}} n\mathrm{PhSiH_2}\text{–}(\mathrm{PhSiH})_{n-2}\mathrm{SiH_2Ph} \quad (26)$$

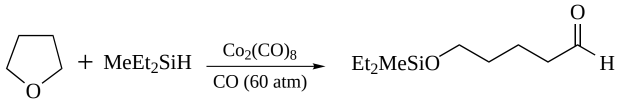
Similar coupling reactions have also been reported with late metals such as platinum and nickel.[86,87]

As the hydrosilation reaction is related to hydrogenation, it also bears a certain relationship to the hydroformylation (*see Hydroformylation*) reaction. The $Co_2(CO)_8$ catalyzed process, which formylates an alkene in the presence of a hydrosilane instead of hydrogen, gives silyl enol ethers in excellent yields (equation 27).[88] The hydrosilane/CO system can also react with cyclic ethers or aldehydes to give ω- or

α-silyloxyaldehydes (equation 28).[89,90]



(27)



(28)

8 TRANSITION METAL-SILYL COMPLEXES

The discovery of the hydrosilation reaction has greatly stimulated research on transition metal-silyl complexes. Currently, there are examples of silyl complexes with almost every transition metal.[91–93] Silyl hydride complexes are of special interest with respect to the chemistry of the hydrosilation reactions.[94] Such compounds can be seen as the products of oxidative addition into the Si–H bond and thus are intermediates in hydrosilation reactions following the Chalk–Harrod mechanism.

Glossary

Phosphoranes: tbp 10-P-5 phosphorus(V) molecules
Phosphoranides: pseudo-tbp 10-P-4 phosphorus(III) anions
Pseudo-oct: a structure in which one or two legs of the oct is occupied by lone pairs of electrons
Pseudo-tbp: a structure in which one, two, or three legs of the tbp is occupied by lone pairs of electrons
Sulfuranes: pseudo-tbp 10-S-4 sulfur(IV) molecules

Abbreviations

ap = Apical; ax = Axial; ba = Basal; 3c/4e = Three-center/four-electron; eq = Equatorial; MO = Molecular orbital; NBS = *N*-bromosuccinimide; oct = Octahedron or octahedral; R_f = Perfluorinated hydrocarbon; sp = Square pyramid or square pyramidal; tbp = Trigonal bipyramid or trigonal bipyramidal; VB = Valence bond.

1 INTRODUCTION AND BACKGROUND

Hypervalent molecules and ions are fascinating species, since they appear to violate the traditional Lewis–Langmuir theory of bonding by expanding the valence shell of a main group element. Although species such as PCl_5, ICl_3, and $SeCl_4$ were first reported almost two centuries ago, appropriate models to describe the bonding in these molecules have only been developed recently.[1] Whilst the term hypervalent is widely used – and often misused – there is currently no universally accepted definition of the word. Thus, it is instructive briefly to explain the origin of the term before giving the working definition for this article.

1.1 The Phenomenon of Hypervalency

In his 1923 monograph, Lewis[2] defined the valence of an atom in a molecule as '... the number of electron pairs which it shares with other atoms'. Lewis recognized that, through a combination of lone or nonbonding pairs and shared or bonding pairs, many atoms (other than hydrogen) in molecules achieve a total of eight electrons in the outermost shell; he called this the 'rule of eight'. Langmuir coined the now more familiar term 'octet'.[2,3]

Since it was proposed, the octet rule has caused misunderstanding and confusion about the status of hypervalent molecules, and is often taken to imply that the bonding in hypervalent molecules is distinct from that in those that obey the rule. It is an empirical rule based on the formulas of most compounds known in the early part of last century, and there is no reason why there should not be exceptions such as SF_6 and PCl_5, as was indeed recognized by Lewis.

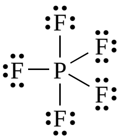
The term hypervalent was introduced in a classic paper by Musher[1] in 1969 to categorize 'molecules and ions formed by elements in Groups 15–18 of the periodic table in any of their valences other than their lowest stable chemical valence of 3, 2, 1, and 0 respectively'. This paper led to a surge of interest in both the theoretical and experimental aspects of species that appear to have 'expanded octets.'According to Musher, these species involve atoms '... which exceed the number of valences allowed them by the traditional theory, and thus utilize more electron pairs of bonding than provide stability in the Lewis–Langmuir theory'. Thus, molecules such as SF_6 and PCl_5 are hypervalent. In addition, according to this definition, F_3PO, F_2SO, and even Me_3NO, are also hypervalent.

If hypervalent literally means exceeding the lowest chemical valence, then even NH_4^+ is hypervalent, despite the fact that the Lewis–Langmuir theory easily accounts for its stability. Furthermore, if the definition of hypervalency is restricted to Groups 15–18, then this artificially excludes species such as SiF_5^- and SiF_6^{2-}, which are isoelectronic and isostructural with PF_5 and SF_6, respectively. The ambiguities in the original definition have led to several changes. Today, no one would regard NH_4^+ as hypervalent, while those that consider PF_5 and SF_6 hypervalent would classify SiF_5^- and SiF_6^{2-} in the same way.

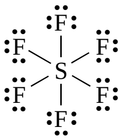
At this point, it is clear that whether or not a species is hypervalent depends not just on valence, but on the total number of valence electrons: a hypervalent molecule or

ion features an atom surrounded by a total of more than eight valence electrons – both bonding and nonbonding. This definition is consistent with the word hypervalent, since the expanded octet is a result of increased valence or bond formation. The major difficulty in this definition is how to count electrons.

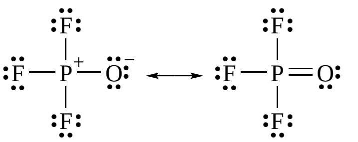
Can we use the Lewis structure as the determining factor? If so, there can be no doubt about the hypervalency of PF_5 (**1**) and SF_6 (**2**). But what about F_3PO (**3**) and F_2SO (**4**)?



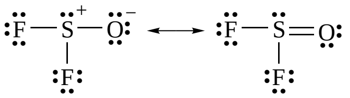
(**1**)



(**2**)

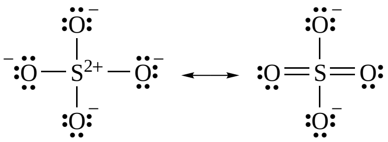


(**3**)



(**4**)

While many chemists would draw double bonds to oxygen because of their knowledge of structure and reactivity, perfectly acceptable nonhypervalent (octet-obeying) Lewis structures can also be drawn. In addition, the Lewis structure of SO_4^{2-} (**5**) can be drawn with only single bonds between sulfur and oxygen; however, there is little doubt that significant sulfur–oxygen π-bonding exists. An extreme example of this conundrum is the conclusion that the ion $[F_3CO]^-$ is hypervalent.[4] The carbon–oxygen bond in this ion is very short, and ab initio molecular orbital (MO) calculations show negative hyperconjugation and high polarity in this bond, implying significant double bond character and a structure for the ion that can be represented as $[F_3C{=}O]^-$].



(**5**)

1.2 Definition of Hypervalency

Initially, hypervalent molecules like PCl_5 and SF_6 were described in terms of sp^3d^n hybrid orbitals, in an extension of the sp^n orbital description used to characterize molecules that obey the octet rule. However, ab initio calculations have shown that d orbitals play only a minor role in the bonding of hypervalent molecules.[5] An alternative approach proposed by Pauling invoked combinations of resonance structures involving four covalent bonds and one or more additional ionic bonds, as shown in Scheme 1 for PF_5.

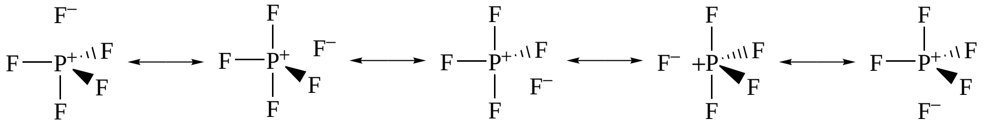
Perhaps the most useful definition of hypervalency makes use of the three-center/four-electron (3c/4e) bond.[6] Indeed, Musher in his original paper detailed this type of bonding based on the models of Rundle and Pimentel. The 3c/4e bond approach has several advantages: (1) it is easily recognizable from geometries derived from simple single-bonded Lewis structures based on Valence-Shell Electron Pair Repulsion Model rules (VSEPR) (*see Valence Shell Electron Pair Repulsion Model*); (2) strategies to stabilize hypervalent bonding are similar for each group; and (3) most inorganic chemists recognize this type of bond.

The 3c/4e hypervalent bond is used to classify the molecules and ions discussed throughout most of this article. Section 9.3 briefly mentions some common species referred to as hypervalent that do not fall into this classification.

2 THE HYPERVALENT BOND: GEOMETRY AND DESCRIPTION

2.1 Theoretical Description

The hypervalent bond is found in molecules and ions in which an atom is formally surrounded by more than an octet of electrons and contains a linear three-center arrangement of atoms. One example is PF_5, which has a trigonal bipyramidal (tbp) geometry. The traditional valence bond (VB) approach



Scheme 1

to describing the bonding in PF_5 is to expand the valence shell of the central atom to accommodate the extra electrons by *Hybridization*. One of the 3s electrons in the ground-state [Ne]$3s^23p^3$ electronic configuration of the phosphorus atom is promoted to a 3d orbital. Combining the one 3s, three 3p, and one 3d orbitals gives rise to five sp^3d hybrid atomic orbitals, which are disposed in a tbp arrangement. These hybrid orbitals overlap with the fluorine 2p orbitals to form five 2c/2e P–F covalent bonds. Indeed, this explanation is the only one given in most first-year college chemistry textbooks.

An alternative explanation, one that employs a highly ionic model neglecting d orbital participation, has been proposed. Described originally by Musher in VB terms, it has an equivalent MO description, which is given here.[7] It is in this model that the hypervalent bond is clearly seen. The essential features of the MO model in its most rudimentary form are (1) the central atom uses only valence s and p orbitals; (2) only one p orbital on the central atom is involved in bond formation in the linear three-center atomic arrangement; (3) the remaining central atom valence orbitals bind other atoms in ‘normal’ bonds or contain lone pairs. The MO description of the hypervalent bond is illustrated in Figure 1 for PF_5. (Not shown is the bonding in the *xy* plane in which phosphorus uses the 3s, $3p_x$, and $3p_y$ orbitals to form three sp^2 hybrid orbitals that bind the three fluorine atoms.) The three p_z atomic orbitals combine to give three MOs. The in-phase combination of fluorine $2p_z$ orbitals is orthogonal to the phosphorus $3p_z$ orbital and gives rise to the nonbonding Ψ_nMO. The out-of-phase combination of fluorine $2p_z$ orbitals overlaps with the phosphorus $3p_z$ orbital to give the bonding and antibonding MOs, Ψ_b and Ψ_a, respectively. Ten valence electrons fill the MOs: six go into the three P–F bonding orbitals in the *xy* plane, and the remaining four fill Ψ_b and Ψ_n. Ψ_b and Ψ_n, when filled, comprise the 3c/4e hypervalent bond (*see* ***Electronic Structure of Main-group Compounds*** and ***Molecular Orbital Theory***).

This model can account for the bonding not only in a tbp geometry but also in *pseudo*-tbp structures in which one or more lone pairs occupy vertices of the tbp (Figure 2) (*see also* ***Coordination Numbers & Geometries***). For *pseudo*-oct geometries, such as square pyramidal (sp) IF_5 and square-planar XeF_4, there are two sets of hypervalent bonds for each molecule. Only in the case of an octahedron or octahedral (oct) geometry, in which the central atom is surrounded by 12 valence electrons (such as SF_6), is the description slightly different.[7] Here, the sulfur 3s orbital contributes to the bonding and is filled. The three Ψ_b MOs are filled; this leaves only two Ψ_n MOs, and these are also occupied. However, for the oct $SeCl_6^{2-}$, where 14 valence electrons surround selenium, there are three filled Ψ_b MOs and three filled Ψ_n MOs; the remaining two electrons reside in a stereochemically inactive 4s orbital.

This description is overly simplified, and quantum chemical calculations have revealed a degree of involvement from s and/or d orbitals. Furthermore, π-bonding and

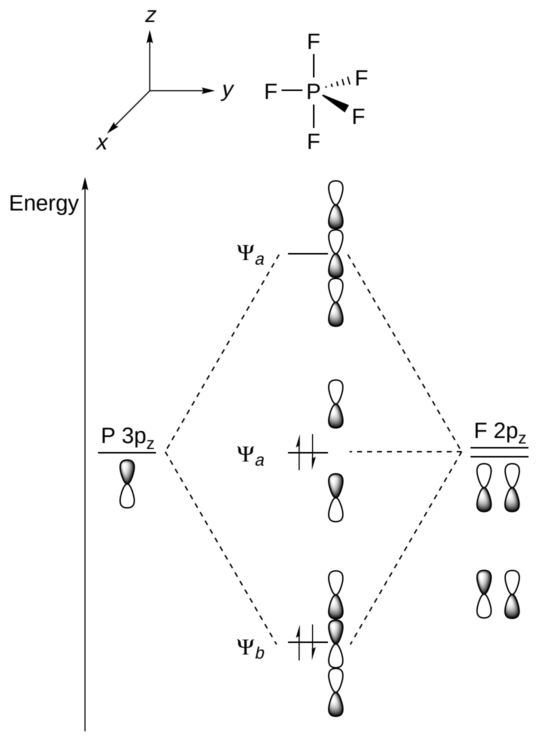


Figure 1 MO description of the 3c/4e hypervalent bond in PF_5. The bonding in the *xy* plane is not shown

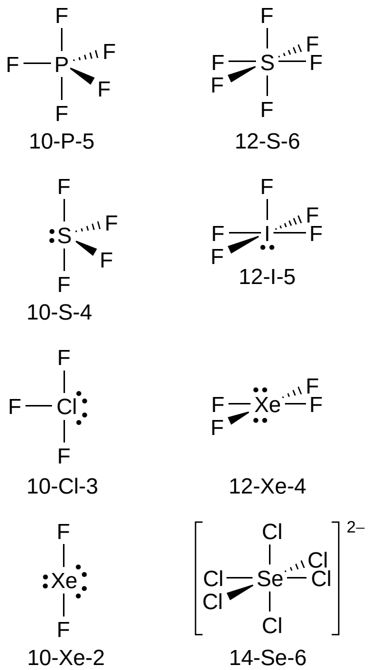

Figure 2 Examples of various geometries based on VSEPR rules. Also given is the N-X-L notation (Section 2.3). Note that the lone pair of electrons in $SeCl_6^{2-}$ is in a stereochemically inactive 4s orbital

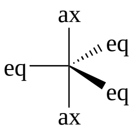
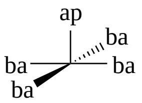
hyperconjugation may also be important to account fully for the bonding in these derivatives.[4] Indeed, one well-regarded inorganic chemistry text has called the complete neglect of s and d orbitals in this bonding model ‘a ruthless approximation’.[8] Nevertheless, this model has served to explain many structural and chemical features of hypervalent species. For example, the nonbonding component of the 3c/4e EX_2 bond (Ψ_n) is localized on the X groups or ligands, and has no contribution from the central E atom. This buildup of charge is best accommodated by electronegative substituents (*see Electronegativity*) and, in fact, most of these molecules and ions contain electronegative groups at these positions, specifically the axial positions in a tbp (or pseudo-tbp) and the basal positions of a square pyramid (sp). The less electronegative groups will usually prefer the equatorial sites for the tbp (**6**) and apical sites for the sp (**7**). The bonding model is also in agreement with the usual experimental findings that the 3c/4e hypervalent bonds are longer (and weaker) than the 2c/2e bonds.



(**6**) tbp



(**7**) sp

Both the ionic resonance structures of Pauling (q.v.), and the 3c/4e bonds proposed by Musher, are consistent with the octet rule, and also take account of the natural polarity of E–X bonds. They explain the paradox whereby the E atom in a molecule EX_n appears to have more than eight valence electrons by recognizing that these bonds are polar. In formulating the octet rule, Lewis implicitly assumed that each bonding pair of electrons contributes fully to the valence shell of both atoms between which it is shared, irrespective of the polarity of the bond. Ionic resonance structures and 3c/4e bonds each locate the excess electron density on the peripheral X atoms. In practice, most hypervalent molecules possess electronegative X atoms or groups that stabilize this redistribution of charge. Thus, when bond polarity is taken into account, the octet rule may be reformulated so that the valence shell of an atom may contain no more than eight electrons. Hence the rule may be obeyed by a hypervalent atom if the ligands are sufficiently electronegative to remove from it a substantial amount of electron density in the form of polar E–X bonds.

It is significant to note that this model places the ‘extra’ electrons on the ligands attached to the central atom and not on the central atom. Thus the octet may only be expanded in a formal sense.

2.2 What About Period 2 Elements?

A natural question arises for a bonding model that neglects d orbitals. If d orbitals are unimportant, why is it that elements of period 2 (the first row) do not form hypervalent derivatives? First of all, there is good evidence that they do in some cases, although under more restrictive circumstances than elements of periods 3 and below (see Section 9.2). Importantly, the size of period 2 elements may be too small to accommodate the extra electron density and increased coordination numbers; there would be too much ligand–ligand repulsion, except in unusual environments. Experimental and theoretical evidence suggests that the tbp geometry in the nucleophilic displacement mechanism at tetravalent carbon is a transition state, whereas for silicon it is an intermediate.[9] Quantum chemical calculations[10] have added another dimension to the relative stabilities of hypervalent period 2 and 3 elements. These suggest that delocalization of electron density from the axial bonds into the σ^* orbitals of the equatorial bonds results in a significant stabilization for tbp SiH_5^-. For CH_5^-, this interaction is destabilizing. Incidentally, SiH_5^- has been observed experimentally[11] and is the only hypervalent species known that possesses just hydrogen atoms as ligands.

2.3 Recent Developments

Since about 1990, the availability of fast, high-level computing power has led to a range of theoretical studies of formally hypervalent compounds, and of the phenomenon of hypervalency. Ab initio calculations were carried out by Schleyer, and bond orders were obtained for a large number of hypervalent molecules.[4] In all systems studied, the total bond order was found to be less than 4.0; that is, the central atom possessed fewer than eight valence electrons, with electronegative ligands like O and F producing the lowest values. Subsequently, Cioslowski determined bond orders using a different method,[12] but reached the same conclusions; namely that in molecules like SF_6, the S–F bond order is low (0.64), so that the sulfur atom only contains 7.68 electrons in its valence shell. Gillespie used the electron localization function (ELF) to study the same phenomenon.[13] The ELF partitions electron density in the molecule into regions where there is a high probability of finding a pair of electrons of opposite spin: these regions then correspond to bonding or nonbonding electron pairs, and the polarity of bonds is revealed in the unequal partitioning of bonding pairs between the atoms

Table 1 Valence-shell electron populations in a variety of formally hypervalent compounds

Molecule	Valence shell pop.	Molecule	Valence shell pop.
PF_5	5.33	SF_6	6.18
PCl_5	7.13	SeF_6	2.18
PMe_5	9.42	$SeMe_6$	10.98

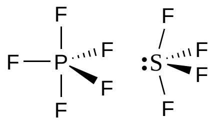
involved. Analysis of the ELF in a range of systems in fact revealed that most hypervalent molecules have a valence shell containing a total of eight or fewer electrons. However, some compounds possessing less electronegative ligands do exceed a total of eight electrons in their valence shell, as detailed in Table 1. Gillespie concluded that the bonding in hypervalent molecules does not differ in any significant way from that in molecules that obey the octet rule, and reiterated that the Lewis model is an empirical observation with no grounding in theory.

2.4 N-X-L Notation

At this point, it is instructive to introduce a system to classify the bonding around an atom: the N-X-L system.[14] First suggested in 1980, it is particularly useful for the species discussed in this article. In this classification scheme, N is the number of valence-shell electrons formally assigned to the central atom X; and L is the number of ligands directly bonded to X. The N-X-L designations are illustrated in Figure 2 for each species listed.

2.5 VSEPR Theory Basics

It is also useful to review briefly the rules of VSEPR theory with respect to the two simple molecules PF_5 and SF_4 (Figure 3). Only when the central atom possesses no lone pair electrons and is surrounded by simple, identical ligands is an ideal geometry realized. Thus, PF_5 will have an exact tbp geometry. However, the *pseudo*-tbp geometry of SF_4 shows distortions caused by repulsion from the sulfur lone pair. The spatially more demanding lone pair occupies an equatorial site, which provides it with more space than an axial site would allow. Note that both the F_{ax}–S–F_{ax} and F_{eq}–S–F_{eq} bond angles are contracted from the 'ideal' angles of 180° and 120°, respectively. However, the equatorial angle is contracted to a greater extent. This contraction will have significance when 10-X-5 and 10-X-4 geometries are compared in Section 5.4 for more complex ligands.



Angle F_{ax}–X–F_{ax} (deg)	180	173.1
Angle F_{eq}–X–F_{eq} (deg)	120	101.6
Distance F_{ax}–X (pm)	158	164.6
Distance F_{eq}–X (pm)	153	154.5

Figure 3 Structures of PF_5 and SF_4

2.6 Primary Literature References

Aspects of hypervalent silicon,[15] tin,[16] phosphorus,[17] arsenic,[18] sulfur,[19] halogens,[20] noble gases,[21] and pentacoordination[22] have been reviewed previously. In addition, comprehensive reviews on organic,[23] organometallic,[24,25] and coordination chemistry[26,27] are useful. Several inorganic texts[8,28] have a wealth of information, particularly relating to halogenated hypervalent molecules and ions. More recent reviews have been published on hypervalent iodine[29–31] and boron/aluminum[32] chemistry in organic synthesis, hypervalent silicates as organocatalysts,[33] bonding descriptions of hypervalent compounds,[13,34,35] inter-ligand hypervalent interactions,[36,37] cyclic aromatic systems with hypervalent centers,[38] hypervalent xenon chemistry,[39] hypervalent tin[40] and crystal engineering using hypervalent interactions.[41] The topics of hypervalent chalcogen stereochemistry,[42] hypervalent transition metal catalysed ligand coupling reactions,[43] and low coordinate hypervalent phosphorus[44] have also been covered.

3 SYNTHESIS AND STABILITY OF HYPERVALENT COMPOUNDS

3.1 Primary Factors Stabilizing the Hypervalent Bond

There are two main principles for the stabilization of the hypervalent bond. The first has already been stated: electronegative groups stabilize the hypervalent bond. This is illustrated by reference to equations (1–6), where a halogen or halide source reacts with a nonhypervalent species to produce a hypervalent product; for tbp or pseudo-tbp geometries, the halogen occupies the axial positions.[15,17,19,20,28] Addition may or may not be accompanied by oxidation of the central atom. Moreover, addition is not limited to halogens; for example, nitrogen and oxygen bases are perfectly suitable (equations 7 and 8).[27]

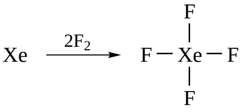
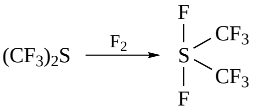
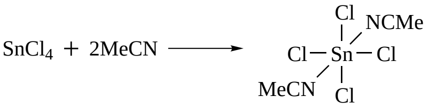
10-Si-5 (4)



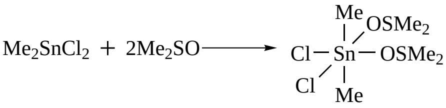
12-Xe-4 (5)



10-S-4 (6)



12-Sn-6 (7)



12-Sn-6 (8)

Substituent site preferences in a tbp are based on (what is commonly referred to as) an apicophilicity scale which takes into account several factors, so the ordering of axial/equatorial site preferences may not always strictly follow electronegativity expectations (Section 5.1). For a sp geometry, the more electronegative groups occupy the basal positions.

The second principle may be even more important than the first: the hypervalent bond is stabilized by the steric constraints of small rings. Specifically, this usually means the incorporation of the central atom into four- and five-membered rings. These rings stabilize 90° bond angles about the central atom, and such an orientation introduces the least strain in the ring. This principle is often stated as the preference of four- and five-membered rings to span axial/equatorial positions in a tbp. Equations (9–11) illustrate the principle for reactions involving the synthesis of hypervalent products from nonhypervalent reactants.[15,17] Rings can also be incorporated via substitution reactions using hypervalent starting materials (equations 12 and 13).[17,19]

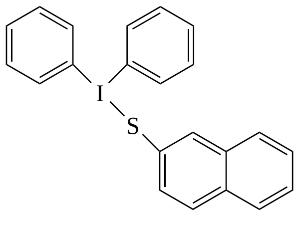
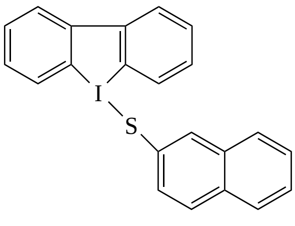
(13)

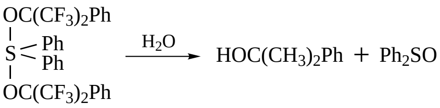


(**8**)

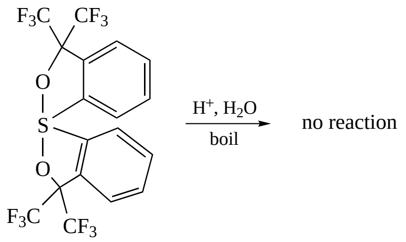


(**9**)

The importance of rings in supporting these hypervalent systems is clearly shown by the relative stabilities of cyclic versus acyclic structures. For example, (**8**) undergoes slow decomposition at ambient temperature, while (**9**) shows no decomposition over several months.[20] A more dramatic demonstration of the stability introduced by rings is illustrated for sulfuranes (**10**) and (**11**) in equations (14) and (15).[6] However, recently the first noncyclic 10-S-5 sulfuranide dioxide anion, $[(CF_3)_3SO_2]^-$ has been reported and structurally characterized. The compound exhibits a tbp structure with equatorial oxygen atoms.[45]

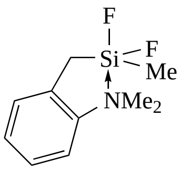


(**10**) (14)



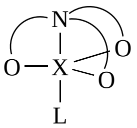
(**11**) (15)

Judicious choice of ring systems can even overcome the usual preference of electronegative ligands for axial sites. For example, it is well known that the usually tetrahedral 8-Si-4 silanes can function as Lewis acids, particularly when very electronegative substituents are attached to silicon. Molecule (**12**) illustrates the formation of a five-membered ring through intramolecular coordination.[15] Here, the steric requirements of the ring to span axial/equatorial positions outweigh the electronegativity preferences, and one of the two fluorine substituents is forced into an equatorial site.

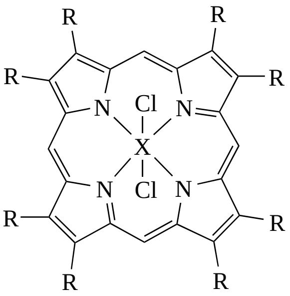


(**12**)

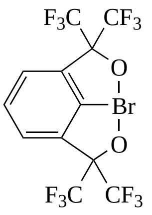
Polydentate ligands also lead to isolation of derivatives with hypervalent bonds. Examples of tetradentate-ligated species are the 'atranes' (**13**)[22,46,47] and porphyrins (**14**).[48] Various linkages, both saturated and unsaturated, can connect the oxygen and nitrogen ligand atoms in the atranes, and the R substituent on the porphyrin ring can be varied systematically. Planar tridentate-ligated examples are (**15**)[6] and (**16**).[49] In fact, 10-X-3 (X = P, As, Sb) species can only be isolated under the severe constraints of the ligand illustrated. A striking example of the delicate balance that exists between ligand and product is shown for (**17**) in equation (16).[50]



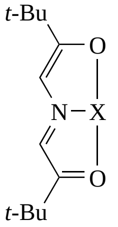
(**13**) X = Al, Si, P



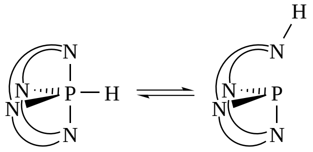
(**14**) X = Sn, Ge



(**15**)



(**16a**) X = P
(**16b**) X = As
(**16c**) X = Sb



10-P-5 8-P-3 (16)

(**17a**) (**17b**)

Compound (**17**) is synthesized by the treatment of the appropriate cyclic amine with tris(dimethylamino)phosphine at 100 °C, resulting in the elimination of three moles of dimethylamine. The products obtained are dependent on the number of methylene groups bridging the nitrogen atoms. When all four bridges are ethylene, $(CH_2)_2$, only (**17a**) is observed; when all are trimethylene, $(CH_2)_3$, only (**17b**) is found. When there are two of each type, both tautomers are present.

3.2 Other Stabilizing Factors

The above principles are the most important factors in the stabilization of the hypervalent bond. However, there are other general considerations to take into account.[6] One is the preference for a relatively electropositive central atom: a positive charge develops at this center, and is most easily accommodated by such an atom. In addition, an electropositive equatorial ligand will assist in stabilizing this positive charge at the hypervalent center. Other factors, primarily governing site preference and orientation in tbp and pseudo-tbp geometries, have significance, and these are elaborated in Section 5.

3.3 Periodic Trends

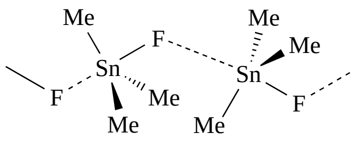
There are few periodic generalizations that can be made concerning hypervalent molecules, since the factors contributing to stability, such as oxidation potential, central atom size, type of ligands, and ionic versus covalent bonding type, all interact in a complex manner. However, some general trends are evident.

3.3.1 Inert Pair and Alternation Effects

Electronegativity generally decreases down a group in the p-block, and it may be thought that higher oxidation states are therefore more stable for the heavier congeners in a group. However, this is not the case, as insertion of the first row of transition elements and of the lanthanide elements in the third and fifth periods causes the p-block elements directly following these changes to have a higher electronegativity than would otherwise be the case. Group 15 exemplifies this phenomenon admirably: the electronegativity of As (2.2) is identical to that of phosphorus, and that of Bi (2.0) is almost the same as that of Sb (2.1). This Alternation Effect in electronegativity down the Group affects the stability of higher oxidation states for As and Bi: a reduction in ionic resonance energy accompanies the increase in electronegativity and is reflected in weaker bonds to F, O and Cl than would otherwise be the case. Thus, PCl_5 and $SbCl_5$ are stable molecules at ambient temperatures, whereas $AsCl_5$ decomposes above −50 °C, and $BiCl_5$ has never been reported. Operating in tandem with this phenomenon is the *Inert Pair Effect*, whereby a monotonic decrease in bond strengths down a group serves to destabilize higher oxidation states for the heavier congeners. The two effects conspire in the fifth period, and hypervalent compounds of bismuth form only under the most forcing conditions.

3.3.2 Increase of Coordination Number with Size

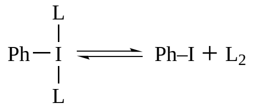
The ability to increase coordination number with central atom size within a group is perhaps the most generally reliable periodic trend. The increased coordination shows up distinctly in period 5. For example, no complex forms between pyridine and Me_3SiCl, while Me_3SnCl· pyridine is stable.[27] In addition, trialkyltin halides have a much greater tendency to associate in the solid state than do their silicon and germanium analogs; for example, trimethyltin fluoride (**18**) is associated in the solid state. Even in solution, tributyltin fluoride associates to give polymeric structures. Likewise, PF_5 and AsF_5 are both monomeric, but SbF_5 is associated, even in the gas phase. SF_4 and SeF_4 are monomeric; TeF_4 in the solid state forms polymeric 12-Te-5 pseudo-octahedra via fluoride bridges. Size is also a factor for the linear trihalide monoanions X_3^-: in general, their thermal stabilities increase with increasing central atom size.[47]



(**18**)

3.3.3 Oxidizability of the Central Atom

For hypervalent molecules formed by oxidation, the ability to remove electrons from the central atom is a key factor. The formation of noble gas derivatives,[47] such as XeF_2, is related to the ionization energy of the element in a rather straightforward manner. In fact, Bartlett originally reasoned that since PtF_6 oxidized molecular oxygen to give O_2^+ PtF_6^-, xenon should be similarly oxidized, since the ionization energies of O_2 and xenon are comparable. The ionization energies of the noble gases above krypton are prohibitively high to allow this kind of chemistry. Indeed, although argon has now been activated photochemically at 10 K to form HArF,[51] only xenon and krypton form tractable compounds. (*see* ***Noble Gases: Inorganic Chemistry***). The formation of hypervalent organoiodine(III) dihalides (**19**) is directly related to the oxidizing ability of the ligating halogen (equation 17).[20] This equilibrium is shifted to the left for L = Cl and to the right for L = Br and I.



(17)

10-I-3 8-I-1

(**19**)

3.3.4 Central Atom Charge

Central atom charge is also important, particularly for hypervalent species formed by simple addition. This is best illustrated by trends in the Group 14 derivatives $R_{4-n}ML_n$ (M = Si, Ge, Sn, Pb; L = I, Br, Cl, F). In general, the Lewis acidity of the central atom increases in the order L = I < Br < Cl < F, and $n = 1 < 2 < 3 < 4$. For $n = 1$, complexes appear to be limited to tbp 1:1 adducts, while for $n > 1$, oct 1:2 adducts are common.[27]

3.3.5 Covalent Versus Ionic Bonding

The tendency to form covalent rather than ionic bonds is crucial in the formation of hypervalent compounds. Incorporation of fluoride as a ligand usually stabilizes covalent species. For example, PF_5 is covalent. However, PCl_5 is characterized by the equilibria shown in equations (18) and (19). In the gas and liquid phases, the molecular form exists, while in the solid state it is ionic, consisting of PCl_4^+ and PCl_6^- ions. In solution in nonpolar solvents, the molecular form is favored, while the ionic form described in equation (18) predominates in polar solvents. At low concentrations, some PCl_4^+ and Cl^- may be present owing to the equilibrium in equation (19). For equation (20) (R = alkyl and aryl), if L is a reasonably basic anion such as Cl, Br, I, or OPh, the ionic phosphonium salt (**20**) is favored. With L = F or *O*-alkyl, the

pentacoordinate species (**21**) is observed.[52,53]

$$2PCl_5 \rightleftharpoons PCl_4^+ + PCl_6^- \quad (18)$$

$$PCl_5 \rightleftharpoons PCl_4^+ + Cl^- \quad (19)$$

$$R_4P^+L^- \rightleftharpoons R_4PL \quad (20)$$

8-P-4 (**20**) 10-P-5 (**21**)

4 SPECTROSCOPY AND DIFFRACTION AS STRUCTURAL PROBES

4.1 Diffraction Techniques

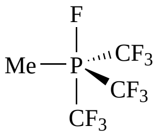
Leaving aside single-crystal X-ray diffraction, which has produced the vast majority of structural data for compounds of all types, gas-phase electron diffraction deserves special mention in the study of hypervalent molecules. Many hypervalent p-block species are gases or volatile liquids at ambient temperatures, and hence are not amenable to study by conventional X-ray diffraction techniques. Main group molecules like PF_5, SF_4, and ClF_3, and noble gas compounds like XeF_6 were structurally determined by electron diffraction during the 1960s, and these studies were expanded to encompass important mixed-ligand species like the methyl and chloro-substituted derivatives of PF_5. These gas-phase studies produced the main body of evidence around which VSEPR theory developed.[54]

4.2 Vibrational Spectroscopy

IR and Raman spectroscopy are extremely useful for the determination of structures of hypervalent species, particularly for simple molecules where complete spectral assignments can be made.[55] For mixed halide systems in tbp or pseudo-tbp geometries, such as PF_2Cl_3 or SF_2Cl_2, vibrational data can discriminate unambiguously between possible isomers. The fast timescale of vibrational spectroscopy proved particularly useful in showing that the 14-X-6 species BrF_6^- is octahedral in solution; in contrast to IF_6^-, where the nonbonding electron pair displays stereochemical activity.[56] For high-symmetry molecules, rotational-vibrational spectroscopy can afford accurate molecular constants that permit a full structural determination of molecular structure, as was demonstrated elegantly for H_3PF_2 (Figure 4).[57]

4.3 NMR Spectroscopy

Multinuclear NMR spectroscopy is indispensable to the study of hypervalent species for several reasons. First of all, exchange processes can be identified and measured. For example, the ^{19}F NMR spectrum of SF_4 shows two types of fluorine resonances at low temperature; these coalesce to a single feature at higher temperatures. For PF_5 and $RSiF_4^-$, only one resonance is observed, even at low temperatures. However, for the derivatives RPF_4 and $R_2SiF_3^-$, behavior similar to SF_4 is observed. Exchange mechanisms have been advanced to explain this fluxional behavior (see Section 5.2). Secondly, the chemical shift can usually be correlated with coordination number: higher coordination leads to resonances at higher fields. For example, 31P the chemical shift values for PCl_3, PCl_4^+, PCl_5, and PCl_6^- are 219, 96, −80, and −281 ppm, respectively. However, this trend is highly substituent-dependent, and similar ligands must be present to rely on such a correlation. A third application is the use of coupling constants to assign substituent sites in a tbp or pseudo-tbp. Coupling constants are dependent on the amount of s character in a bond: the greater the s character, the larger the coupling constant. A dramatic illustration of this phenomenon is found in the low-temperature ^{13}C NMR spectrum of $Me(CF_3)_3PF$ (**22**), a tbp molecule that has one fluorine and one CF_3 group occupying axial positions. The one-bond P–C coupling to the equatorial CF_3 groups is 258 Hz whereas that to the axial CF_3 is only 17 Hz.[58]



(**22**)

4.4 Other Spectroscopic Techniques

Although less important than gas-phase electron diffraction, microwave spectroscopy is a valuable technique for the structural characterization of gases and volatile liquids. For example, HPF_4 and H_2PF_3 (Figure 4) were shown in a combined electron diffraction and microwave spectroscopy study to be tbp species in which the hydride ligands occupy equatorial sites.[59]

Mössbauer Spectroscopy has also proved useful for the study of hypervalent species, since many of the central atoms, such as Sn, Sb, Te, I, and Xe, are suitable for study by this technique.[60] Gas-phase UV photoelectron spectroscopy, while not particularly important for geometry elucidation, has

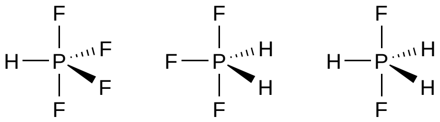


Figure 4 Equatorial H atoms in tbp hydrido derivatives of PF_5

been used to obtain information on the electronic structures of hypervalent molecules.[61] X-ray photoelectron spectroscopy is also useful for determining charge distributions, particularly in demonstrating the greater negative charge on the axial substituents in a tbp.[62]

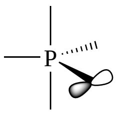
5 PENTACOORDINATE AND RELATED STRUCTURES

The greatest body of work in hypervalent chemistry has been carried out on 10-X-5 structures, most often tbp phosphoranes. However, the results have been generalized in most cases to include all pentacoordinate main group elements. They also have implications for pseudo-tbp structures such as the 10-S-4 sulfuranes. Some of the more important aspects are described in this Section.

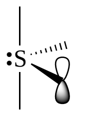
5.1 Apicophilicity

Apicophilicity can be defined as the change in energy when an apical (or axial) ligand and an equatorial ligand in a tbp structure are exchanged; the more apicophilic ligand prefers the axial site. This relative scale has been constructed and quantified by experimental and theoretical techniques. For example, Trippet[63] devised a scale based on dynamic NMR measurements of pentacoordinate phosphoranes. Apicophilicity is dependent on several factors such as electronegativity, π-bonding ability, and size of the ligand. This scale has been examined by many researchers, and no two approaches give exactly the same ordering. However, the following is a general ordering of decreasing apicophilicity: F > H > CF_3 > OPh > Cl > SMe > OMe > NMe_2 > Me > Ph. Caution is necessary in using this scale: some results imply that Cl may be more apicophilic than F in certain systems.[64]

Theoretical work on the model phosphorane PH_5 has shown that π-acceptor ligands prefer axial sites and π-donors favor equatorial positions in a tbp.[65] However, a significant difference is observed when the orientation of a π-donor p orbital at an equatorial site is examined for a 10-P-5 phosphorane and a 10-S-4 sulfurane.[66] For the phosphorane, the preferred orientation is in the equatorial plane (**23**), while for the sulfurane it is perpendicular to it (**24**). The difference arises from the interaction of the ligand donor orbital with the sulfurane lone pair.



(**23**)



(**24**)

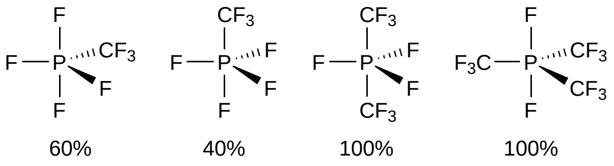


Figure 5 Trifluoromethyl derivatives of PF_5

One particularly intriguing family of molecules is the trifluoromethyl derivatives of PF_5, illustrated in Figure 5. The structure adopted by these molecules depends strongly on their makeup: three CF_3 groups occupy the equatorial sites in a tbp, two occupy the axial ones, and a single CF_3 moiety occupies either position with statistical probability.[67] The CF_3 ligand has a group electronegativity comparable to that of Cl, and so electronic factors would place it preferentially in an axial site. However, the steric bulk of the ligand appears to override these considerations, so that these phosphoranes adopt structures that minimize contacts between CF_3 groups. This series of molecules demonstrates that apicophilicity is a complicated phenomenon, and that each case should be judged on its merits.

5.2 Site Exchange: Pseudorotation

One of the unique aspects of hypervalent chemistry is the fact that two different types of bonds can exist in one molecule (for example, the axial and equatorial P–F bonds in PF_5) and that these bonds may interconvert by an isomerization process. On account of its slow timescale, NMR spectroscopy is the ideal method to study such exchange processes, and PF_5 was one of the first pentacoordinate molecules to be studied using this technique. Only one resonance (a doublet due to ^{31}P coupling) is observed in the ^{19}F NMR spectrum down to $-190\,°C$. However, RPF_4 derivatives display temperature-dependent spectra: at ambient temperatures only one fluorine resonance is seen, while at low temperatures resonances owing to inequivalent fluorine atoms are observed. Berry[68] first proposed an intramolecular exchange process to account for these observations. He showed that, in a tbp (Figure 6(a)), bending two of the equatorial atoms away from each other and the two axial atoms toward each other equilibrates these atoms at the basal sites of a sp transition state (b). Continuing this deformation results in an interchange of the atoms at the axial and equatorial positions (c). This process is known

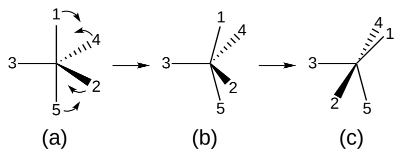

Figure 6 The Berry pseudorotation process

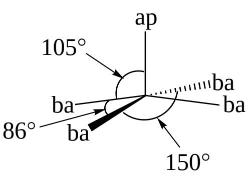
as the *Berry pseudorotation* (or simply *pseudorotation, see Pseudorotation*). Note that one of the equatorial atoms, 3, remains fixed in this scheme and acts as the fulcrum for the process. Continuation of this process with different equatorial pivot atoms results in an equilibration of all five atoms. The energy barrier to this process is very low and for PF_5 cannot be measured by NMR spectroscopy; however, introduction of other substituents (as in RPF_4) raises the exchange barrier to a point where it can be frozen out on the NMR timescale. For some species of the type R_2PF_3, exchange does not occur even at ambient temperature, owing to the necessity of placing one or more R group in an energetically unfavorable axial position.

Pseudorotation has also been shown to be important in 10-S-4 and 10-Si-5 species such as SF_4[19] and $R_2SiF_3^-$.[15]

While pseudorotation is usually invoked to explain the observed exchange phenomena, alternative intramolecular processes have been proposed, such as the *Turnstile Mechanism*.[52] This involves rotation of a pair of ligands on one side of the tbp and the remaining three on the other side. Both Berry and turnstile mechanisms result in a similar exchange, albeit via different transition states. It is difficult to differentiate these mechanisms experimentally; however, the structural data described in the next Section appear to support the Berry process.

5.3 Structural Distortions in the Solid State

The low barrier to exchange of axial and equatorial substituents suggests that structural distortions of 10-X-5 derivatives from a tbp might be observed in ground-state geometries as well. Calculations show that the lowest energy arrangement of five points on a sphere is a tbp; however, the sp is only slightly less stable, and certain substituents might prefer this geometry. The idealized angles for the sp are 105° (ap/ba), 150° (trans-ba/ba), and 86° (cis-ba/ba), as depicted in structure (**25**).[17]



(**25**)

It is important to note that the sp of (**25**) is related to the IF_5 sp (see Figure 2) in the sense that the ligands attached to the central atom are disposed at the vertices of a similar polyhedron. However, they differ electronically, since the sp of (**25**) is a 10-X-5 species and that of IF_5 is 12-X-5. The central atom in the sp of a 10-X-5 species will lie above the basal plane, while that in a 12-X-5 species will lie below the basal plane owing to lone pair/bond pair repulsion.

The most detailed structural work on pentacoordinate structures has been carried out and compiled by Holmes,[17,22] and some of his findings are summarized here. Basic VSEPR rules can account qualitatively for geometries with simple acyclic ligands; for example, the series Me_nPF_{5-n} ($n = 1-3$). However, as ligands become more complex, other factors predominate. Preference rules have been derived for both the tbp and sp geometries and are listed here in order of probable importance.

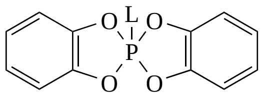
For the tbp:

1. Four- or five-membered cyclic systems preferentially span axial/equatorial positions.
2. The most electronegative ligands preferentially occupy axial sites.
3. π-Donor ligands, in general, are positioned at equatorial sites.
4. Steric effects are minimized by locating bulky groups in equatorial positions.

For the sp:

1. Four- or five-membered cyclic systems preferentially span cis basal positions.
2. The most electronegative ligands preferentially occupy basal sites.
3. π-Donor ligands, in general, are positioned at the apical site.
4. Steric effects are minimized by locating a bulky group in the apical position.

In addition, factors favoring the sp over the tbp have been identified. The most important appears to be the incorporation of unsaturated five-membered rings into 10-X-5 species. Apparently, less ring strain is introduced when such rings span cis basal positions in a sp rather than axial/equatorial sites in a tbp. In fact, the sp geometry predominates when two such rings are present, as in structure (**26**).



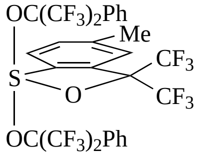
(**26**)

Referring to geometries like (**26**) as a sp or RPF_4 as a tbp are only approximations, since only a species with all five substituents identical (like PF_5) will exhibit an exact tbp geometry. In fact, the geometry of (**26**) is close to a sp and that of RPF_4 is close to a tbp. But how close? A simple metric plots the axial and equatorial angles, versus a measure of the distortion coordinate, the dihedral angle between faces 124 and 245 (see Figure 6(a)). A more complicated scheme involves determining all of the dihedral angles.[17,22] No matter which method is used, the findings are essentially the same. Virtually all of the known structures of 10-P-5 molecules are

either close to a tbp or sp geometry, or show distortions that lie along the Berry pseudorotation coordinate (the conversion of (a) to (b) in Figure 6). This has now been extended to most other 10-X-5 species, both neutral and ionic. The fact that these ground-state geometries closely approximate the Berry coordinate lends support to the pseudorotation exchange mechanism described in Section 5.2.

5.4 Apicophilicity ‘Anomalies’ in 10-S-4 Sulfuranes

In general, the trends found in 10-X-5 derivatives find parallels in 10-X-4 species; however, the presence of a nonbonding pair of electrons on the central atom can alter certain aspects, such as the equatorial lone pair orientation described in Section 5.1. More importantly, the F_{ax}–S–F_{ax} angle in SF_4 (Figure 3) suggests that the ring strain introduced by having a small ring span two equatorial positions should be less important than in 10-X-5 species. In fact, sulfurane (**27**) has the ring spanning equatorial sites.[69]



(**27**)

5.5 The Puzzling $SbPh_5$ Structure[8,47]

The vast majority of pentacoordinated molecules unperturbed by rings adopt regular or approximate tbp structures: for example, the organic derivatives Ph_5P, Ph_5As, Me_5As, and Me_5Sb. However, Ph_5Sb is sp in the solid state and appears to retain this geometry in solution. No adequate explanation for this behavior has been advanced. Even (p-$MeC_6H_4)_5Sb$ is tbp. The only other simple species shown unambiguously to favor a sp over a tbp structure is $InCl_5^{2-}$ as the NEt_4^+ salt,[70] although this appears to be highly dependent on crystal packing since the analogous PPh_4^+ and $PPh_2Cl_2^+$ salts each contain tbp $InCl_5^{2-}$.[71,72]

6 REACTIVITY OF HYPERVALENT COMPOUNDS

6.1 General

Sterically unsaturated hypervalent halides are quite reactive. Typical reactions involve the transfer of halogen and a reduction in coordination number. For example, hydrolysis is usually facile and sometimes violent (equations 21 and 22). Many of the fluorides are excellent fluorinating reagents. SF_4 is useful for the conversion of ketones and carboxylic acids to CF_2 and CF_3 groups, respectively (equations 23 and 24).[73] ClF_3 is a powerful fluorinating agent for inorganic chlorides and oxides (equations 25 and 26).

$$PCl_5 + 4H_2O \longrightarrow H_3PO_4 + 5HCl \quad (21)$$

$$SF_4 + 2H_2O \longrightarrow SO_2 + 4HF \quad (22)$$

$$Me_2CO + SF_4 \longrightarrow Me_2CF_2 + F_2SO \quad (23)$$

$$PhCO_2H + 2SF_4 \longrightarrow PhCF_3 + 2F_2SO + HF \quad (24)$$

$$AgCl + ClF_3 \longrightarrow AgF_2 + \tfrac{1}{2}Cl_2 + ClF \quad (25)$$

$$NiO + \tfrac{2}{3}ClF_3 \longrightarrow NiF_2 + \tfrac{1}{3}Cl_2 + \tfrac{1}{2}O_2 \quad (26)$$

Octahedral hypervalent halides, on the other hand, are much less reactive (*see Coordinative Saturation & Unsaturation*). For example, PF_6^- is a widely used noncoordinating anion (*see Noncoordinating Anion or Cation*); $SiF_4\cdot$ bipyridine is stable in the presence of moisture; and SF_6 is remarkably inert: it can be treated with steam at 500 °C or with molten KOH without any effect. It is nontoxic and used as an insulating gas in high voltage applications.

Many coordinatively unsaturated species are good Lewis acids, owing to the positive charge induced on the central atom as a result of electronegative substituents. For example, PF_5, and to an even greater extent AsF_5 and SbF_5, are excellent fluoride ion acceptors, yielding robust XF_6^- anions that stabilize such acidic cations as S_4^{2+} and XeF_5^+.

Oxidative Addition is also common for those central atoms that can increase their oxidation state (*see Oxidation Number*) (equations 27 and 28). Substitution of halogen by organic groups is useful for the preparation of organo derivatives, as mentioned in Section 3.1 (equations 12 and 13).

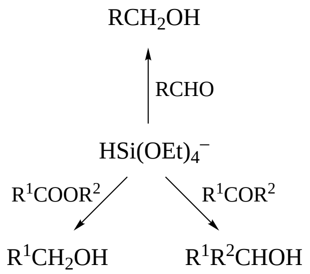
$$\underset{\text{10-S-4}}{SF_4} + ClF \longrightarrow \underset{\text{12-S-6}}{SF_5Cl} \quad (27)$$

$$\underset{\text{10-Cl-3}}{ClF_3} + F_2 \longrightarrow \underset{\text{12-Cl-5}}{ClF_5} \quad (28)$$

6.2 Silicon in Organic Synthesis[15]

Hypervalent silicon compounds have found wide utility in organic synthesis. In general, pentacoordinated anionic silicates are more reactive toward nucleophiles than are tetracoordinated silanes. For example, Mes_2SiF_2 is unreactive toward water, while (the 18-crown-6 potassium salt of) $Mes_2SiF_3^-$ is completely hydrolyzed within minutes. Similarly, the pentacoordinate anion $HSi(OEt)_4^-$ is an effective reducing agent for aldehydes, ketones, and esters at or below room temperature (Scheme 2); no such reaction occurs with $HSi(OEt)_3$. The difference in relative reactivities of hypervalent and nonhypervalent species is relevant to the intermediates proposed in Section 7.6.

The oct 12-Si-6 dianion $RSiF_5^{2-}$ has been carefully studied, and reactions with this reagent are stereospecific. Some of

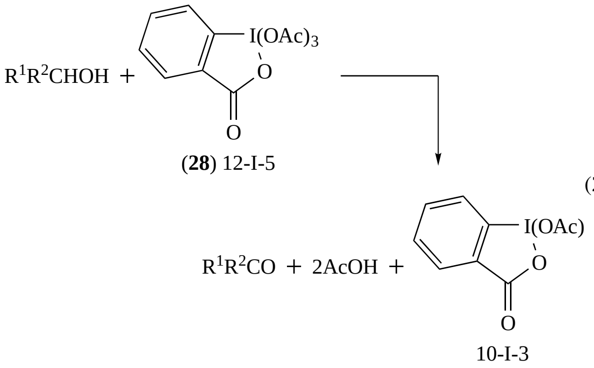


Scheme 2

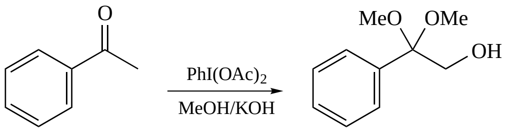
these are illustrated in Scheme 3. For R = alkyl, treatment with *N*-bromosuccinimide (NBS), bromine, or copper(II) bromide yields alkyl halides with inversion of configuration at carbon. For R = alkenyl, cleavage by halogens leads to alkenes with retention of configuration. By comparison, 8-Si-4 alkenyltrimethylsilanes proceed with inversion of configuration under similar conditions. This is a result of the usual trans addition and anti elimination in the latter case, while direct electrophilic displacement may account for the stereochemistry in the former. Reaction of $RSiF_5^{2-}$ with other metal salts (Ag^+, Cu^+, P^{2+}) can lead to reductive coupling.

6.3 Hypervalent Iodine Reagents

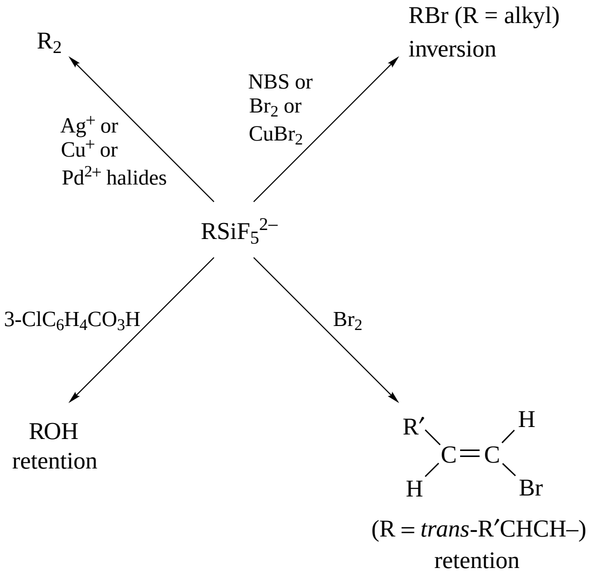
Hypervalent organoiodine compounds have found wide utility in organic synthesis. Primary and secondary alcohols can be oxidized to aldehydes and ketones with the 12-I-5 compound (**28**), according to equation (29).[74] α-Hydroxy dimethyl acetals can be synthesized under basic conditions with the 10-I-3 reagent $PhI(OAc)_2$ (equation 30).[75] The topic has been recently reviewed.[29–31,76]



(29)



(30)



Scheme 3

6.4 Basicity of Hypervalent Lone Pairs

10-X-4 derivatives possess lone pairs of electrons in an equatorial position that may show donor ability toward metals and other Lewis acids. For example, SF_4 can be oxidized to OSF_4; however, the BF_3 complex of SF_4 exists as the ionic salt $[SF_3][BF_4]$. The high degree of s character in the equatorial lone pair orbitals of 10-S-4 sulfuranes and 10-P-4 phosphoranide anions should lower their donor ability relative to the excellent ligands R_2S and R_3P. In addition, the presence of very electronegative groups might reduce their basicities; however, since PF_3 is an excellent ligand, the presence of electronegative groups should not ipso facto diminish coordinating ability. Compounds that can be formally considered complexes of phosphoranides exist, (**29**) and (**30**), but they are usually prepared by routes other than simple coordination, such as nucleophilic attack on pentacoordinated phosphorus[77] and oxidative addition of fluorine to a metallated difluorophosphine[78] (equations 31 and 32). Note the use of the hypervalent fluorinating reagent in the latter reaction. Perhaps these are best viewed as metallasubstituted phosphoranes. However, the 10-X-3 species (**16**) show excellent donor properties,[79,80] and both lone pairs can be coordinated under suitable conditions (Scheme 4).

7 HYPERVALENT INTERMEDIATES AND TRANSITION STATES

7.1 General Considerations for Intermediates

Some of the most important hypervalent species are the reactive intermediates formed by nucleophilic attack at the central atom of a tetracoordinated molecule or ion. Indeed, many 10-P-5 and 10-Si-5 species can be considered as stabilized intermediates formed through such a process. Usually, it is assumed that the attacking group enters at an axial position, and the leaving group leaves from an axial position. Pseudorotation may occur in the tbp intermediate to place the leaving group at an axial position. For phosphorus, this is a well documented process. For silicon, the entry position appears to be usually axial, but some data suggest equatorial entry for organometallic reagents. Since the axial bonds are longer and weaker, it is reasonable that a group will leave from this position.

The possible pathways for reactions at tetracoordinated phosphorus and silicon are summarized in Figure 7. Path 1 is directly analogous to carbon chemistry, in which

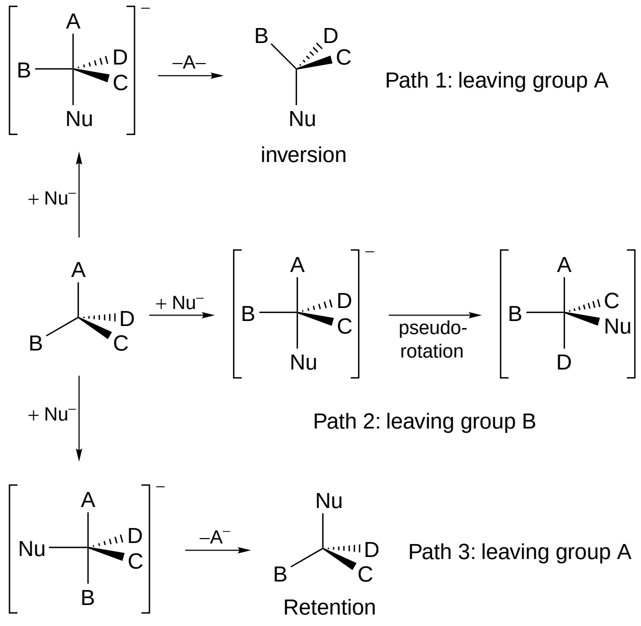

Figure 7 Pathways for nucleophilic substitution at tetracoordinated phosphorus and silicon. Path 3 is postulated for silicon only[81]

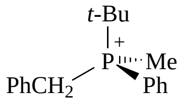
inversion of configuration is observed; however, for carbon the pentacoordinate structure is a transition state, not an intermediate. Path 2 involves pseudorotation of the intermediate and leads to retention of configuration. Only for silicon has equatorial entry been suggested via Path 3. Some very important reactions proceed through 10-P-5 intermediates, such as the Wittig reaction.[52,53] Several specific examples from phosphorus, silicon, and sulfur chemistry are discussed below to illustrate the principles stated above and to demonstrate the importance of reactions involving hypervalent intermediates.

7.2 Hydrolysis of Cyclic Phosphate Esters

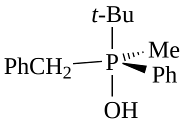
Cyclic phosphate esters containing five-membered rings hydrolyze 10^5–10^8 times faster than their acyclic analogs. However, for six- and seven-membered rings, hydrolysis rates are comparable to those of their acyclic congeners. From the principles already discussed, these data suggest that the preference for five-membered rings to span axial/equatorial positions in a tbp may be a factor in the rate enhancement. In fact, Westheimer[82] developed a now well-established mechanism based on this fact; one that not only accounts for the observed rate enhancement but also for product distributions where pseudorotation of an intermediate occurs. For example, the acid-catalyzed hydrolysis of (**31**) gives two phosphorus products; one ring opened and the other with the ring intact. X-ray diffraction analysis of (**31**) and other related cyclic systems shows the O–P–O angle in the ring to be 99°; hence spanning the axial/equatorial positions in a tbp relieves about 9° of ring strain. The proposed mechanism (Scheme 5) involves initial nucleophilic attack by water to give (**32**). If displacement from this intermediate occurs, (**34**) is formed. However, pseudorotation of (**32**) can occur to give (**33**), and this would lead to the final product (**35**). For the specific case of hydrolysis of (**31**), the products (**34**) and (**35**) are produced in an approximate 60:40 ratio. The exact mechanism is somewhat more complicated, but the key points are that the intermediates are stabilized by the ring orientation (leading to enhanced rates), and that formation of (**35**) can only occur via pseudorotation.

7.3 Acyclic Phosphonium Salts

In general, hydrolysis of acyclic phosphonium salts leads to inversion products via Path 1. The incoming group will attack at the tetrahedral face, resulting in a tbp with the leaving group at the opposite axial position. This mechanism can be modified by increasing the steric bulk of substituents. For example, base hydrolysis of (**36**) leads to retention of configuration. The *t*-butyl group effectively prevents the incoming nucleophile from attacking at a face that would put the preferred group (CH_2Ph, owing to electronegativity and leaving ability) in an axial position. Thus, the initial intermediate formed is (**37**), in which the bulky *t*-butyl group is in an unfavored axial position. Instead, pseudorotation places the leaving group ($PhCH_2$) in the preferred axial position for elimination of toluene via Path 2, which gives the final inverted product, (*t*-Bu)(Ph)MeP=O.



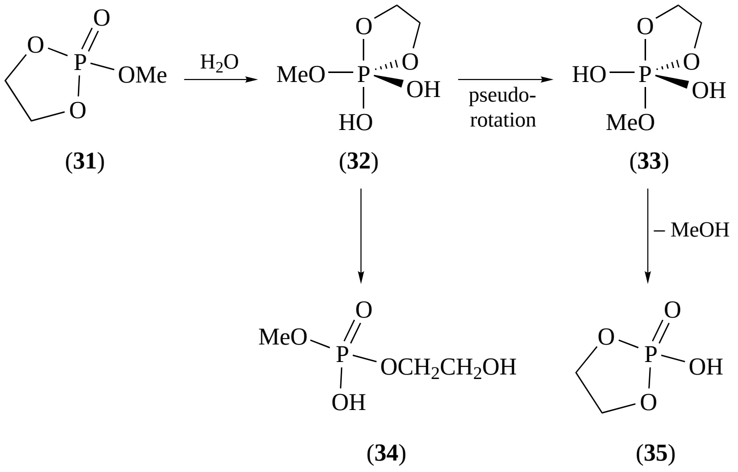
(**36**)



(**37**)

7.4 Enzyme Systems[17,22]

The wealth of structural and mechanistic information available for pentacoordinated phosphorus has provided a firm foundation upon which to explore more complicated

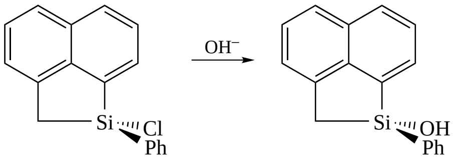


Scheme 5

systems where pentacoordinated phosphorus may play a key role. There are several important biological reactions that are catalyzed by phosphoryl- and nucleotidyl-transfer enzymes. Many of these are postulated to go through 'in-line' pentacoordinated mechanisms, in which both the incoming and departing groups are axial. For example, the transphosphorylation step of ribonuclease action on a dinucleotide substrate is suggested to go through a transition state that resembles the intermediates in Scheme 5.

7.5 Halosilanes

Nucleophilic attack at the silicon atom in halosilanes can lead to inversion or retention of configuration, depending on the nature of the leaving group.[81] When the leaving group is chloride, inversion is the usual course. Since fluoride is a poorer leaving group, both retention and inversion are observed with this halide, depending on various other factors. As usual, the incorporation of rings can alter the usual inversion path; retention is observed in equation (33).



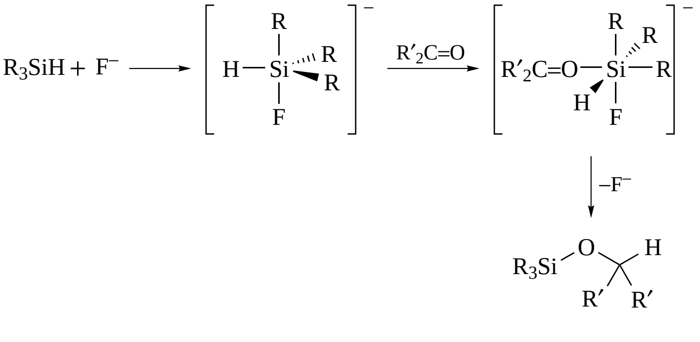
(33)

7.6 Catalytic Activation of Organosilicon Reagents by Nucleophiles[15]

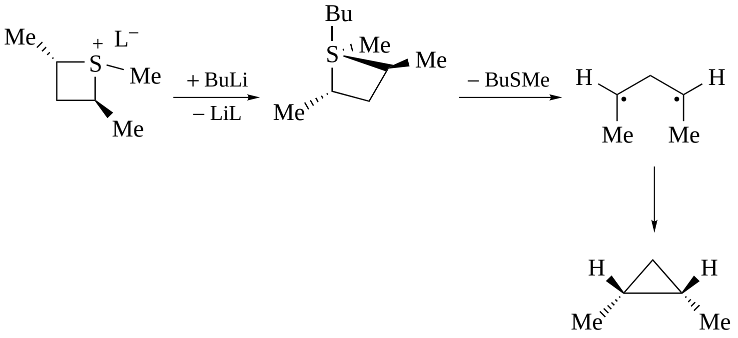
This is one of the most useful applications of organosilicon reagents in organic chemistry, and ionic fluorides are the most common catalysts for this purpose. For example, the reduction of carbonyl groups is proposed to go through both a 10-Si-5 and a 12-Si-6 intermediate, as shown in Scheme 6. Many other reactions, such as the activation of enoxysilanes for the synthesis of carbon–carbon bonds, are believed to proceed through hypervalent intermediates. With the knowledge that many 10-Si-5 silicates are significantly more reactive than their 8-Si-4 counterparts (Section 6.2), these mechanisms appear highly plausible.

7.7 Hypervalent Intermediates in Sulfur Chemistry[19,23]

Evidence for hypervalent intermediates in sulfur chemistry is less well established than in phosphorus and silicon chemistry. Racemization and reduction of sulfoxides each appear to go through hypervalent 10-S-4 sulfurane intermediates. In addition, pathways for the reaction of sulfonium salts with organometallics involve plausible hypervalent intermediates (Scheme 7). Ligand coupling with retention of configuration is presumed to occur via a sulfurane intermediate

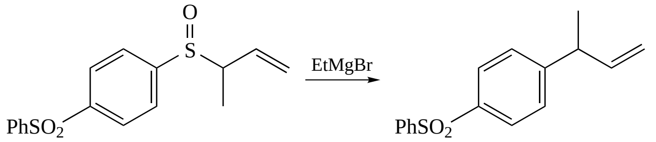


Scheme 6



Scheme 7

(equation 34).[83]



(34)

7.8 Transition State Model for Edge Inversion at 8-X-3 (X = Group 15 Element) Centers[84–86]

The isolation of stable 10-X-3 (X = P, As, Sb) derivatives (**16**) led to the idea that this geometry might represent the inversion transition state for trivalent XL_3 molecules. Inversion of these species had been considered to proceed in a similar manner to NH_3; that is, a vertex pathway whereby a vertex is inverted through the center of a tetrahedron via a trigonal planar transition state. In an edge inversion mechanism, the edges of a tetrahedron are inverted via a square-planar transition state. These processes are illustrated in Figure 8. Of course, vertex inversion is highly unlikely when all four substituents are atoms or ligands. However, when one of the substituents is a nonbonding pair of electrons (substituent A in Figure 8), both mechanisms are possible. Many factors are involved in the choice of one path over the other, but the transition state for the edge inversion process involves a 3c/4e hypervalent bond with ligands C and D. Calculations have predicted that PH_3 and PH_2F invert via the vertex process, while PHF_2 and PF_3 favor the edge pathway. Note that the crossover occurs when two highly electronegative substituents are attached. In an elegant study, (**38**) was synthesized and its inversion barrier measured by NMR magnetization transfer experiments. Such a molecule has to invert by the edge mechanism, and calculations based on this mechanism produced results in good agreement with the experimental values.

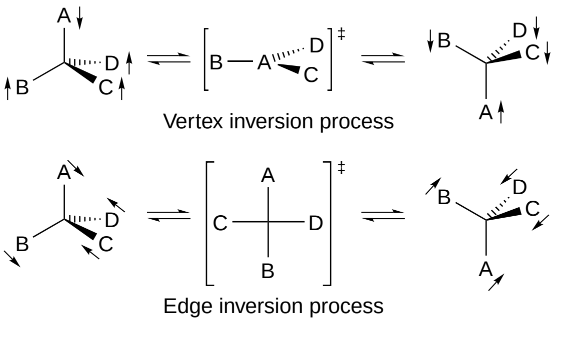


Figure 8 The vertex and edge inversion processes for 10-X-3 XL_3 (X = Group 15 element) molecules; A is the lone pair; L are B, C, D

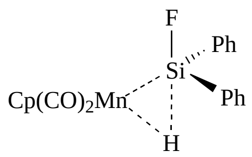
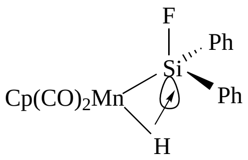
8 INTER-LIGAND HYPERVALENT INTERACTIONS

The development of the discipline of organometallic chemistry over the past several decades is due in large part to the way in which transition metals can bind and preorganize substrates for further reaction. It is quite common for two apparently distinct ligands to engage in reactions with each other, or to show structural features indicative of strong interactions, leading to nonclassical structures and bonding arrangements. The undoubted champion in this respect is the hydride ligand; with its absence of core electrons and a 1s valence orbital, hydrogen forms strong bonds with many elements. M–H bonds engage in a wide spectrum of secondary bonding interactions with other M–L moieties[37] (*see Agostic Bonding*; *Activation*). These may generally be termed Inter-Ligand Hypervalent Interactions.

As long ago as 1988, Crabtree proposed that the silane σ-bond complex $[CpMn(CO)_2(HSiFPh_2)]$ (**39**) was better formulated as a classical silyl hydride.[87] This complex displays a long Si–F bond; Crabtree suggested that this arose from donation of electron density from the Mn–H bond into the suitably disposed Si–F σ^* orbital (**40**), with the Si atom adopting a tbp geometry. Thus, instead of viewing the M-Si-H moiety as resulting from arrested oxidative addition, addition is considered to be complete and a secondary back-interaction occurs between the resulting silane and hydride ligands.





(**39**) (**40**)

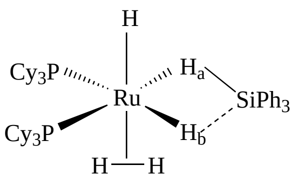
A neutron diffraction structure of the dihydrogen-hydride complex $[(EtPh_2P)_3Fe(H)(\eta^2\text{-}H_2)]$ (**41**) provided accurate positions for the three ligand hydrogen atoms, and revealed the H_2 ligand to be twisted from the expected arrangement so as to bring one of its hydrogen atoms into close proximity with the unique hydride H atom. An attractive interaction appears to occur between the (η^2-H_2) and H ligands. This interaction seems to be different in nature to that proposed for representation (**40**), with little or no changes evident in the bond lengths of the (η^2-H_2) and M–H moieties. Rather is it probably an electrostatic interaction, with the negatively charged hydride H atom being attracted

to the somewhat positive dihydrogen moiety. However, a distinct type of interaction occurs in trihydride complexes such as $[CpIr(PR_3)H_3]^+$. Here it is impossible to discern individual hydride and dihydrogen moieties. Although neutron diffraction has shown the H···H distances in this complex to be too long for significant bonding interactions to exist, the ^1H NMR spectrum displays massive couplings between the three hydride nuclei: these can be as high as 45 000 Hz. This phenomenon puzzled chemists for several years, until it was realized that the effect was quantum mechanical in origin, with the close hydrogen nuclei exchanging sites by a tunneling mechanism.[88]

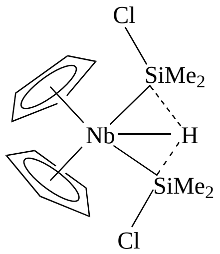
The complex $[(PCy_3)_2RuH_2(\eta^2\text{-}H_2)(\eta^2\text{-}HSiPh_3)]$ (**42**) was reported to contain two different σ-bond ligands, namely molecular hydrogen and triphenylsilane.[89] Closer inspection revealed, however, that the Si···H 'nonbonded' distance was only 6% longer than the Si–H 'bonded' one; in other words the two H atoms trans to the phosphine ligands are virtually indistinguishable, and both are clearly interacting with the Si atom. In such a situation, it is more realistic to consider a single group $[H_2SiPh_3]^-$ acting as a tridentate ligand in this Ru complex, with a 3c/4e bond holding the H-Si-H moiety together. The ligand is then a pentacoordinate, hypervalent silicon species, which may be considered an analog of the trihydrogen anion, $[H_3]^-$. It is noteworthy in this respect that the recently reported complex $[K(18\text{-crown-}6)][H_2SiPh_3]$ contains an uncoordinated 10-Si-5 $[H_2SiPh_3]^-$ ion, in which the hydride ligands occupy the axial sites in a tbp structure.[90] Analogous behavior has also been reported for the borohydride ligand in a transition metal hydride complex. Thus, while the two metal centers in the bimetallic ruthenium complex $[(triphos)Ru(H)(BH_4)(H)Ru(triphos)]^+$ are bridged by BH_4^-, the analogous iron species is formulated instead as $[(triphos)Fe(BH_6)Fe(triphos)]^+$. The bridging moiety here is formally $[BH_6]^{3-}$; a 12-B-6 entity: all B–H distances are statistically equivalent, and only a single ^1H resonance is discernable in the hydride region of the NMR spectrum.[91,92]

Since the mid-1990s, a wide range of silyl hydride metallocene complexes of Nb and Ta has been reported by Nikonov, with one example shown in (**43**). These exhibit short Si–H distances, and show large Si, H coupling constants in their NMR spectra.[36] The Si atom adopts a tbp geometry, with a ligand such as Cl trans to the interacting hydride. Donation of electron density from the M–H bond can then occur into the Si–Cl σ* orbital, in the manner described above for (**40**). Example (**43**), in which an M–H unit simultaneously interacts with two Si centers, can also be considered to be held together by a 5c/6e bond (q.v.).

What is clear from all these examples is that hydrogen can participate in a wide variety of strong secondary interactions with neighboring ligands in transition metal complexes. IHIs constitute a distinct type of nonclassical bonding that is different from other types, such as in σ-bond complexes and agostic interactions (*see Agostic Bonding*). IHIs are important, as major catalytic processes like migratory insertions proceed



(**42**)



(**43**)

through a transition state in which a close approach and interaction of the ligands involved leads to a redistribution of bonding. Whilst such inter-ligand hypervalent interactions have been intimated in reaction schemes for several decades, it is only recently that they have been observed in the ground state of transition metal complexes.

9 OTHER HYPERVALENT SPECIES

9.1 5c/6e Hypervalent Bonding[93]

Theoretically, the concept of hypervalent bonding can be expanded by adding two centers and two electrons at a time in a linear array. Practically, however, the limit may be reached at a 5c/6e system. There are several species of this type known, such as $[R_f\text{–I–F–I–}R_f]^-$ and $[F\text{–Xe–F–Xe–F}]^+$. Pentahalide monoanions like Br_5^- are bent and hence do not conform to this 5c/6e model. The addition of two atoms introduces two more σ atomic orbitals to the scheme, which give rise to a total of five MOs. The lowest three of these are occupied in the hypervalent bonding scheme. The lowest energy MO is bonding with respect to all five atoms; the next is bonding for the first and second and the fourth and fifth atoms, with a node at the central atom; the highest occupied MO is totally nonbonding with nodes at the second and fourth atoms.

9.2 Hypervalent Compounds of Period 2

The vast majority of hypervalent species, whether isolable and stable or proposed as reactive intermediates (rather than transition states), contain a central atom from period 3 or below. However, there is indisputable evidence that elements of period 2 can form species with hypervalent bonds. In fact, hydrogen bonding can be considered a form of hypervalent bonding for a first period element, in which hydrogen exceeds its 'duet'. For example, the well-known symmetrical ion $[F\text{–H–F}]^-$ has a very similar σ-bonding scheme to that illustrated in Figure 1, except that hydrogen uses an s orbital rather than a p orbital,[94] and the IHIs described in Section 8 require hydrogen to be formally hypervalent.

Nitrogen(V) is an accessible and common oxidation state, which occurs in such everyday laboratory species as nitric acid

HNO_3 and the nitrate ion NO_3^-. Nitrogen is precluded from forming sp^3d^n hybrid orbitals, and this caused early conceptual resistance to the idea that these molecules were hypervalent, with the nonexistence of NF_5 being cited as a counterexample. In fact, it is now clear that the instability of NF_5 owes more to the steric interactions that this pentacoordinate molecule would suffer:[95] the conjugate cation NF_4^+ is accessible and has been stabilized in a variety of salts. Furthermore, the surprisingly unreactive isoelectronic molecule ONF_3 has a short nitrogen–oxygen distance, which can only be categorized as a N=O bond, and hence is clearly a hypervalent N(V) species. Although nitrogen does not possess valence d orbitals, all these compounds can be easily accommodated using 3c/4e bonding schemes or resonance structures, as described in Section 1.

The carbon atoms found at the center of a tbp cage, examples of which are the theoretical CLi_5[96] and the isolated cation $C[AuPPh_3]_5^+$,[97] might be considered hypervalent on first inspection. However, cage bonding (forming Li–Li and Au–Au linkages) is the key factor in the stability of these molecules. The first hypervalent fluorine species was reported in 1976 by Ault and Andrews;[98] the F_3^- ion trapped in an argon matrix. The mutual exclusion rule for IR and Raman spectroscopy was convincing evidence for the linear, symmetrical arrangement of the three fluorine atoms with a Cs^+ counter ion. In 1984, Lee and Martin[99] used NMR spectroscopy to show that several boron compounds, such as (**44**) and (**45**), were authentic 10-B-5 and 12-B-6 species in solution. The first report of hypervalent 10-C-5 carbon (**46**) came in 1979 by Forbus and Martin.[100] This work was expanded in a series of papers in 1993,[9,101,102] which presented NMR and electrochemical evidence for isolation of the first molecule, which is a model for the transition state for an S_N2 reaction at a tetrahedral carbon center.

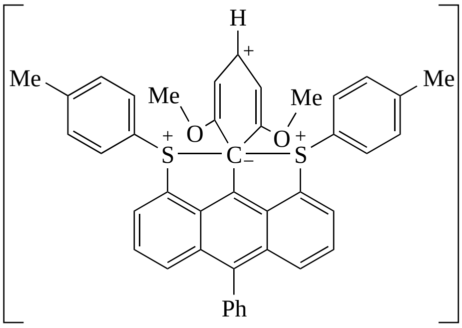
9.3 Other Species Considered as Hypervalent

Although coordination numbers higher than six were not explicitly considered above, certain species, such as the seven-coordinate 14-I-7 molecule IF_7 in a pentagonal bipyramid geometry, contain a linear F–I–F 3c/4e hypervalent bond.

Hypervalent bonding has also been extended to species that are generally drawn to include double bonds to oxygen or CR_2,



10-C-5
(**46**) Overall monoanion

such as the organic sulfoxides R_2SO, sufones R_2SO_2, sulfur ylides R_2SCR_2, phosphine oxides R_3PO, and phosphorus ylides R_3PCR_2. Virtually any molecule or ion for which a reasonable Lewis structure can be written with multiple bonds such that the central atom will expand its octet may reasonably be thought of as hypervalent (see Section 1). This includes all noble gas molecules and complex ions, as well as high-valent halogenated derivatives.

1 INTRODUCTION

Indium is a very soft, silvery–white metal with a brilliant luster, rather like tin in appearance, located behind gallium in the periodic table of the elements. It is considered a nontoxic metal, and is ductile, malleable and diamagnetic. The pure metal gives a high-pitched 'scream' when bent. It wets glass, as does gallium, and so it can be used to seal glass to metals. It can form alloys with extremely low-melting points, down to below room temperature (The alloy of 24% indium and 76% gallium is liquid at room temperature). It is used for electric fuses, safety plugs for storage tanks, and mainly for the automatic release of fire alarm and sprinkler systems, and also for cooling and as a heat-exchange medium in nuclear technology. The majority of the world's supply of indium is produced in Canada, where it would not normally be made in laboratory as it is commercially available. Indium is a by-product of the formation of lead and zinc. Indium metal is isolated by the electrolysis of indium salts in water. Further processes are required to make very pure indium for electronics purposes.

Indium is stable in air or in oxygen at room temperature, and does not react with water even at the boiling point but on heating goes to the oxide.[1] Indium oxide, an n-type semiconductor with a wide band gap of about 3.6 eV, is an ideal material for flat-panel displays owing to its high electrical conductivity and optical transparency, and also is used for gas sensors and conducting glass.[2] When heated, elemental indium easily reacts with the halogens to form the corresponding halide, and with sulfur, selenium, nitrogen, and phosphorous to give the corresponding indium-containing III-V/VI compounds that are well-known semiconductor materials and have technological importance for blue/violet light-emitting diodes (LEDs), laser diodes, solar cells and other optoelectronic devices. In addition, indium and its compounds are also used to promote some organic synthesis.[3]

The inorganic chemistry of indium during the past decade has received unbroken attention that originates from two aspects. One stems from the resurgence of the chemistry of low-valent indium, which is currently extended to various fields. A special highlight is the use of CpIn ($Cp = C_5H_5$), R_4In_4 ($R = Cp$, $C(SiMe_3)_3$, $Si(SiMe_3)_3$), and R_4In_2 ($R = SiBu^t{}_3$, $CH(SiMe_3)_2$) compounds to further prepare new compounds and clusters, which illustrate the lively development and the current trends in this field.[4,5] The other is from the understanding that indium compounds are potential precursors for applications in the field of new materials. In addition, the development of nanotechnology and the utility of indium reagents in organic synthesis present new and exciting opportunities for indium chemistry.

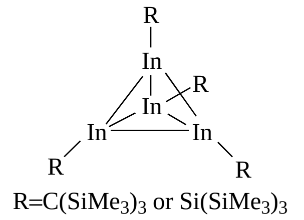
2 INDIUM (I) CHEMISTRY

2.1 Introduction

The current interest in monovalent indium compounds originates from the understanding of the structures and properties of these novel compounds, with particular focus on InX, CpIn, and In_4R_4 complexes. Indium (I) halides can be used as starting materials to prepare other indium (I) compounds and play an important role in the study of the oxidation chemistry of indium (I). The cyclopentadienylindium (I) (CpIn), obtained from the reaction of indium halide with LiCp, is another starting point for the synthesis of a number of indium (I) derivatives. The third approach to obtain indium (I) compounds depends on the tetraalkyltetraindium (I) compounds In_4R_4 ($R = C(SiMe_3)_3$, $Si(SiMe_3)_3$) as a source of In (I) compounds, which exhibits a distinctive chemical reactivity (Scheme 1).[4] The monomer fragment InR has similar frontier orbitals to carbon monoxide, and can form transition metal compounds analogous to metal carbonyls with bridging or terminal InR ligands. Furthermore, In_4R_4 can be oxidized with oxygen, sulfur, selenium, or halide to form heterocubane-type structures containing four indium atoms. These reactions open a new route to organometallic compounds and lead to novel compounds with unusual structures.

2.2 Halogen Derivatives

Indium (I) halides can be prepared by dissolving an excess of indium in hydrohalide acid or reduction of trihalides with metal. The structures of the bromides have been



Scheme 1 The molecule structure of In_4R_4 with R = $C(SiMe_3)_3$ and $Si(SiMe_3)_3$, Ref. 4

reinvestigated.[6] Some theoretic calculations indicate that the reduced phases (InBr, In_2Br_3, and In_3Br_7), among the binary indium bromides, are 'soft' and easy to perturb upon chemical reaction, and the coordination polyhedra around In^+ ions are highly irregular. The total In–Br bonding interaction is weak, but in none of the cases has there been found a directed electron 'lone-pair' effect for In^+.[7] The bromide In_5Br_7 exists in two polymorphs, both of which have a layer structure and consist of the structure fragments $[In^I{}_6Br_2]^{4+}$ and $[In^{II}{}_4Br_{12}]^{4-}$. The latter is composed of two ethane-like $[In^{II}{}_2Br_6]^{2-}$ units, which contain In–In bonds.[8] The mixed-valence species also are found in the compounds In_4Br_7 and In_7Br_9, which can be described as $(In^{3+})_3(In^+)_5\ (Br^-)_{14}$ and $(In^+)_6(In^{3+})\ (Br^-)_9$ respectively.[9]

The mixed transition metal indium bromides $InMBr_3$ (M = Fe, Mn), In_2MBr_6 (M = Th, Zr), and $In_3Ti_2Br_9$ are known. In_2ThBr_6 adopts monoclinic crystal structure, which is built up from three- dimensional (3D) interconnected $ThBr_8{}^{4-}$ bisdisphenoids and $InBr_9{}^{8-}$ monocapped cubes, the latter polyhedra being significantly distorted. Within $InMBr_3$, the transition metal cations are octahedrally coordinated by Br^- anions; monovalent indium cations are found in strongly distorted trigonal Br^- prisms, which are tricapped by additional Br^- anions.[10,11]

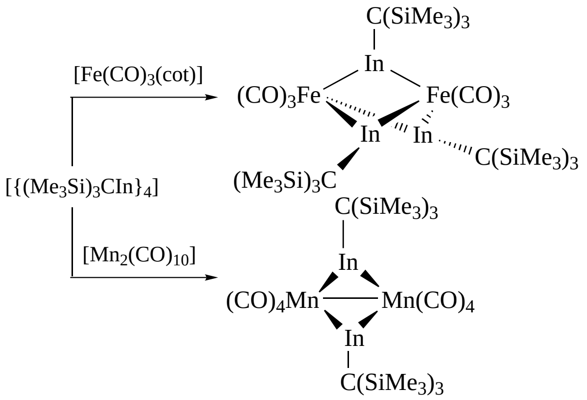
Fluoride compound, $PtIn_7F_{13}$ is prepared by reduction of InF_3 with In powder, which is built up from the $[PtIn_6]$ octahedra. These units are stacked in a alternating fashion together with $[InPt_6]$ octahedra along [001]. Within the $[InPt_6]$ cluster, platinum centers are octahedrally coordinated by six In atoms. The Pt–In bond lengths are significantly shorter than that in intermetallic phases with sixfold coordinated Pt atoms, and the In–In distances are only slightly longer than in elemental In or molecular In clusters.[12] The compound $InBF_4$ is isotypical to KBF_4.

Indium (I) halides insert into nickel halogen bonds of carbonyl group free organonickel complexes to form Ni–In bond compounds, which can be viewed as derivatives of trimethylindium or indiumtrihalides.[13]

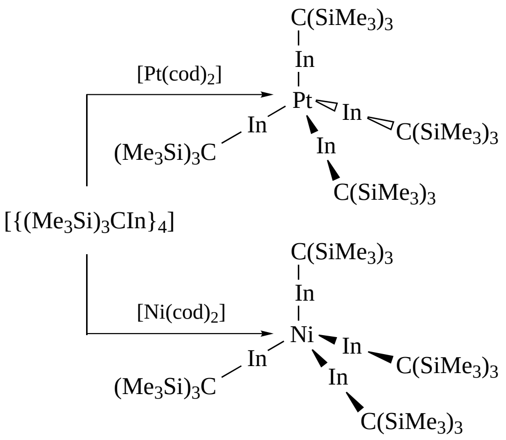
2.3 Reaction of In_4R_4 (R = $C(SiMe_3)_3$)

The tetrahedral tetraindium (I) compound In_4R_4 (R = $C(SiMe_3)_3$) is readily available by the reaction of indium monohalides with LiR (R = $C(SiMe_3)_3$). The monomeric fragments, possessing two empty p orbitals perpendicular to the In–C bond axis and an electron lone pair, thus making it isolobal to carbon monoxide. It can be used to form transition metal compounds that are similar to the metal carbonyls. The cubane In_4R_4 reacts with $(CO)_5Mn–Mn(CO)_5$ to form bis {μ-[tris(trimethylsily)methyl]indanyl}-di- manganese, in which two CO ligands are replaced by two InR fragments. Thus, two $Mn(CO)_4$ groups are bridged by two monoalkylindium units and a planar Mn_2In_2 molecular center.[14] Reaction with tricarbonyl- ironcyclooctatetraene produces $Fe_2(CO)_6\ (InR)_3$, which is one of the very rare examples of a compound with two $Fe(CO)_3$ fragments symmetrically bridged by three main-group elements. It involves a trigonal-bipyramidal Fe_2In_3 moiety with all indium atoms in equatorial positions (Scheme 2).[15] Similar replacements of CO ligands by InR is also demonstrated for $Ni_2Cp_2(\mu\text{-}CO)_2$, $Fe_2(CO)_9$, and $Fe_3(CO)_{12}$ by insertion of InR into the M–M bond and further replacement of one or both bridging carbonyl complexes.[16,17] The reaction of In_4R_4 with bis(cyclooctadiene) nickel (0) gives $Ni(InR)_4$, which is an analogoue of the thermally unstable carbonyl complex $Ni(CO)_4$ with a nickel atom tetrahedrally coordinated by four InR ligands. The Ni-In-C units with two-coordinated In atoms are exactly linear (Ni-In-C, 180.0°).[18] Similar reaction with bis(cyclooctadiene) platinum (0) also gives $Pt(InR)_4$ complex (Scheme 3).[19] In addition, CpIn is also isolobal to CO and displays transition metal carbonyl fragments. The structure of $Pd_3(InCp)_4(\mu_2\text{-}InCp)_4$ exhibits three edge-bridging $PdIn_4$ tetrahedrons. The three central palladium atoms are arranged with only a small deviation from linearity of 10°. The distortion of the $PdIn_4$ tetrahedrons is expressed in the In–Pd–In angles, which are smaller than 109° for the terminal In atoms and larger than 109° for the bridging In atoms.[20]

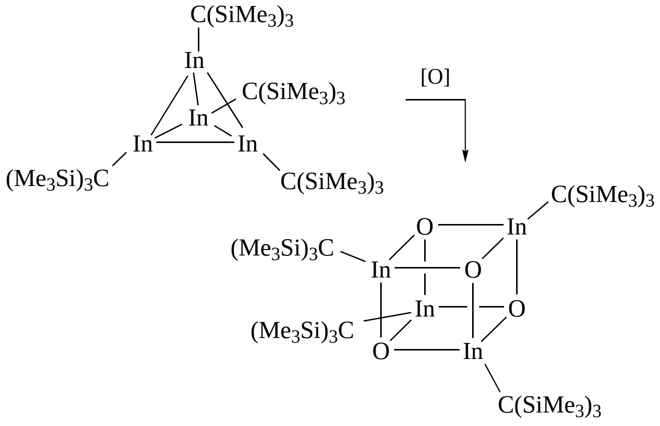
The In_4 cluster can be completely or partial oxidized with halogen or chalcogen to form In_4X_4 heterocubanes or mixed-valence compounds. The complex $In_4[C(SiMe_3)_3]_4$ abstracts O from *o*-nitrosotoluene forming the extremely



Scheme 2 Reaction of In_4R_4 (R = $C(SiMe_3)_3$) with $Fe(CO)_3$(cot) and $Mn_2(CO)_{10}$. cot = cyclooctatetraene, Refs. 14,15



Scheme 3 Reaction of In_4R_4 (R = $C(SiMe_3)_3$) with $Pt(cod)_2$ and $Ni(cod)_2$. cod = cyclooctadiene, Refs. 18,19



Scheme 4 The oxidization reaction of $[InC(SiMe_3)_3]_4$ to produce $In_4O_4[C(SiMe_3)_3]_4$, Ref. 21

hygroscopic $In_4O_4[C(SiMe_3)_3]_4$ (Scheme 4). The structure exhibits a distorted In_4O_4 moiety with normal In–O bond lengths, but short intracage In to In and O to O distances.[21] The reaction with chalcogen gives the compounds $In_4X_4R_4$, which adopt a slightly distorted In_4X_4 heterocubane structure with an alternating arrangement of In and X atoms (X = chalogen atom).[22] Partial oxidation of In_4R_4 with the sulfur atom donor yields the mixed-valent compound $[In_4S\{C(SiMe_3)_3\}_4]$, in which only one face of the In_4 tetrahedron of In_4R_4 is bridged by a sulfur atom. Partial oxidation of In_4R_4 with halogen donors affords novel alkylindium halides $In_2X_2R_2$ (R = $C(SiMe_3)_3$, X = Cl or Br) and $In_3I_2R_3$, in which the indium atoms still possess low oxidation states. The tetrahedral arrangement of four indium atoms in a cluster is retained in the compound $In_4Br_2R_4$, in which one bromine atom occupied a μ_3-bridging position above one triangular face of the In_4 tetrahedron, and one edge of that triangle is bridged by the second bromine atom.[4]

2.4 In Cluster Compounds

Several interesting new forms of indium cluster compounds have been described during the last decade. The compound $(Bu^t{}_3Si)_6In_8$, prepared by the reaction of CpIn with $Bu^t{}_3SiNa$, has a novel eight-indium cluster framework in which a distorted cube of indium atoms is surrounded by the silyl groups;[23] the compound $[(Bu^t{}_3Si)_8In]_{12}$ possesses an In_{12} deltahedral framework with 20 triangular faces and 12 In atoms. The compound is not spherical, but resembles a stretched ellipsoid.[24] The reaction of LiC_6H_3-2,6-mes$_2$ (mes = C_6H_2-2,4,6-Me_3) with InCl produces the complex $In_8(C_6H_3$-2,6-mes$_2)_4$, possessing a distorted cubane arrangement of eight indium atoms, in which only four atoms of the metal carry a terphenyl substituent.[25]

2.5 Indium–Boron/Phosphorous Compounds

The most interesting aspect of the pyrazolylborates (pz) for indium is their ability to stabilize the univalent indium oxidation state. Thus, bulky poly(pyrazolyl)borate ligands such as $[HB(3\text{-}Bu^tpz)_3]^-$, $[HB(3\text{-}Phpz)_3]^-$, $[HB(3,5\text{-}Bu^tpz)_3]^-$, and $[HB(3,5\text{-}(CF_3)_2pz)_3]^-$ are used to stabilize the indium (I) species.[26,27] The complex (3,5-Bu^tpz)In is synthesized by the treatment of Na(3,5-Bu^tpz) with InCl, in which the 3,5-Bu^tpz ligand adopts a highly twisted configuration owing to steric interactions of the *tert*-butyl substituents in the 5 positions of the pyrazolyl groups. The compound (3,5-Bu^tpz)In can undergo oxidative-addition reactions with I_2 and S_8 to give the complex (3,5-Bu^tpz)InI_2 and (3,5-Bu^tpz)In(μ^2-S_4), respectively. In addition, $[In(\eta^5\text{-}P_2C_3Bu^t{}_3)]$ and $[In(\eta^5\text{-}P_3C_2Bu^t{}_2)]$ are also prepared, which have a half-sandwich structure, similar to the η^5-coordination mode $[In(\eta\text{-}C_5H_5)]$ or InCp.[28]

2.6 Aqueous Solution Chemistry

Solutions of indium (I) can be prepared by treatment of indium amalgam with silver triflate in dry acetonitrile in the absence of oxygen, and then diluted with water to give the low-concentration aqueous solution, which plays a sizable role in the study of the details of intermolecular electron transfer processes in solution.[29] Aqueous In(I) solution has been used to examine the behavior of this hypovalent center in inorganic redox transformations. Reactions with complexes of the type $[(NH_3)_5Co^{III}(Lig)]$ and $[(NH_3)_5Ru^{III}(Lig)]$ (Lig = Cl^-, Br^-, I^- or $HC_2O_4{}^-$) show two consecutive one-electron reactions initiated by the formation of the metastable state In^{II}, which is then rapidly oxidized to In^{III}, and the first of which is predominating an inner-sphere mechanism.[30,31]

3 INDIUM (II) CHEMISTRY

3.1 Introduction

Most of the divalent indium compounds appear in the dimeric form, which involves an indium–indium bonded species or R_4In_2. The structure of the indium (II) halides has been identified, in which the divalent In^{2+} ions is present in the dimeric species $[In_2X_6]^{2-}$.[32] A special highlight is the compound R_4In_2 ($R = CH(SiMe_3)_2$, $SiBu^t_3$, $SiBu^t_2Ph$), which has a remarkable reactivity and is used in the preparation of various indium complexes including indium cluster compounds.[33]

3.2 Halogen Derivatives

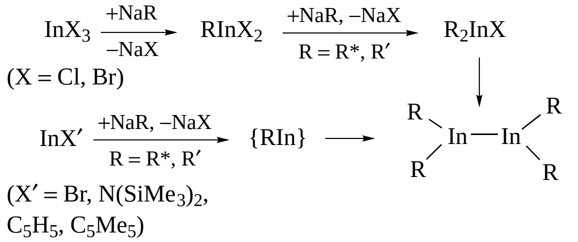
The halides of indium (II) can be prepared by heating together the appropriate mixture of elements, or by reduction of the trihalides with indium metal. In the compounds In_2Br_3 and In_5Br_7, the divalent In^{2+} ions are bonded within the dimeric species $[In_2Br_6]^{2-}$, in which each In^{2+} ion is threefold coordinated by Br^- ions, with a mean distance of 257 pm. The other In^{2+} ion augments the coordinating geometry via an In^{2+}-In^{2+} single bond (270 pm) to form a distorted tetrahedron.[7,8] $KInBr_3$ is the first ternary indium bromide containing divalent indium. The divalent In^{2+} ions are found in an $[In_2Br_6]^{2-}$ unit in an eclipsed ethane structure, while potassium ions are located in two different polyhedra.[32] The ethane analogous In_2X_6 (X = S, Se) units are also found in the structures of $MIn_5\ S_7$ (M = Na, K, Tl), MIn_5S_6 (M = K, Tl), and MIn_7X_9 (M = Rb, Cs; X = S, Se).[34]

3.3 Synthesis of R_4In_2 Derivatives

Diindanes R_2InInR_2 ($R = SiBu^t_3$) can be prepared by the reactions of NaR ($R = SiBu^t_3$) with InX_3 (X = Cl, Br) through $RInX_2$ and R_2InX intermediate process.[5] The reactions of NaR ($R = SiBu^t_3$, $SiBu^t_2Ph$) with InX ($X = N(SiMe_3)_2$, C_5H_5, C_5Me_5) also produces R_2InInR_2.[22] R_2InInR_2 ($R = CH(SiMe_3)_2$) is also prepared by the reaction of $[LiN(SiMe_3)_2]$ with C_5H_5In, whereas the reaction of $InCl_3$ and $LiSi(SiMe_3)_3$ gives $[(Me_3Si)_3Si]_4In_2$ (Scheme 5).[35] The reaction of $In_2Br{\cdot}2TMEDA$ (TMEDA = tetramethylethylenediamine) with $[LiCH(SiMe_3)_2]$ can lead to $[(Me_3Si)_2CH]_4In_2$. The reaction of indium metal with $Pr^n{}_3PI_2$ also yields the 'subvalent' indium (II) complex $In_2I_4(PPr^n)_2$, which is the first example of an indium tertiary phosphine complex containing an indium–indium bond.[36]

3.4 Reaction of R_4In_2 Derivatives

Reaction of R_2In–InR_2 ($R = CH(SiMe_3)_2$) with the chalcogen compounds can give the corresponding homoleptic compounds $R_2InEInR_2$ (E = S, Se or Te) by insertion of



Scheme 5 Syntheses of ditrielanes R_4In_2 with $R = R^* = Si\textit{t}Bu_3$ and $R = R' = Si\textit{t}Bu_2Ph$, Refs. 5,22,35

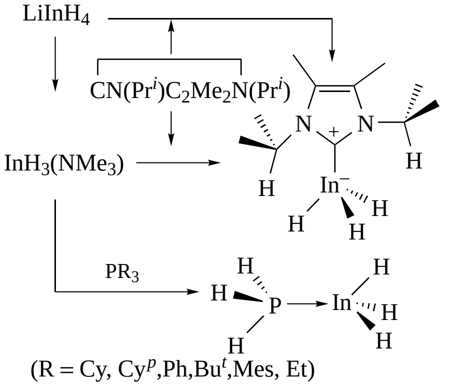
chalcogen atoms into the In–In bond, while reaction with lithium phenylethynide produces, by the addition of one ethynido ligand to one of the central In atoms, the anionic adducts with intact In–In single bonds.[33] R_2In–InR_2 reacts with $LiCH_2SMe$ to afford $[R_2In(CH_2SMe)_2][Li(TMEDA)]$ probably formed by a metal exchange reaction.[37] Reaction with trimethylamine N-oxide by the insertion of oxygen atoms in their In–In single bonds produces R_2In–O–InR_2, which is monomeric in the solid state owing to the high steric shielding by the voluminous bis(trimethylsilyl)methyl groups,[38] while with protic reagents results in the cleavage of the In–In bond and precipitation of element indium.[39]

R_4In_2 ($R = SiBu^t_3$) can transform, with excess hydrogen bromide, into $RInBr_2$ and RH (molar ratio 1:1). Here R_4In_2 behaves as a Lewis base against HBr. R_4In_2 can be oxidized (e.g. with halogens or chalcogens) or reduced with metal. Bromination of R_4In_2 into $RInBr_2$ may proceed either by In–In or by In–Si bond cleavage via R_2InBr or $R_2In_2Br_2$. Fluorination of R_4In_2 with AgF_2 also produces $RInF_2$. The reaction of R_4In_2 with selenium can produce the heterocubane $R_4In_4Se_4$.[5]

4 INDIUM (III) CHEMISTRY

4.1 Introduction

The main development of the indium chemistry during the last decade has centered on the indium (III) compounds, particularly InH_3, InX_3, and R_3In. Indium hydride (InH_3 or $In_2\ H_6$) is unstable in the gas phase or solid state, but the stable indium trihydride complexes can be obtained in the form of adducts.[40] InX_3 and R_3In compounds are electron deficient and can accept pairs of electrons and form their neutral adducts or coordination compounds with the electron-pair donator ligands. This is potentially relevant to the fabrication of the III-V/VI semiconductor materials. The behavior of In^{3+} in solution has been investigated and a large number of stable and soluble In^{3+} complexes are obtained, which can be used as dyes, diagnostic radiopharmaceuticals, and other applications in materials sciences.



Scheme 6 Syntheses of Indium hydride compounds, Refs. 43,44

4.2 Hydrides and Related Compounds

Indium hydrides are thermodynamically unstable, and $Me_2InB_3H_8$ is the first reported example of a volatile indium hydride.[41] Reaction of $InCl_3$ with $HSnBu_3$ generates the compound $HInCl_2$, which is stable up to ambient temperature.[42] The thermally stable indium trihydride complexes are obtained with phosphines or carbenes. $LiInH_4$ with $NMe_3{\cdot}HCl$ gives the adduct $InH_3(NMe_3)$, and further reacts with the stable carbene [:$CN(Pr^i)C_2Me_2N(Pr^i)$] to afford the carbene-metal trihydride complex [InH_3{:$CN(Pr^i)C_2Me_2N(Pr^i)$}] (Scheme 6).[43] The reaction of $InH_3(NMe_3)$ with PR_3 (R = cyclohexyl (Cy), cyclopentyl (Cp) or phenyl) affords the indium trihydride complexes [$InH_3(PR_3)$] and [$InH_3(PCy_3)_2$]. The first phosphido-indium hydride complex [{$InH_2(PCy_2)$}$_3$] is obtained by the treatment of [$InH_3(NMe_3)$] with $LiPCy_2$. These complexes possess remarkable stability that may be attributed to the phosphone ligand's steric bulk and nucleophilicity. The complex [$InH_3(PCy_3)$] is used to prepare a range of monomeric indium chalogenolato complexes [$In(Eph)_3(PCy_3)$] (E = S, Se or Te) (Scheme 6).[44,45]

4.3 Indium (III) Halides and their Derivatives

Indium trihalides can be easily prepared from the reaction of indium metal with halide acids, which can form various complexes with water molecules and other ligands. *Trans*-[$InCl_2(H_2O)_4$]$^+$ and *trans*-[$InCl_4(H_2O)_4$]$^-$ species are isolated for the first time as parts of supramolecular adducts with cucurbituril are isolated from aqueous solutions and structurally characterized.[46] The behavior of Br_2 $InCH_2Br$ as Lewis acid against NEt_4Br, 1,4-dioxane and THF(OC_4H_8) is examined, which shows that by complete intramolecular tautomeric transfer of the bromide it is possible to obtain [Br_3 $InCH_2$]$^-$ as an anion.[47] Reduction of R_3PI_2 (R = Ph, Pr^i) with indium powder produces the four- and five-coordinate complex $InI_3(PPh_3)_2{\cdot}InI_3(PPh_4)$ and the monomeric tetrahedral indium (III) complex $InI_3(PPr^i{}_3)$, which illustrates the subtle effect of the organic substituents on the phosphorus atom for the reaction of R_3PI_2 with indium metal.[37]

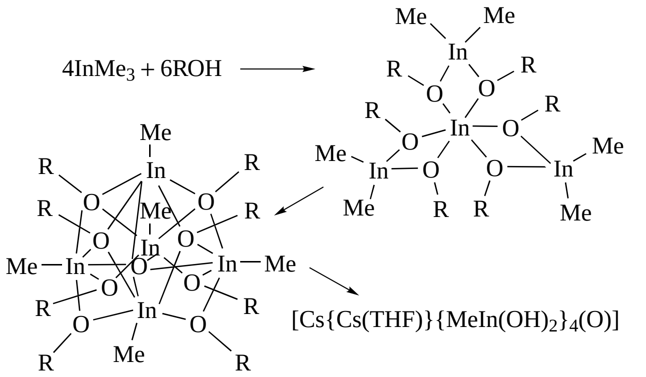
4.4 Adducts of InX_3

The adducts of the indium trihalides are readily prepared by simple nonaqueous phase reactions. A series of adducts of $InBr_3$ has been obtained from the treatment of $InBr_3$ with THF (tetrahydrofuran), DMF (dimethyl formamide), and other ligands, which have a pyramidal coordination sphere.[48] In a similar fashion, the coordination geometry of the adduct $InCl_3(THF)_2$ also is a trigonal bipyramid with three Cl atoms in equatorial positions and two axial THF ligands. Reaction of $InBr_3$ with $HN(SiMe_3)_2$ gives stable adducts $Br_3In{\cdot}H_2NSiMe_3$ and $Br_3In{\cdot}HN(SiMe_3)_2$;[49] with $LiR{\cdot}(THF)_n$ (R = $C(SiMe_3)_3$, THF = OC_4H_8), it produces [$Li(THF)_4$][$RInBr_3$] in good yield.[50] $InCl_3$ with amines can give the corresponding adducts, in which In atoms have a trigonal-bipyramidal coordination sphere with the amines in apical position.[51] The complex [$(Me)_2ATI$]$_2$InCl (ATI = aminotroponiminate) was prepared and characterized, showing fluxional behavior in solution at room temperature and adopting trigonal-bipyramidal geometry around the metal center with the halide occupying an equatorial site.[52] The complex $(PPh_3)_4Pt_2(\mu^3\text{-S})InCl_3$ represents the first report of a square-based pyramidal structure of a five-coordinated adduct of InX_3.[53]

The reactions of indium trihalides with DP or TP ligands (DP = 1, 2-bis-(diphenylphophanyl) benzene, TP = bis[(2-diphenylphosphanyl)phenyl] phenylphosphane) lead to a variety of molecular and ionic complexes, such as [$(DP)_2InCl_2$]$^+$ [$InCl_4$]$^-$, $(DP)InX_3$, [$(DP)InX_2$]$^+$ [InX_4]$^-$ (X = Br, I), and [$(TP)InX_2$]$^+$ [InX_4]$^-$ (X = I). The environment of the metal center is octahedral, square pyramidal, and tetrahedral in the cations respectively.[54]

4.5 Indium Alkoxides

The reaction of Me_3In with ROH (R = $PhCH_2$, Hex and Bu^t) leads to tetranuclear complex [In{$(RO)_2InMe_2$}$_3$], described also as [{Me_2InOR}$_2${$MeIn(OR)_2$}$_2$], then at higher temperature forms an O-centered corner-cut rhombic dodecahedron, [$(MeIn)_5(OR)_8O$], in which the four μ_2-bridging oxygen atoms form a basal plane and the In-O skeleton can be degraded with elemental cesium to a hexa- and heteronuclear complex [Cs{Cs(THF)}{[MeIn $(OR)_2$]$_4$O}] (Scheme 7).[55,56] The compound [$In(OBu^t)_3$]$_2$ is the first example of a homoleptic and homometallic indium alkoxide, which is obtained by alcoholysis of $In(N(SiMe_3)_2)_3$ with Bu^tOH.[57] The N,O-5 chelates [$Me_2In(\mu\text{-ORNMe}_2)$]$_2$ (R = CH_2CHR'; R′ = Me, Pr^i, Bu^t) are synthesized from trimethylindium and the dimethylamino alcohols by elimination of methane. The coordinative N → In bonds of the five-coordinate indium complexes show dynamic dissociation/association processes.[58]



Scheme 7 Syntheses of Indium alkoxides, Refs. 55,56

The reaction of InX_3 ($X = Cl$, Br) with sodium alkyloxistannate gives $THF{\cdot}X_2In(OR)_3Sn$ ($X = Cl$, Br; $R = Bu^t$), in which the indium atoms are in the centers of distorted octahedral from 4 oxygen and 2 halogen atoms whereas the tin atoms are coordinated by three oxygen atoms in a trigonal pyramidal fashion.[59] Reaction of $InMe_3$ or $InCl_3$ with the Li+ salt of S-BINOLate (S-BINOL = (S)-(−)-2,2′-dihydroxy-1,1-binaphthyl) gives alkoxides with a tetranuclear InO_6Li_3 skeleton, which forms a distorted octahedral coordination sphere around In atoms, built up by three BINOLate ligands, the three Li+ counterions acting as bridging units by metal−oxygen coordination.[60]

4.6 $InMe_3$ Adducts and Derivatives

The Me_3In adducts also have the similar bipyramidal structure to that of InX_3 adducts. The adduct $Me_3In{\cdot}2$(mbda) (mbda=*N*,*N*,*N*′,*N*′-tetramethyl-4′,4′-methylene-bis-aniline), with a trigonalbipyramidal In, is said to have the longest known In–N bonds.[61] Me_3In reacting with isocyanides CNR (R = *p*-MeC_6H_4, *p*-$MeOC_6H_4$) gives the corresponding adducts Me_3InCNR, then reacts with pyrrolidine by insertion of the isocyanide into the In–N–Pyr bond to form $[Me_2InC(=NR)(Pyr)]$ (Pyr = conjugate base of pyrrolidine).[62]

The adducts $InMe_3{\cdot}C_3H_6N_3R_3$ ($R = Me$, Pr^i or Bu^t) are prepared by simple mixing of the Lewis acid and base in diethylether solution and the adducting bonding of three lone pairs is slightly stronger than a standard one lone-pair adduct bond.[63] Reaction of Me_3In with $[(\eta^5\text{-}C_5Me_5)(CO)_2FeE{=}(NMe_2)_2]$ ($E = P$ and As) affords the adducts $[(\eta^5\text{-}C_5Me_5)(CO)_2FeE\{InMe_3\}(NMe_2)_2]$, which feature η^1-coordination of the phosphaalkene or the arsaalkene ligand towards the Lewis acid via the pnictogen atom.[64]

4.7 Indium–Nitrogen Compounds

Reactions of InX_3 ($X = Cl$, Br) with various amines give the corresponding neutral or ionic complexes in which indium atoms locate in trigonal-bipyramidal, trigonal planar, or distorted tetrahedral environments. In the structure of $[ClIn(NMeSiMe_2)_2NMe]_2$, a chloride and one amide group of $[MeN(SiMe_2NMe)_2]^{2-}$ ligand are bonded to each In atom in terminal positions and the other amide group of the chelating ligand is shared between two In atoms.[65] Reaction of $[RNC(R')NR]Li$ with $InCl_3$ affords a novel family of monomeric five-coordinate compounds $In[RNC(R')NR]_2Cl$ (R = cyclohexyl, $SiMe_3$; $R' = Me$, Bu^t), possessing a distorted trigonal-bipyramidal coordination.[66]

The first azaindatrane $[N(CH_2CH_2NMe)_3In]_2$ is prepared by the reaction of $[In(NEt_2)_3]_2$ with $N(CH_2CH_2NMeH)_3$, in which both indium atoms are pentacoordinate, with widely differing In–N distances.[67] Within $[py_2Na][py_2In(N_3)]_4$, the In and Na atoms are each hexacoordinated by four azido group and two additional solvent molecules.[68]

The reaction of $RSi(NH_2)_3$ ($R = 2,6\text{-}Pr^i{}_2C_6H_3NSiMe_2Pr^i$) with InR_3 ($R = Me$, Et) leads to Si–NH–In cage molecules, which may be regarded as a model system for In metal-containing iminosilicates. Further functionalization without cleavage of the cage molecule is achieved by reaction with elemental bromide and iodine.[69]

Indium diphthalocyanine $In(Pc)_2$ contains sandwich-type molecules in which the indium atom is eight-coordinate by the isoindole nitrogens of two phthalocyanie rings. The distance between the phthalocyanie planes in this sandwich macromolecule is equal to 274.1 pm, and the two phthalocyaninato moieties are rotated about 41.2(4)° with respect to each other.[70]

The chloro(phthalocyaninato or naphthalocyaninato) indium $R^1{}_4R^2{}_4PcInCl$ or $R^1{}_4R^2{}_4NcInCl$ react with R^3MgBr to produce the axially substituted aryl (phthalocyaninato or naphthalocyaninato) indium compound, $R^1{}_4R^2{}_4PcInR^3$ or $R^1{}_4R^2{}_4NcInR^3$, which has high solubility owing to steric crowding arising from the new unsymmetrical peripheral substitution pattern and the bulky electron-withdrawing axial liangs.[71,72]

The structure of $In_4X_4(NBu^t)_4$ ($X = Cl$, Br, I) contains heterocubane In_4N_4 cores with an alternating arrangement of In and N atoms. The In atoms are coordinated nearly tetrahedrally by three N atoms and a terminal halogen atom. $In_3Br_4(NBu^t)(HNBu^t)_3$ contains a tricyclic In_3N_4 core, which can be formally derived from an In_4N_4 heterocubane by removing one In atom.[73]

MeCN can be trimerized in the presence of $InMe_3$ and a trace of CsF to form the InN_2C_3 heterocycle $[Me_2In\{HNC(Me)\}_2C(CN)]$, which forms an infinite chain-like coordination polymer, $[Me_2In\{HNC(Me)\}_2C(CN)]_n$, along [001] by the cooperative interactions of In···N contacts and N–H···N bridges.[74]

4.8 Indium–Phosphorous Compounds

The organoindium phosphides are dimeric, trimeric, and tetrameric in benzene solution. The compounds

$[Pr^i{}_2InPPh_2]$ and $[(PhCH_2)_2InPPh_2]$ exist as a monomer-dimer equilibrium mixture in solution and a trimer in the solid state. The dimer $[\{InPR_2(CH_2CMe_3)_2\}_2]$ (R = Et, Pr^i) contains a planar In_2P_2 core, and the trimer $[\{InP(H)(C_6H_{11})(CH_2CMe_3)_2\}_3]$ has an In_3P_3 six-membered ring in a boat conformation. The similar In_3P_3 six-membered rings are also observed in the trimers $[Pr^i{}_2InPPh_2]_3$, $[Me_2InP(SnMe_3)_2]_3$ and $[(PhCH_2)_2InPPh_2]_3{\cdot}OEt_2$. The compound $[(mes)InP(mes)]_4$ is tetrameric in solution, but crystallized as $[(mes)InP(mes)]_4{\cdot}4.5THF$, a heterocubane with an In_4P_4 core shield by the bulky organic groups.[75] The analogous heterocubanes with an In_4P_4 core is also observed in compound $[EtInPSiPr^i{}_3]_4$. The four-membered-ring compounds $[R_2InPBu^t{}_2]_2$ (R = vinyl, allyl, or benzyl) could absorb light at relatively long wavelengths with cutoffs ranging from ~300 nm to 330 nm depending on R groups.[76] The central structural motif of $[Pr^i{}_2Si\{P(H)InEt_2\}_2]_2$ is an adamantine-like cage composed of four indium, four phosphorous, and two silicon atoms, which is the first ternary cluster with combinations of these elements.[77] The one-dimensional compound $[Ph_4][In(P_2Se_6)]$ contains infinite $[In(P_2Se_6)]_n{}^-$ chains with a structure related to that of $K_2FeP_2Se_6$.[78]

4.9 Indium Phosphate Compounds

A new series of layered indium phosphate complexes have potential applications in the areas of sorption, ion exchange, and sensors. The first organically templated indium phosphate is prepared as single crystals from a nonaqueous pyridine-butan-2-ol medium and has a unique two-dimensional (2D) structure consisting of $[Hpy][In(HPO_4)(H_2PO_4)_2]^-$ layers held together by hydrogen bonding to generate cavities containing the pyridium cations. The layers consist of corrugated sheets constructed from ribbons of edge-sharing four-membered rings of alternating InO_6 and PO_4 units linked via $PO_2(OH)_2$ groups.[79] The layered structure also exists in the complexes, $In(O_3PR)(O_2P)(OH)R){\cdot}H_2O$ (R = C_6H_5 or $CH_2C_6H_5$) and $In(O_2P(H)C_6H_5)_3$, in which the ligand is present as both a mono- and dianion.[80] A pillared layer structure of the indium phosphate, $[In_8(HPO_4)_{14}(H_2O)_6(H_2O)_5(H_3O)(C_3N_2H_5)_3]$, consists of layers assembled from InO_6 and $InO_5(H_2O)$ octahedra and $PO_3(OH)$ tetrahedra which are pillared through InO_6 octahedra to produce a 3D framework. The framework contains a 2D array of channels in which sit imidazolium cations, hydroxonium ions, and water molecules.[81] The similar pillared layer structure is observed in complexes $[In_4(4,4'\text{-bipy})_3(HPO_4)_4(H_2PO_4)_4]{\cdot}4H_2O$ and $[In_4(4,4'\text{-bipy})_3(HPO_4)_4(H_2PO_4)_4]$. The structure of $PbIn(OH)PO_4$ consists of spirals of *cis* corner-sharing InO_6 octahedra with hydroxyl O as the bridging atom, and the In–O–In bonds nearly equidistant.[82] The framework of $Ca_2(In_{1-x}Fe_x)(PO_4)(HPO_4)_2{\cdot}H_2O$ is based on linear chains formed by (MO_6) octahedral and $(PO_4)(HPO_4)$ tetrahedral sharing corners. The (HPO_4) groups and water molecules link the chains through hydrogen bonding to form layers stacked perpendicular to the *c* axis. The calcium cations are located between the layers and are coordinated by nine oxide anions.[83]

4.10 Indium Chalcogenide Compounds

The indium chalcogenide compounds may be prepared by the insertion of chalcogenide into either an In–C or In–S bond. The reaction of InR_3 (R = Bu^t, Bu^n or CMe_2Et) with selenium or tellurium yields the corresponding compounds $[\{RIn(\mu_3\text{-}E)\}_4]$ (E = Se or Te).[84] Reaction of $[In(mes)_3]$ (mes = 2, 4, 6-trimethylphenyl) with various A(ER) (A = H or Li; E = S or Se; R = Bu^t, *tert*-amyl, 2-*t*-BuC_6 H_4, $SiPh_3$) gives $[\{In(mes)_2(\mu\text{-}ER)\}_2]$. A trimeric indium thiolate, $[\{InMe_2(\mu\text{-}SSiPh_3)\}_3]$, is isolated from the reaction of $InMe_3$ with $HSSiPh_3$.[85] Similar selenium compounds are also described as $[InMe(\mu\text{-}SePh)(SePh)]_\infty$, a spiral chain composed of alternative four-coordinate indium atoms and three-coordinate selenium atoms.[86]

Homoleptic chalcogenolates $In[ESi(SiMe_3)_3]_3$ (E = Se, Te) are also prepared by chalcogenolysis of $InCp_3$. Addition of L ligand (L = THF, TMEDA (N,N,N',N'-tetramethyl ethylene diamine), or DMPE (1,2-bis(dimethylphosphino)ethane)) to $In[SeSi(SiMe_3)_3]_3$ gives 1:1 adducts (L) $In[SeSi(SiMe_3)_3]_3$.[87] The SePy (SePy = 2-Se–NC_5H_4) and SePy* (SePy* = 3-Me_3Si–Se–NC_5H_4) ligands form air-stable homoleptic coordination compounds of indium (III) $[In(SePy)_3]$ and $[In(SePy^*)_3]$, which are distorted fac-octahedra molecules with chelating SePy ligands and are useful low-temperature precursors to In_2Se_3.[88]

The tellurides $K_6In_2Te_6{\cdot}4en$ (en = $C_2H_8N_2$) and $(Ph_4P)_2$ In_2Te_6 are known. The former possesses a highly charged dimeric $[In_2Te_6]^{6-}$ anion, which is composed of two edge-sharing $InTe_4$ tetrahedra. The $InTe_4$ tetrahedra are linked together by sharing two Te corners and by joining the two other Te corners to form two $Te_2{}^{2-}$ units with neighboring tetrahedra.[89] The complex $[InCl\{Ph_2P(Se)NP\ (S)Ph_2\text{–}Se,S\}$ exhibits a very distorted trigonal-bipyramidal geometry at indium, where both the selenium and chlorine atoms are in equatorial positions, while the sulfur atoms are in axial positions.[90]

The reaction of $InCl_3$ with $PhC\{O\}S^-$ A^+ (A = Li, Na, and K) in the molar ratio 1:4 gives the corresponding ionic complexes $[A(MeCN)_x\{In(SC\{O\}Ph)_4\}]$, (A = Li, X = 0; A = Na, X = 1; A = K, X = 2), which have a one-dimensional polymeric structure. The structural variations may be attributed to the change in the alkali metal ion from Li to Na to K.[91]

Thioindates of alkali metal compounds can be prepared by starting from stoichiometric mixtures of the elements, and several compounds MIn_3S_5 (M = Rb, Cs), KIn_5S_6, MIn_5S_7 (M: Na, K), and MIn_7X_9 (M = Rb, Cs; X = S, Se) are known. MIn_3S_5 (M = Rb, Cs) represents a new type of ternary chalcogenide. On the quasi binary section M_2S–In_2S_5 with the two binary phases in a molar ratio of 1:3, in which the indium

atoms are coordinated by sulfur atoms with tetrahedral as well as octahedral arrangement, the coordination numbers of the independent M atoms are nine or ten, and the sulfur and alkali metal atoms are in slightly distorted ccp arrangement.[92,93]

5 INDIUM PRECURSORS FOR CVD

5.1 Introduction

The recent interest in organoindium compounds stems from the finding that organoindium compounds are potential precursors for a wide variety of applications in material science. The deposition of In-containing semiconductor layers is important to diverse areas of research. Generally, the preparation of these thin films involves metal organic chemical vapor deposition (MOCVD). Despite its commercial use, several precursor issues are associated with the conventional MOCVD method, such as safe precursor handling and 'snowing' of the films. Moreover, under the condition of separate precursors, the composition control of such multinary films is affected by a precise adjustment of the mole fractions of the different precursors for the film constituting components in the gas phase. This makes it very difficult to obtain multinary films owing to the differences of precursors in volatility, thermal reactivity, and surface mobility.

An alternative route to make the films is the use of a precursor that contains the required atoms in a single molecule. The process control is shifted to the constitutional and structural optimization of the precursor. Therefore, single-source precursors have considerable advantages over conventional separate sources.

5.2 Intermetallic Phase Precursor Compounds

Indium-containing intermetallic phases are especially suitable as epitaxial metallizations, being inert against unwanted interface reactions and useful for Schottky barriers for semiconductor techniques. Thus, MOCVD processes are of interest for these materials and many organoindium precursors have been synthesized for this end. A special highlight is the compound $[Ni(InR)_4]$ ($R = C(SiMe_3)_3$), a first example for the existence of compounds that are homoleptic with regard to an earth metal as ligator, which can be used as a single-source precursor for NiIn films.[94] Ni/In films can also be prepared from the compounds $\{[Cp(PEt_3)Ni]_2InCl\}_2$, $[Cp(PEt_3)Ni]_3In$, and $Cp(PEt_3)NiInI_2$. In the Co/In system, only $CoIn_2$ and $CoIn_3$ are stable. $(CO)_4CoInR_2$ ($R = CH_2CH_2CH_2NMe_2$) can give CoIn films with Ni/In = 3.0 to 1.0 depending on the substrate temperature, which can be assigned to these phases; $[Cp(CO)CoInR_2]$ at 350 °C can provide single-phase films with the hexagonal ε-NiIn phase. This is an example of an unexpected Cp transferring to the In atom, leading to stable CpIn that desorbs and gets into the exhaust gas.[95] In the case of $Cp(CO)_2Fe–InR_2$, the deposition of Fe/In films is proceeded by the release of ferrocene.[96]

In addition, Cr/In, W/In, Mn/In, and Au/In films have also been obtained from the corresponding organometal compounds respectively, which indicate lively development in this field.

5.3 Indium Chalcogenide Precursor Compounds

Indium chalcogenides are potentially useful as single-source precursors for the synthesis of III-VI semiconductor materials. The complex $[InMe_2(S_2CNEt_2)]$ is the ideal precursor for deposition of indium sulfide (InS and In_6S_7 phases) films, and $[InEt_2(S_2CNEt_2)]$ can give single phase, cubic β-In_2S_3 films at a temperature of 325–400 °C.[97] β-In_2S_3 films can also be prepared from $[In(SOCNEt_2)_3]$ and $[In(SOCNPr_2)_3]$ respectively.[98,99] The deposition of α-In_2S_3 films can be obtained from the precursor, $[In(S_2COPr)_3]$ or $[In(S_2CNEt_2)_3]$.[100] $[mes_2In(\mu\text{-SR})]_2$ (mes = 2, 4, 6-trimethylphenyl, R = t-Bu, t-amyl, $SiPh_3$) and $[Me_2In(\mu\text{-SSiPh}_3)]_3$ are also used as a single-source precursor for deposition of indium sulfide films.[101] In addition, $[HL][In(SCOMe)_4]$ is also used to deposit tetragonal β-In_2S_3 films.

Indium selenide films can be produced from the corresponding compounds containing selenium by MOCVD, and the film quality is dependent on the growth temperature. $[In^tBu_2(Se\,^tBu)]_2$ gives indium-rich films at a temperature of 230–420 °C, and $[In(CEtMe_2)(\mu_3\text{-Se})]_4$ produces crystalline InSe films.[102] Pyrolysis of $In(SePh)_3$ can form hexagonal In_2Se_3 films at 470–530 °C, and of $[Me_2EtC]InSe]_4$ can provide hexagonal InSe films at temperatures between 290–350 °C.[103] The cubic In_2Se_3 films can be obtained from $[In(Se_2CNMe\,^nHex)_3]$ and $[In\{SeC(SiMe_3)_3\}_3]$, respectively.

Films of chalcopyrite $CuInE_2$ are formed by MOCVD from the precursor $[(Ph_3P)_2Cu(\mu\text{-ER})_2In(ER)_2]$ (E = S or Se and R = Et or ^{i}Bu).[104] The compound $[Bu_2In(SPr)Cu(S_2CNPr_2)]$ is also reported to deposit $CuInS_2$ films by MOCVD. $[(n\text{-}Bu_3P)_2Cu(SR)_2In(SR)_2]$ (R = Et and n-Pr) and $[Bu_2In(SPr)Cu\ (S_2CNPr_2)]$ are also used to deposit $CuInS_2$ films.[105] The thiocarboxylates, $[(Ph_3P)_2AgIn(SC(O)R_4)]$ (R = Me, Ph), were excellent single-source precursors for $AgInS_2$ and $AgIn_5S_8$ films by MOCVD.[106]

5.4 Indium Nitride Precursor Compounds

The first adduct stabilized, volatile covalent indium bis-azide compound, $[(InN_3)_2\ (CH_2CH_2CH_2NMe_2)]$, has been characterized by single crystal X-ray diffraction. It has been used as a precursor for indium nitride thin films.[107] Other azide derivatives of indium, such as $[Cl_2InN_3]$, $[Br_2InN_3]$, $[py_2Na][py_2In(N_3)_4]$, pyridine, and tetrahydrofuran adducts, are also being studied as

precursors for InN materials.[108] Amido derivatives of indium compounds are also important in the preparation of InN materials. Synthesis and characterization of $[H_2InNH_2]$, $[N(CH_2CH_2NMe)_3In]_2$, $[InNH_2CH_3]$, and $[InNH(CH_3)_2]$, which are potential precursors for InN materials, have been reported.[109,110] The reaction of $[Li(Me_3Si)N–NHBu^t]$ with [MeInCl] can give different hydrazine derivatives of indanes, which are dependent on the solvent. With hexane as a solvent, the dimeric compound $[Me_3In(Li)(Me_3Si)N\text{-}NHBu^t]_2$ is produced. In diethyl ether, the cage compound $[MeIn\{N(SiMe_3)LiN(SiMe_3)NHBu^t\}]$, which can be regarded as an $(Me_3SiN{=}InMe)_2$ adduct with $[Li(Me_3Si)N–NHBu^t]_2$, is isolated. These compounds are good single-source precursors in MOCVD processes for InN thin films.[111]

The thermally stable In(I) compounds $[In(\eta^5\text{-}P_3C_2Bu^t{}_2)]$ and $[In(\eta^5\text{-}P_2C_3Bu^t{}_3)]$ have a half-sandwich structure, and are potential single sources for chemical vapor deposition of InP semiconductors.[28] The reaction of R_3PI_2 with indium metal produces a variety of novel indium compounds $[InI_3(PPh_3)_2{\cdot}InI_3(PPh_3)]$, $In_2I_4(PPr^n{}_3)_2$, and $InI_3(PPh^i{}_3)$, which may have applications in the microelectronics industry as precursors for MOCVD.[37] A key feature of $[R_2InPBu^t{}_2]$ (R = vinyl, allyl, and benzyl) is the presence of alkyl groups that are capable of facile β-hydride and/or alkyl radical elimination reactions, thus lowering deposition temperature into the range 400–590 °C.[76] In addition, $\{Et_2InSb(SiMe_3)_2\}_3$ is also used as precursor for the CVD of indium antimonide materials.[112]

6 INDIUM NANOMATERIALS

6.1 Introduction

Inorganic nanomaterials have attracted considerable attention owing to their novel physical and chemical properties that arise from size reduction and the potential applications in diverse areas. Moreover, these materials can also be used as 'building blocks' to assemble new generations of nanoscale electronic and optical devices. Indium, a low-melting metal, is easily alloyed and converted to InP, InAs, and InS, which are III-V/VI semiconductors that display interesting optoelectronic properties. Indium is easily oxidized to In_2O_3, which can be used as a sensor and light-emitting material. Indium oxides can form with SnO_2 the mixed indium tin oxide (ITO), a conducting glass.[2] Therefore, various indium-containing nanomaterials have been prepared in the last ten years.

6.2 Indium Nanomaterials

Indium nanoparticles can be prepared by metal vapor deposition, by evaporation of metal into a polymerizable monomer, or by reduction of $InCl_3$ with the appropriate quantity of alkalides or electrides.[113,114] In the latter, the indium particles often display an oxidized surface. The monodispersed indium nanoparticles can be obtained by thermal decomposition of organometal precursor $[In(\eta^5\text{-}C_5H_5)]$ using polyvinylpyrolidone (PVP) or trioctylphosphane oxide (TOPO) as a ligand. These particles can be further oxidized into well-crystallized In_2O_3 particles with unchanged morphology.[115,116] The bare indium nanoparticles have been prepared by solution dispersion route from bulk indium granules, which may be the simplest and cheapest method for making indium nanoparticles (Figure 1).[117] The cationic indium nanoparticles are also synthesized in a single crystal of zeolite X through an indium-exchanging process.[118]

The organometallic route can be extended to the formation of one-dimensional indium materials. On the use of long-chain amines as templates, In and In_3Sn nanowires have been prepared from the organometallic precursors InCp ($Cp = C_5H_5{}^-$) in the presence of UV irradiation. In this case, irradiation is crucial for the formation of the wires. In nanowires are also produced in the metal organic chemical vapor deposition grown InGaN layers.[119,120]

6.3 Indium Oxide Nanomaterials

Indium oxide, an n-type semiconductor with a wide band gap of about 3.6 eV, has been widely used as microelectronic device materials in solar cells, sensors, and conducting glasses. In_2O_3 nanoparticles can be prepared by sol-gel processes, or by thermal decomposition of In(acac)$_3$ precursors in the presence of a surfactant.[121] Oxidation of indium nanoparticles also gives In_2O_3 nanoparticles.[116] Without the presence of catalyst, the evaporation of In_2O_3 powders at 1400 °C can yield In_2O_3 nanobelts, which are single crystalline and grow along the 100 plane, with the surfaces being enclosed by {100} (Figure 2).[122] Under an H_2O/oxygen-containing argon atmosphere, thermal evaporation of indium granules also yields In_2O_3 nanowires. In this case, the growth of In_2O_3 nanowires is more likely to be controlled by the vapor–solid process.[123] In_2O_3 nanofibers are also obtained by annealing InOOH nanofibers at 490 °C. The InOOH nanofibers are prepared by controlling hydrolysis of $InCl_3$ at 190–240 °C.[124] Under argon/oxygen atmosphere, rapidly heating an indium-containing target covered with a thin Au layer can also give In_2O_3 nanowires. In this case, Au nanoclusters play a crucial role in directing the growth of In_2O_3 nanowires.[125]

In_2O_3 nanotubes have been synthesized by a sol-gel porous alumina templating method. The length and diameters of nanotubes can be varied by selecting the template dimensions and sol immersion time.[126] Evaporation of a mixture of In/In_2O_3 under vacuum also gives In_2O_3 nanotubes. Interestingly, the In_2O_3 nanotubes are filled with metallic indium, and the length and the position of In fillings can be modified by electron-beam irradiation.[127] Under argon/oxygen atmosphere, heating an indium–tin mixture also produces ITO nanofibers. The tin plays a crucial role in directing the growth of the ITO nanofibers based on the vapor-liquid-solid mechanism.[128]

6.4 Indium Nitride Nanomaterials

Indium nitride plays an important role in blue/violet light-emitting diodes and laser diodes. Nanocrystalline InN can be prepared by the reaction of azido-indium compounds such as iPr$_2$InN$_3$ or tBu$_2$InN$_3$ with H_2NNMe_2 used as a reductant at 203 °C. H_2NNMe_2 not only serves as a stoichiometric hydrogen-atom donor to assist alkane elimination, but also can reduce some of the azido precursor to form metallic indium, which should promote both precursor decomposition and crystal-lattice construction.[129] A benzene thermal conversion route has been developed to prepare nanocrystalline indium nitride through the reaction of In_2S_3 with Na_2S at 180–200 °C. This may be the lowest temperature at which crystalline InN has been obtained.[130] In addition, crystalline InN powders with the size of 50–300 nm are also prepared by the nitridation of In_2O_3 and In(OH)$_3$ with NH_3 gas.[131]

InP nanocrystals can be made by dehalosilylation of $InCl_3$ and (Me$_3$Si)$_3$P with subsequent thermolysis at 200–400 °C.[132] Monodisperse and soluble InP nanocrystals are obtained by thermolysis reactions in trioctylphosphine oxide. InP nanoparticles can also be obtained by the decomposition of organometallic precursors.[133,134] A novel route has been developed to prepare nanocrystalline InP by the reaction of $InCl_3$, P_4, and KBH_4 at temperatures as low as 80 °C, which is the lowest temperature reported for InP nanocrystals.[135] The synthesis of InP nanotubes by laser ablation is also reported.[136]

Nanocrystalline InAs is obtained by the reaction of (Me$_3$Si)$_3$As with $InCl_3$ or by reaction of $InCl_3$ with Na_3As, respectively. A solvothermal route has been proposed to prepare InAs nanocrystals, which involves co-reduction of $InCl_3$ and $AsCl_3$ by Zn.[137] The high quality nanocrystalline InAs can be obtained by the thermolysis of a mixture of $InCl_3$ and As(NMe$_2$)$_3$.[138] In addition, InSb nanocrystals can also be obtained by the solvothermal reduction route.[139]

6.5 Indium Chalcogenide Nanomaterials

Copper indium chalcogenides $CuInE_2$ (where E = S, Se, and Te) are ternary semiconductors, which have emerged as a leading material for high efficiency and radiation-hard solar cell applications. $CuInS_2$ nanocrystals are prepared by a simple colloidal route, using $InCl_3$, CuI, and bis(trimethylsilyl) sulfide as starting materials and TTP (triphenyl phosphite) as surfactant. In this case, the particle surface is shielded by a surfactant.[140] $CuInSe_2$ nanocrystals are also prepared using a two-step reaction from $InCl_3$ and CuCl in a suitable solvent, followed by the addition of trioctylphosphine selenide.[141] Solvothermal routes are also used in the synthesis of $CuInSe_2$, $AgInS_2$, and $CdIn_2S_4$ nanocrystals.[142–144]

7 INTERMETALLIC COMPOUNDS

7.1 Introduction

The development of new intermetallic compounds demands greater understanding of the relationship among structure, bonding, and properties. The Zintl concept provides an effective way to describe the structures of compounds formed between electropositive metals and main-group elements, in which the electropositive atoms serve to donate their valence electrons to main-group atoms. Elements to the right of the Zintl border (separating group 13 and 14) with electropositive metals usually form valence compounds (Zintl compounds), with narrow ranges of composition and the valence electron concentration per atom (vec) exceeding 4. On the other hand, the compounds with elements to the left of the Zintl border behave like traditional intermetallic compounds (Hume-Rothery phases) with wide ranges of homogeneity for different structures and vec values between 1 and 2. There are no clear classification schemes for the range between 2 and 4. Furthermore, many indium-containing intermetallic compounds have a vec near 3 and the degree of In–In bonding in these compounds depends strongly on the indium content as well as the electron count.[145] Therefore, much attention has been directed to understanding the indium-containing compounds 'between' Hume-Rothery and Zintl phases in the past ten years.

7.2 Binary Compounds

The binary indium-rich transition metal compounds show a variety of different indium networks. In the structures of T_2In_5 (T = Ti, Hf), the indium atoms form infinite two-dimensional (2D) planar networks, which can be described as a tessalation of triangles, squares, and pentagons. The 2D network is also found in the structures of the La_3In_5 compounds, which contain well-defined indium square pyramids and some intercluster indium–indium distances that are only 11–15% greater than the average intracluster bond lengths. The apparent In_5^{9-} cluster in La_3In_5 can be described as a closed shell nido-deltahedron, and the compound structurally as a Zintl phase. The β-Y_3In_5 compounds with a similar structure to La_3In_5 present a slow first-order phase transition to α-Y_3In_5 at high temperature. Clusters in the low-temperature α-Y_3In_5 phase are twisted and joined by short bonds at trans-basal positions into chains that are more weakly interconnected into a three-dimensional structure.[146]

The 3D network of indium atoms is found in the TIn_3 (T = Co, Rh, and Ir) compounds. The compounds TIn_3 (T = Co, Rh, and Ir) belong to a large family and are built up from tungsten-like building blocks of indium atoms and AlB_2-like slabs of compositions $In\square Co$, $In\square Rh$, and $In\square Ir$, respectively, where $\square$ represents the vacancies in the AlB_2 fragments of TIn_3. $RhIn_3$ shows evident antibonding Rh–Rh interactions, and three compounds display similar bonding characteristics to $RuIn_3$.[147]

7.3 Alkaline Earth-transition Metal–Indium Compounds

The main features of ternary alkaline earth-transition metal–indium compounds are 2D or 3D infinite transition metal–indium polyanions in which the degree of In–In bonding strongly depends on the indium content and the structure type. CaAuIn compounds adopt the KHg_2-type structure with an ordered arrangement of gold and indium atoms on the mercury position. Each calcium atom has a distinctly ordered near-neighbor environment of six gold and six indium atoms in the form of two Au_3In_3 hexagons.[148] Within SrPtIn, the indium atoms have a distorted tetrahedral platinum coordination. These $InPt_{4/4}$ tetrahedra are edge- and corner-shared, forming a 3D [PtIn] polyanion in which the strontium atoms are embedded.[149] The CaRhIn structure also consists of strongly puckered Rh_3In_3 hexagons in which each rhodium atom has a distorted tetrahedral indium environment and the calcium atoms fill the channels within the 3D [RhIn] polyanion.[150]

The structures of $CaTIn_2$ (T = Pd, Pt, Au) are transition metal (T)-centered trigonal prisms formed by the calcium and indium atoms. The transition metal and indium atoms form a 3D [TIn_2] polyanion in which the large alkaline earth metal atoms occupy one-dimensional pentagonal tubes, and the strongest bonding interactions are found for the In–In and T–In contacts.[150,151]

The 3D [TIn_4] polyanions are also found in the structure of $CaTIn_4$ (T = Rh, Pd, Ir), in which the calcium atoms occupy distorted pentagonal tubes formed by indium and transition metal.[152] The main motifs of both $Ca_2Au_3In_4$ and $Sr_2Pt_3In_4$ are condensed, platinum (gold)-centered trigonal prisms formed by the alkaline earth and indium atoms. The platinum (gold) and indium atoms form complex 3D [Pt_3In_4] and [Au_3In_4] polyanions respectively, and the alkaline earth cations are located in distorted hexagonal tubes.[149]

7.4 Rare Earth-transition Metal–Indium Compounds

The ternary rare earth-transition metal–indium compounds display a pronounced tendency for clustering of the transition metal atoms and a 2D and sometimes 3D indium substructure depending on the relative content of indium. The structures of (RE)$In_{1-x}Sb_2$ (RE = La–Nd) is built up of alternating layers of compositions $[Sb]_m$ and $[In_{0.8}Sb]_m$ ($m = 2 \sim \infty$), separated by the La atoms. The $[Sb]_m$ layer is described as a nearly square net of Sb atoms held by weak one-electron bonds, while the $[In_{0.8}Sb]_m$ layer is derived from an edge-sharing [$InSb_4$] tetrahedron distorted in such a way as to produce In–In zigzag chains.[153] The one-dimensional [Ni_7] clusters are observed in the compound $LaNi_7In_6$.[154]

The complexes (RE)TIn_2 (RE = Eu, Yb; T = Pd, Au) also form transition metal (T)-centered trigonal prisms by the rare earth metal and indium atoms. The transition metal and indium atoms form a 3D [TIn_2] polyanion in which the large rare earth metal atoms occupy one-dimensional pentagonal tubes.[155] The strongest bonding interactions are found for the In–In and Pd–In contacts; the Eu–Pd and Eu–In interactions are much weaker.

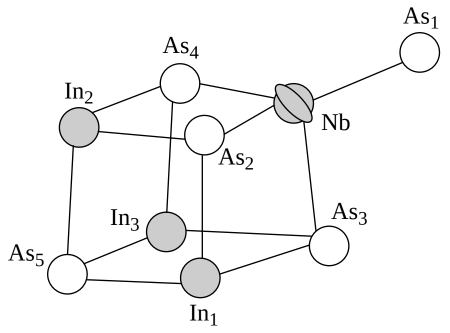
The structural motifs of $LaPtIn_3$ are condensed distorted trigonal [$PtIn_6$] prisms, and Pt–In and In–In bonding play an important role in the structure. The La atoms occupy large cavities within the polyhedral network.[156] Within $LaPtIn_4$ or $YbPtIn_4$, together with indium atoms platinum atoms form a complex 3D [$PtIn_4$] polyanion in which the lanthanum or ytterbium atoms occupy large hexagonal tubes.[157] In the structure of $LaNiIn_4$, the nickel and indium atoms also form a 3D [$NiIn_4$] polyanion and the indium substructure consists of distorted bcc-like indium cubes.[154]

Within $YbCoIn_5$ and $YbRhIn_5$, the transition metal atoms have eight indium neighbors in a square prismatic coordination by indium atoms; these prisms are condensed via common edges, forming layers. The ytterbium and additional indium atoms are located between these layers. The ytterbium atoms are cubooctahedrally coordinated by 12 indium atoms.[157]

The gold and indium atoms in $La_3Au_4In_7$ build a 3D [Au_4In_7] polyanion in which the lanthanum atoms fill distorted pentagonal and hexagonal channels. Within the polyanion, short Au–In and In–In distances are indicative of strongly bonding Au–In and In–In interactions.[158] Within $EuRh_2In_8$, the rhodium and indium atoms together build a complex 3D [Rh_2In_8] polyanion in which the europium atoms are located within distorted pentagonal channels. In $RE_4Pd_{10}In_{21}$ (RE = La, Ce, Pr, Nd, Sm), all palladium atoms have a trigonal prismatic coordination. The strongest bonding interactions occur for the Pd–In and In–In contacts. The structures are composed of covalently bonded three-dimensional [$Pd_{10}In_{21}$] networks in which the rare earth metal atoms fill distorted pentagonal channels.[159,160] In addition, the 3D [$Pt_{12}In_{32}$] network is also observed in the structures of $Gd_3Pt_4In_{12}$ and $Tb_3Pt_4In_{12}$.[161]

7.5 Multinary Compounds

The compound $Cs_7NbIn_3As_5$ contains an unprecedented anion, $[\{In_3As_4Nb\}-As]^{7-}$, a cubane made of three indium, four arsenic, and one niobium atom and a 'handle' composed of an arsenic atom that is multiply bonded to the niobium corner (Scheme 8).[162]



Scheme 8 Structure of the cubane with a 'handle' $[\{As(InAs)_3\}Nb-As]^{7-}$, Ref. 162

The structure of $[PtIn_6][GaO_4]_2$ contains the [$PtIn_6$] octahedral, which are linked via $[GaO_4]^{5-}$ tetrahedral to a 3D network. Starting from $[PtIn_6][GaO_4]_2$, the substitution of Ga^{3+} ions by larger In^{3+} ions leads to the formation of a solid solution series according to the general formula $[PtIn_6][GaO_4]_{2-x}[InO_4]_x$ and becomes apparent in an increase of the lattice parameter.[163]

The first compound representing the next stage of a structural hierarchy, that is supertetrahedra of supertetrahedra, specifically is a T2 supertetrahedron of T4, a discrete anionic cluster of 214 atoms and 80 tetrahedral centers. The structure contains the finite tetrahedral anionic units of $[Cd_{16}In_{64}S_{134}]^{44-}$ that have an underlying T2 type of structure in which the individual tetrahedra have each been replaced by a T4 supertetrahedron forming a super-supertetrahedron.[164]

In the compound $Ba_6ZnIn_2Cl_{20}$, Zn^{2+} is surrounded tetrahedrally and In^{3+} octahedrally by chloride ions. Half of the [$InCl_6$] octahedra are isolated from each other; the other half share common edges to form [In_2Cl_{10}] double octahedra. Ba^{2+} has coordination numbers of eight and nine.[165]

$Na_3K_{23}Cd_{12}In_{48}$ is obtained by stoichiometric fusion of the elements and is composed of indium icosahedra, indium triangular clusters, and the novel $Cd_{12}In_6$ tubular cluster. The latter contains two Na^+ ions and a 96-atom polyhedra (fullerane), and is sheathed by 20 K^+ and $12Na^+$. The clusters are linked together through two-center two-electron bonds with a 3D anionic network.[166]

8 INDIUM CATALYZED ORGANIC SYNTHESIS

8.1 Introduction

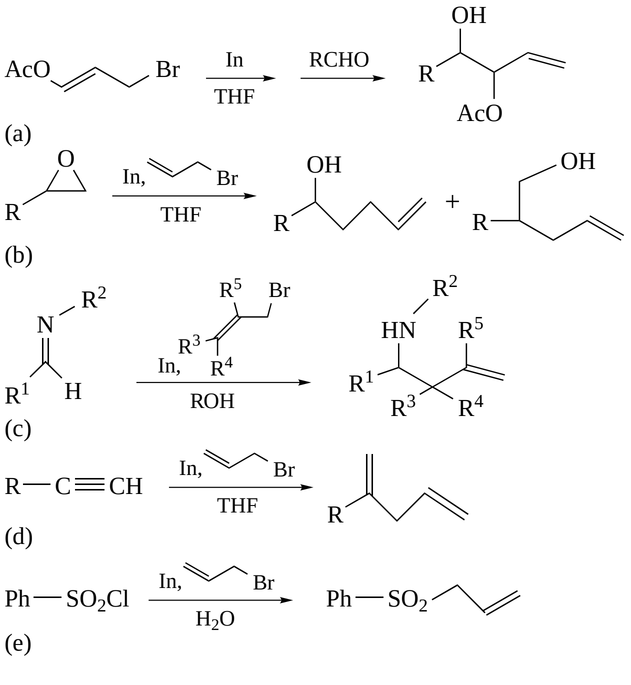
Since the discovery of the indium-mediated Barbier–Grignard reaction in 1991, indium reagents have become more popular in organic synthesis.[167] The attraction of indium catalysis is that it provides the ability to perform organic reactions in water. During the last decade, a large proportion of this work has been focused on the use of indium reagents to promote organic reactions in aqueous media. Moreover, indium-assisted reactions often display a low heterophilicity and low nucleophilicity that imparts high regio- and chemoselectivity in various chemical transformations of groups of similar reactivity, without protecting other groups.

The recent emergence of indium halides as efficient Lewis acid catalysts presents new and exciting opportunities for indium chemistry.[168]

8.2 Allylation

The indium-mediated allylation reaction is an aldol-type reaction where the nucleophile is an allylindium species usually generated from allylic halide and indium. By far the greatest number of indium-mediated organic reactions involves the allylation of unsaturated compounds, and the list of indium-mediated allylations is formidable. In principle, there are five types of indium-mediated allylation reactions depending on the unsaturated functional groups (Scheme 9). (a) Treatment of allylindium reagents with carbonyl compounds can produce the corresponding allylalcohols;[169–171] (b) Reaction with terminal epoxides affords the corresponding bishomoalcohols;[172] (c) Allylation of aldimines gives the corresponding homoallylic amines;[173,174] (d) Reaction with alkenes or terminal alkynes gives the corresponding alkenes and 1,4-dienes respectively;[175,176] (e) Aromatic sulfonyl halides react with allyl indium reagents to give the corresponding sulfones.[177]

In general, solvent effect can play a significant role in the reactions and the regio- and stereo-selectivity of allylations is determined by the location of other functional groups in the molecules and the reaction solvents; several reports on the effect of other functional groups and solvents on the selectivity are published. Araki's group has noted that hydroxy-bearing cyclopropens can be allylated both in organic and aqueous media, but the regio- and stereo-selectivity can be regulated by both the location of the hydroxyl group in the molecules and the reaction solvents.[178]



Scheme 9 Indium-mediated allylation reactions

8.3 Acylation

The acylation of alcohols and amines is one of the most frequently used transformations in organic synthesis as it provides an efficient and inexpensive means for protecting hydroxy and amino groups in a multistep synthetic process. The Lewis acid catalyzed acylation is a mild alternative to conventional acidic or basic catalyst. The extremely efficient acylation of a diverse range of substrates has been noted using indium halides. Using this method, acylation of a primary OH group in the presence of secondary and phenolic OH groups, and of a primary NH_2 in the presence of secondary NH and primary OH, has been achieved with high selectivity. The practical utility of indium halides is reflected in the high-yielding acylation of polyhydroxy compounds.[179,180]

8.4 Addition to Imines

α-Aminophosphonates have been the subject of considerable recent interest owing to their structural analogy to α-amino acids, and several synthetic methods for the compounds have been developed. Of these, the nucleophilic addition of phosphates to imines, catalyzed by Lewis acids such as $SnCl_2$, $ZnCl_2$, and $MgBr_2$, is the most convenient. However, these reactions cannot be carried out in a one-pot operation starting from a carbonyl compound, an amine, and dialkyl phosphite because the amines and water present during imine formation are likely to decompose or deactivate Lewis acids. To circumvent this disadvantage, an elegant procedure has been developed employing indium (III) chloride as catalyst from the reaction of a carbonyl compound, amine, and diethyl phosphite. The method is operationally simple and applicable to aldehydes and ketones. The reaction is tolerant of sensitive functional groups and chelating groups.[181] In this way, a wide range of structurally diverse carbonyl compounds was converted into the corresponding α-Aminophosphonates in high yields.[3,182] In addition, indium agents are also effective for the conversion of azides to carbamates.[183]

8.5 Reduction

Indium is reported to be an efficient catalyst for the debromination processes of vic-dibromides. An illustration of the utility of this method is in the debromination of aryl-substituted vic-dibromides to produce the corresponding (E)-alkenes with indium metal in MeOH. In general, the reaction proceeds via a common, relatively stable radical intermediate, collapse of which leads directly to the (E)-alkenes, and methanol is found to be the best solvent for this reaction.[184]

Indium metal is equally effective for the reductive of α-halocarbonyl compounds as demonstrated by the

transformation of $PhCOCH_2Br$ to the dehalogenated product $PhCOCH_3$.[185] A wide range of structurally diverse α-halo ketones and esters has been reduced according to this procedure to provide the corresponding dehalogenated carbonyl compounds.[186]

8.6 Other Reaction

A catalytic amount of indium metal effectively promotes the homocoupling of alkyl and aryl halides to provide the corresponding bialkyls and biaryls.[187] Ranu's group has reported that indium (III) chloride is very effective in effecting the rearrangement of epoxides in THF solution to give the corresponding carbonyl compounds very selectively.[188] Indium (III) chloride is effective in catalyst amounts for the Michael reaction between amines and α,β-ethylenenic compounds in water,[189] Diels–Alder reaction between various dienes and dienophiles in water,[190] and the synthesis of alkyl and aryl 2,3-unstaturated C-glycosides through the Ferrier rearrangement.[191] The combination of indium catalyst and other catalyst is extremely effective for deoxygenation process. For example, treatment of tetralone with Me_2SiClH in the presence of indium (III) chloride at room temperature produces tetralin in excellent yields.[192] In addition, $InBr_3$, indium (III) triflate, and In (I) compounds used for catalyst also are reported.[193]

1 INTRODUCTION

The importance of organoindium derivatives has been perpetuated in the last decade by their application as precursors to materials for advanced technologies, in particular, for fabricating multi-component alloys classified as III-V and I-III-VI semiconductors. Key areas that have helped advance the drive for new indium derivatives are thin-film technologies and, more recently, nanotechnology. A number of reviews and reports have been published that discuss in whole, or in part, organometallic compounds of indium.[1–15] Furthermore, general overviews of the chemistry of organoindium compounds related to thin-film technology were presented in books and annual reviews.[16–32] Another area where the use of indium organometallics has found increased use is for organic synthesis, more precisely the formation of indium organometallics *in situ* from elemental indium.[33–38] An area of interest that has gathered considerable interest is the indium meditated coupling of allyl and propargyl halides with aldehydes to give the corresponding alcohols in high yields.[39] An important aspect of this reaction is the ability to obtain good regioselectivity and diastereoselectivity by steric or chelation control.[37]

2 ALKYL AND ARYL DERIVATIVES, InR_3

2.1 Synthesis

The established method of choice for synthesizing indium derivatives follows those classically defined and used for generic organometallic synthesis. These are (a) Metathesis: equations (1), (2), and (3); (b) Transmetallation/Mercuration: equation (4); (c) Mixed metal Synthesis (direct): equation (5); (d) Metal plus organic halide (direct): equation (6).

$$InX_3 + 3RMgX \xrightarrow{Et_2O} InR_3(Et_2O) + 3MgX_2 \quad (1)$$

$$InX_3 + 3RLi \xrightarrow{Et_2O} InR_3(Et_2O) + 3LiX \quad (2)$$

$$InX_3 + 3R_3Al \longrightarrow InR_3 + 3R_2AlX \quad (3)$$

$$2In + 3R_2Hg \longrightarrow 2InR_3 + 3Hg \quad (4)$$

$$2In + 3Mg + 6RX \xrightarrow{Et_2O} 2InR_3(Et_2O) + 3MgX_2 \quad (5)$$

$$In + 3.5RX \xrightarrow[R = Me,\ 3.5Li]{hexane} InR_3 + 3LiX \quad (6)$$

A limiting factor for the use of group I organometallic reagents for the preparation of InR_3 from InX_3 (equation 2) is that many sodium or lithium reagents often act as reducing agents, affording In(I)R derivatives in poor to good yields instead of the desired In(III) organometallics. The use of Grignard reagents (RMgX) or AlR_3 does circumvent reduction of In(III) to In(I). With the exception of the metathesis route using AlR_3, both group I and Grignard reagents require the synthesis to be conducted in a coordinating solvent that subsequently forms an adduct to the desired product, e.g. $[InR_3{\cdot}(OEt_2)]$. However, repeated vacuum distillation, or azeotropic distillation with noncoordinating aromatic/aliphatic solvents results in the removal of the diethyl ether. Alternatively, it has recently been shown that thermal decomposition of $[InR_3{\cdot}(OEt_2)]$ in the presence of CsF affords the adduct free $InMe_3$ in very high yields.[40]

The use of mercurating agents (R_2Hg) has become obsolete owing to extended reaction times and elevated reaction temperatures, but more importantly due to the associated toxicity of mercury compounds. Mixed metal synthesis (equation 5) has proved to be versatile and is widely used owing to the high product yields and purity.[41] The propensity for ultra-high purity InR_3 via mixed metal synthesis has largely been driven by the semiconductor industry and its need to eliminate extrinsic dopants during synthesis (equation 6). This has warranted numerous patents for the preparation of InR_3.[41–51] The use of photoexcited indium atoms and their reaction with CH_4 to afford low-valent In(I) and In(II) has also been studied, and is expanded in Section 8.

Limited heteroleptic organoindium examples are known since they have a tendency to rearrange to form the more stable symmetrical derivatives. The preparation of the majority of the heteroleptic compounds has been investigated via (a) ligand redistribution (equation 7–8), (b) metathesis (equation 9), or (c) methane elimination (equation 10);

$$InR_3 + 2InR'_3 \longrightarrow 3RInR'_2 \quad (7)$$

$$2InR_3 + InR'_3 \longrightarrow 3R_2InR' \quad (8)$$

$$R_2InX + LiR' \longrightarrow R_2InR' + LiX \quad (9)$$

$$In(CH_3)_3 + H\text{-}R' \xrightarrow{\text{Heat}} (CH_3)_2InR' + CH_4 \quad (10)$$

The synthesis of mixed alkyl indium organometallics has again been driven by the need for more volatile and enhanced properties for use in CVD and related areas. This has been a subject of recent review and discussion with attention being focused on the existence of liquid ethyldimethylindium ($EtInMe_2$).[27] Although two patents currently exist for the preparation of high purity $EtInMe_2$,[48,51] an early study by two independent research groups demonstrated that $EtInMe_2$ was indeed a mixture of $InMe_3$ and $InEt_3$ (equation 11).

$$3EtInMe_2 \rightleftharpoons 2InMe_3 + InEt_3 \quad (11)$$

The most definitive examples of heteroleptic organoindium (III) compounds are generally found for mixed alkyl-cyclic systems. Ligand redistribution reactions between $InCp_3$ and InR_3 (R = Me and CH_2CMe_3) in THF solution provided $R_2In(C_5H_5)$ and $RIn(C_5H_5)_2$.[52] These heteroleptic organoindium(III) compounds were isolated as analytically pure crystalline solids; however, in THF solution, the compounds underwent a redistribution mechanism to afford equilibrium mixtures of the THF-adducts of InR_3, $R_2In(C_5H_5)$, $RIn(C_5H_5)_2$, and $In(C_5H_5)_3$. Single-crystal X-ray structural studies unequivocally showed the existence of the mixed alkyl-cyclic derivative $[(Me_3CCH_2)_2In(C_5H_5)]$, which revealed the compound to exist as a polymer with cyclopentadienide units bridging $In(CH_2CMe_3)_2$ moieties (Figure 1).

Heteroleptic derivatives have also been prepared via metathesis and methane elimination reactions as illustrated by the synthesis of $[Me_2In(C_5H_5)]$, which was obtained by the reaction between $[Me_2InCl]$ and $Li(C_5H_5)$ in THF at 145–160 °C.[53] An X-ray structural study identified an infinite linear polymer with cyclopentadienide units bridging $InMe_2$ moieties through the 1 and 3 positions of the ring (Figures 2 and 3).

Like most heteroleptic derivatives, $[Me_2In(C_5H_5)]$ when dissolved in THF exists as an equilibrium mixture of components $[Me_2In(C_5H_5)]\cdot THF$, $[MeIn(C_5H_5)_2]\cdot THF$, and $[InMe_3]\cdot THF$.

2.2 Properties

Indium organometallics are generally pyrophoric and sensitive to air and moisture, with some exceptions.[54] The thermal decomposition pathway has been studied largely in order to understand how to achieve derivatives that will pyrolyze at lower temperatures with minimal impurities such as carbon. InR_3 with β-hydrogen's have been shown to decompose via a β-hydride elimination pathway to give the respective olefins and metal hydride.[54] Generally the possibility of β-elimination lowers the decomposition temperature of the metal alkyls, and in addition some branching at the β position weakens the In–C bond. Furthermore, the onset for the decomposition temperature decreases upon introduction of increased alkyl chain length and steric encumbrance.[27,55] In contrast, thermal solution decomposition studies of indium trialkyls possessing an α-branch, for example, [In(*s*-Bu)$_3$] and [In(*i*-Pr)$_3$], have demonstrated decomposition to occur predominately through an α-fission pathway to selectively give the corresponding alkyl radicals.[54]

A recent study on the stability of various indium alkyl derivatives has been performed using differential scanning calorimetry (DSC), which provides a comprehensive thermal ''fingerprint'' of the compounds.[55] In addition, when this method of thermal analyses is used in conjunction with thermogravimetric analysis coupled to FTIR and/or GCMS evolved gas analysis, it can provide a complete mechanism for the decomposition pathway of prospective compounds.[56]

Selective physical properties of some organoindium compounds are listed in Table 1.

Studies on the properties of trialkyl indium derivatives and their designated use in MOCVD have also been reported,[58,59] and for the first time a detailed study on the vibrational spectrum for $InMe_3$ has been reported.[60]

2.3 In(III) Adducts

Organoindium derivatives behave as Lewis acids, readily forming adducts with electron-donating species. A large number of organoindium chelating compounds have been identified and studied.[55] One of the most noticeable differences between chelated and nonchelated InR_3 is the associated reduced reactivity due in part to the saturation of the indium-metal coordination sphere. A novel use of alkyl indium chelate chemistry is for the purification of InR_3 by removal of extrinsic impurities for the semiconductor industry. This method is in commercial practice by Epichem. The method involves reacting InR_3 with an ultra-pure Lewis base to afford the trialkyl indium chelate as a stabilized nonvolatile adduct. This can subsequently be purified via recrystalization or distillation. The purified InR_3 is then obtained by controlled thermal dissociation of the adduct.[55] $InMe_3$ purified via this technique has been shown to have reduced silicon impurities by a factor of 100 and when used to fabricate III–V semiconductors thin films, enhanced carrier concentration and mobility were recorded.[27]

3 ORGANOINDIUM HALIDES

3.1 Synthesis

Organoindium halides can readily be prepared by many of the synthetic methods outlined for the preparation of organoindium derivatives, but with stoichiometric control to afford the organoindium halide derivative.[61–73] For example, (a) reaction of InX_3 with less than three equivalents of a lithium or Grignard reagent (equations 12–13), (b) reaction of R_3In with HX, which proceeds by elimination of a simple organic moiety (equation 14), (c) a redistribution reaction between InX_3 and R_3In (equations 15–16).

$$InX_3 + nRMgX \xrightarrow{n = 1, 2} R_nInX_{(3-n)} + nMgX_2 \quad (12)$$

$$InX_3 + nLiX \xrightarrow{n = 1, 2} R_nInX_{(3-n)} + nLiX \quad (13)$$

$$InR_3 + nHX \xrightarrow{n = 1, 2} R_{(3-n)}InX_n + nR\text{-}H \quad (14)$$

$$InX_3 + 2InR_3 \longrightarrow 3R_2InX \quad (15)$$

$$3InX_3 + 3R_2InX \longrightarrow 6RInX_2 \quad (16)$$

Specialized methods include (a) reaction of halogens with R_3In to yield R_nInX_{3-n} compounds, and (b) reaction of an indium(I) or indium(II) halide with an organic halide via *Oxidative Addition* (equations 17–18).[74–76]

$$InX + CH_2X_2 \xrightarrow[X = I, Br]{R = Alkyl} X_2InCH_2X \quad (17)$$

$$In_2Cl_4 + CH_2Cl_2 \longrightarrow Cl_2InCH_2InCl_2 \quad (18)$$

These indium halomethyl derivatives possess two-electron donor sites, namely the indium atom and the CH_2 group where coordination may occur. Anionic ligands preferentially coordinate to indium atom (e.g. $[R_4N]^+[X_3InCH_2X]^-$), while neutral ligands attack the CH_2 group via nucleophilic substitution of the methlyene halide following concomitant halide transfer to the indium atom to give X_3InCH_2L.[77] The potential application as indium metal ylids was also investigated for adducts with group 16 ligands.[77] An extension to the novel preparation of indium(III) halomethyl derivatives via oxidative insertion of InX into the carbon–halide bond of methylene dihalides ($X\text{-}CH_2X$) (equation 17) has now been demonstrated to be feasible for haloforms (CHX_3) for the preparation of X_2InCHX_2 compounds (equation 19).[78]

$$InX + CHX_3 \xrightarrow{X = I, Br} X_2InCHX_2 \quad (19)$$

The reactivity of X_2InCHX_2 with anionic ligands is analogous to X_2InCH_2X, where the corresponding salts $[X_3InCHX_2]^-$ and $[X_3InCH_2X]^-$ can be isolated respectively. However, unlike X_2InCH_2X, when X_2InCHX_2 derivatives undergo reaction with neutral ligands (L) the associated adduct of InX_3 is formed. This suggests that the decomposition of the dihalomethyl indium compounds (X_2InCHX_2) proceeds via carbene elimination (equation 20).

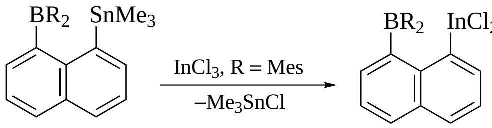
$$X_2InCH_2X + L \longrightarrow InX_3L + :CHX \quad (20)$$

The transmetalation of organotin derivatives to their indium counterparts (Scheme 1) has recently been used to investigate a new route to Group 13 polyfunctional Lewis acids, which are becoming important in catalysis, molecular recognition, and materials synthesis.[79–82]

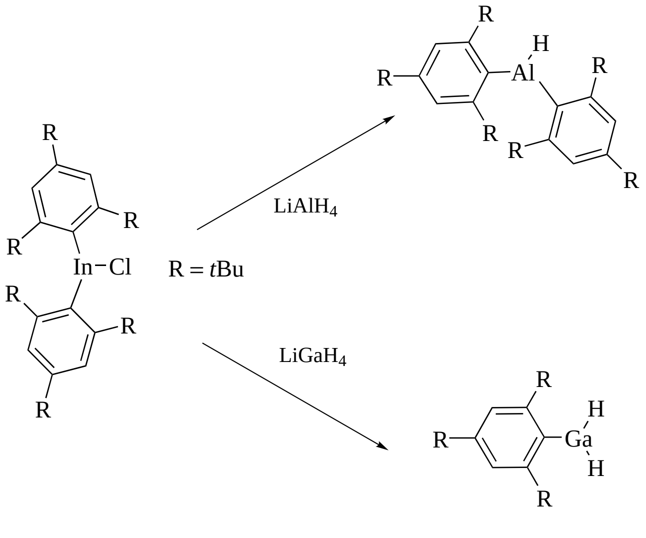
As synthetic reagents, sterically encumbered organoindium halides have been used in transmetalation reactions to prepare the first example of a monomeric base-free group 13 hydride complex (Scheme 2).[83]

The first example of the indium carbene complexes have been reported using the stable imidazolyidene carbene derivatives (Scheme 3).[84–86]

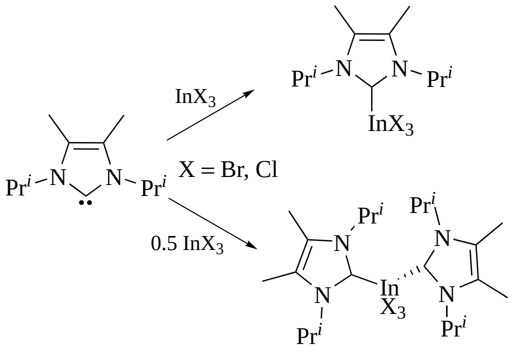
The indium carbene derivatives were prepared from a THF solution at room temperature. The reaction of excess carbene to the InX_3 (5:1) only afforded the 2:1 adduct and unreacted carbene, which suggested that higher adduct formation was not sterically viable. X-ray crystallography showed the 1:1 indium bromide adduct to be monomeric and tetrahedral



Scheme 1 Transmetalation of organotin to organoindium derivatives



Scheme 2 Preparation of a monomeric base- free group 13 hydride complexes



Scheme 3 Formation of organoindium carbene halide derivatives

and both bromo and chloro 2:1 adducts to have a trigonal-bipyramidal geometry, and surprisingly two axial halides and one equatorial. The treatment of the indium halide with one equivalent of the carbene in the presence of water was found adventitiously to afford a novel ionic indium imidazolium species (Scheme 4).[84,87] Additional indium analogues with increasing steric encumbrance provided by the carbene moiety have been investigated to determine the stabilizing effect on the indium coordination sphere.[85,86]

The preparation of ''inert'' organoindium halides with sterically demanding ligands such as Mes (2,4,6-$Me_3C_6H_2$), Trip (2,4,6-$i$$Pr_3C_6H_2$), or Mes* (2,4,6-$t$$BuC_6H_2$), and so on has become a recent trend.[88–90] Most of these derivatives are prepared via the normal synthetic routes outlined earlier. A key property provided by the added steric protection from the ligands is the lack of dimerization, and association of the reaction solvent such as THF or ether (e.g. [In(Mes*)X_2], Figure 4).[89,90]

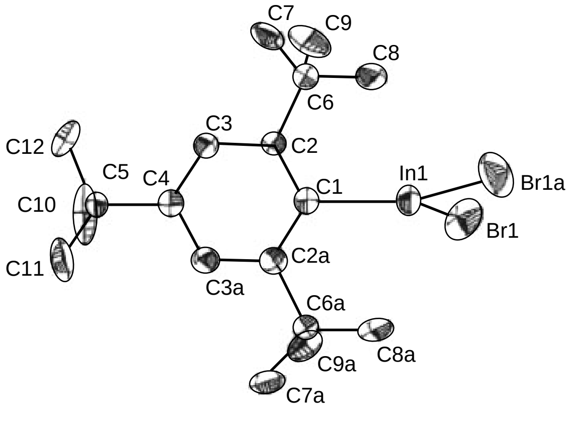


Figure 4 Structure of [In(Mes*)X_2], X = Br, Cl

4 ORGANOINDIUM PNICTOGENS

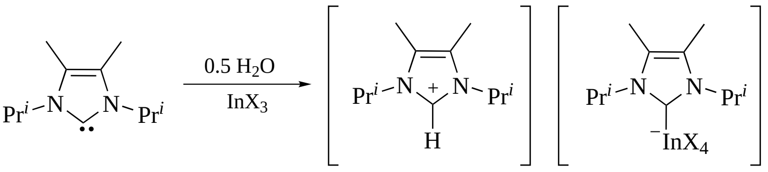
The number of indium and other Group 13 inter and intra pnictogen adducts have been attributed to an investigation of their coordination chemistry, kinetic reactivity, and application as single-source precursors to binary III-V semiconductors and catalysis. Organometallic adducts of Group 13 have been largely dominated by tetrahedral coordination mode. However, there has been a strong impetus to synthesize and characterize organoindium derivatives of higher coordination number, which can be achieved with bulky substituents, the aspiration being to form derivatives with a monomeric nature and inert or reduced kinetic reactivity, and compounds free from reaction solvent incorporation.

There are three main bonding modes which are prevalent for organoindium pnictogens: (a) inter-datively, (b) intra-datively, and (c) direct. In addition, mixed bonding modes (d) are also commonplace (Scheme 5).

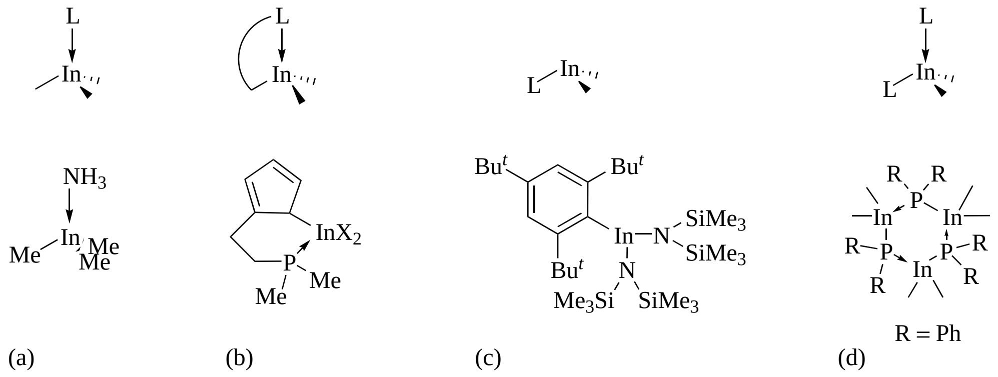
The mixed bonding mode generally occurs for indium pnictogen adducts with reduced steric demand, leading to the formation of the heterocyclic $[Me_2InL(SiR_3)_2]_x$ compounds. These III-V heterocycles are made up of the amphoteric R_2M-LR_2 moiety, which simultaneously reacts as a Lewis acid (In) and a Lewis base (pnictogens). The lone pair character of the heavier pnictogen and the presence of an adjacent empty orbital of indium ensure that associated species with ''head to tail'' ring-coordinate centers are normally observed. Additionally, the affinity of both In and the pnictogen groups toward attaining tetrahedral coordination geometry limits monomeric compound formation (R_2M-ER_2), which is realized by the use of highly sterically demanding substituents.

4.1 Synthesis

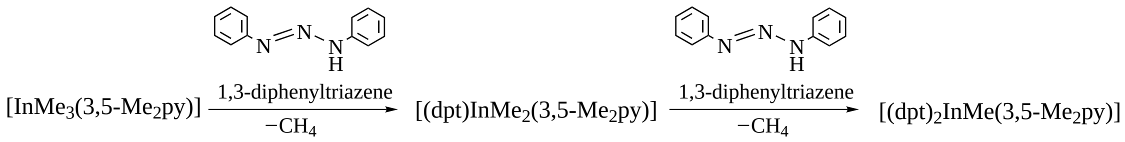
Intermolecular adducts of organoindium can be prepared in a hydrocarbon solvent by reaction with a Lewis base[91,92] (equation 21), or via displacement of more labile adducts



Scheme 4 Formation of ionic indium imidazolium species



Scheme 5 Bonding modes for organoindium pnictogens



Scheme 6 Synthesis of organoindium compounds via methane elimination

such as etherates[93] (equation 22). Adduct formation can generally be reversed cleanly by controlled distillation to obtain adduct free derivatives.[27,55,93] Intramolecular adducts can be formed by metathesis type reactions between organoindium halides with lithium[94–115] and Grignard[93,116–119] reagents (equations 23–24) or by elimination of small gaseous molecules[120–151] (equation 25, e.g. Scheme 6).[137,151]

Additionally, the use of metal halides has been shown to accelerate alkane elimination and product formation, for example, the reaction of phenylacetonitrile with $InMe_3$. The introduction of CsF has been perceived to act as a catalyst by forming intermediate metalates of the types $[XMMe_3]^-$ and $[Me_3MXMMe_3]^-$.[120]

$$R_3M + L \longrightarrow R_3InL \qquad (21)$$

$$R_3M(Et_2O) + L \xrightarrow[-Et_2O]{} R_3InL \qquad (22)$$

$$R_2MX + LiR'LR_2 \xrightarrow[-LiX]{} R_2In\text{-}R'LR_2 \qquad (23)$$

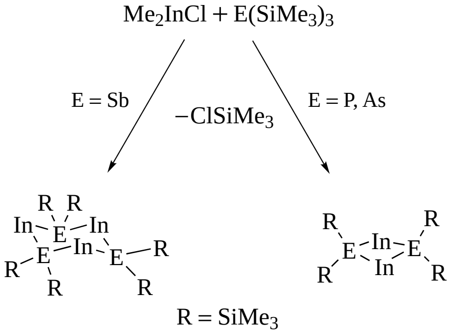
$$R_2MX + XMg(R'LR_2) \longrightarrow R_2In\text{-}R'LR_2 \qquad (24)$$

$$R_3M + R_2LH \longrightarrow R_2InL + CH_4 \qquad (25)$$

$$R_2InX + L(SiR_3)_3 \longrightarrow R_2In\text{-}L(SiR_3)_2 + XSiR_3 \qquad (26)$$

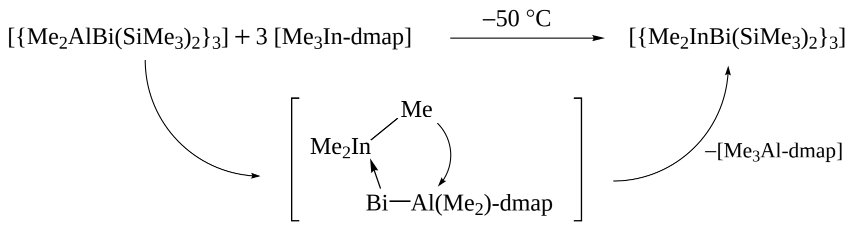
Dehalosilyation reactions involving $L(SiR_3)_x$ and $XInR_2$ also prove to be a versatile synthetic pathway.[152–156] The driving force for the reaction is the high propensity for Si–X bond formation ($381\,kJ\,mol^{-1}$, X = Cl), resulting in the elimination of R_3Si-X (equation 26, Scheme 7).

The dehalosilylation route, however, has not been utilized for the preparation of the analogous $[(Me_2In)Bi(SiMe_3)_2]_3$



Scheme 7 Dehalosilyation synthetic pathway

owing to the lack of stable In-Bi reagents. This has been recently overcome by the low-temperature (−50 °C) metathesis reaction involving $[(Me_2Al)Bi(SiMe_3)_2]_3$ and the Indium Lewis base adduct $[InMe_3(dmap)]$, (dmap = 4-dimethylaminopyridine).[157] The key factor in the reaction pathway is the presence of the strong Lewis base, which increases the reactivity of $[(Me_2Al)Bi(SiMe_3)_2]_3$ by Al-Bi cleavage of the Al-Bi heterocycle. The concerted coordination of $InMe_3$ affords the Lewis base stabilized intermediate $[InMe_3(Me_3Si)_2BiAlMe_2(dmap)]$, which rearranges to give $[(Me_2In)Bi(SiMe_3)_2]_3$.[124,157] In the absence of the Lewis base, no reaction was found to occur. Furthermore, this reaction pathway has also been successfully implemented for the preparation of other Group 13 adducts of group 15 (Scheme 8).[152]



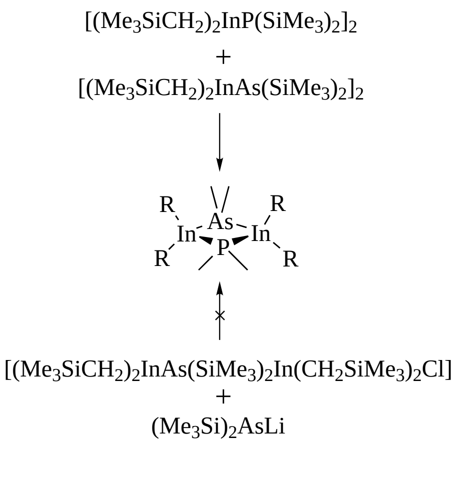
Scheme 8 Formation of In-Bi hetrocyclic derivatives

4.2 Mixed Organoindium Pnictogens

The only example of a mixed organoindium pnictogen was obtained by equilibration of $[(Me_3SiCH_2)_2InP(SiMe_3)_2]_2$ with $[(Me_3SiCH_2)_2InAs(SiMe_3)_2]_2$ in a 1:1 mol ratio.[158] The formation of the $[(Me_3SiCH_2)_2InAs(SiMe_3)_2In(CH_2SiMe_3)_2P(SiMe_3)_2]$ was confirmed by X-ray crystallography, which showed the In-As-In-P ring to be planar (Table 2). In addition, a combination of elemental analysis, multinuclear NMR, and EI-MS shows no residual indication that the product is a mixture of the starting reagents. Attempts to prepare the mixed indium pnictogen via the reaction between $[(Me_3SiCH_2)_2InAs(SiMe_3)_2In(CH_2SiMe_3)_2Cl]$ and $(Me_3Si)_2AsLi$ failed to give the desired compound, but rather $[(Me_3SiCH_2)_3In{\cdot}As(SiMe_3)_3]$, Scheme 9.

4.3 Structures

The structural motifs of organoindium pnictogens bear consequence to the large coordination sphere of the indium center and good overlap between metal and ligand orbitals.[162–166] Variation in the geometric structures can also be influenced by the peripheral groups attached to the pnictogens.[167] For example, in the reaction between $InEt_3$ and R_3SiPH_2, $[EtInPSi(Pr^i)_3]$ is cubane,[168] $[EtInPSiCMe_2(Pr^i)]$ is hexagonal prismatic,[168] and $[EtInPSiCMe_3)]$ is a cyclic structure.[169] As a result, organoindium derivatives can form elaborate geometric structures such as hetrocyclic rings in planar, boat, or chair conformation, in addition to hetrocubane and clusters (Table 2). Additionally, a good understanding of the geometric conformation is sought after for use in MOCVD thin film and nanocrystallite III-V fabrication processes.[27,170–172] Two reported indium hetrocubanes have been prepared by two differing routes. The first by reaction between haloorganoindium derivatives with a lithium phosphide,[115] whilst the second route entailed intramolecular methane elimination of the indiumamino derivative $[(C_6F_5)NHInMe_2]$.[150] In both cases, the 'In–P' and 'In–N' angles of P–In–P 88.8(1), In–P–In 91.2(1)°, N–In–N 84.3(4), and In–N–In 95.5(4)° respectively deviate from those of an ideal cube; however, this is more prevalent in the In–N cubane owing to the larger difference in III-V atomic radii (see Table 2 for structures).



Scheme 9 Preparation of mixed indium pnictogen

5 ORGANOINDIUM CHALCOGENIDES

Without question, the predominant organoindium chalcogenides prepared and studied are the oxygen-containing derivatives (O-In-C), which are notable for their use as precursors for the fabrication of thin-film In_2O_3. Many of the O-In-C compounds bear the diketone,[121,123,173–175] Schiff base,[130,134,136,140,176] carboxylate, or alkoxide[177–179] ligands. The heavier organoindium chalcogenides are now receiving greater attention for their use in attaining thin film or nanocrystallite-semiconducting In_2S_3 phases, which amongst other things are highly important for third generation solar cell hetrojunction formation.[180–190] Deposition of In_2S_3 phases has been realized by using precursors such as the heteroleptic dithiocarbamate complexes $[R_2InS_2CNMe(CH_2)_3NMe_2]$ ($R = Me$, Et, naphthyl, C_5H_{11})[188,189] or thiocarboxylate and thiolate complexes.[190]

Organoindium oxygen derivatives have also been determined to be valuable catalysts in organic synthesis.[191–194] Chiral organoindium chalcogenides have been utilized as catalysts in asymmetric ring openings of cyclohexene norbonylene, and cyclooctene oxides with TMSCN (Scheme 10). The expected β-isocyanohydrins were obtained in yields varying from 45% to 80%, with the enantioselectivity varying from

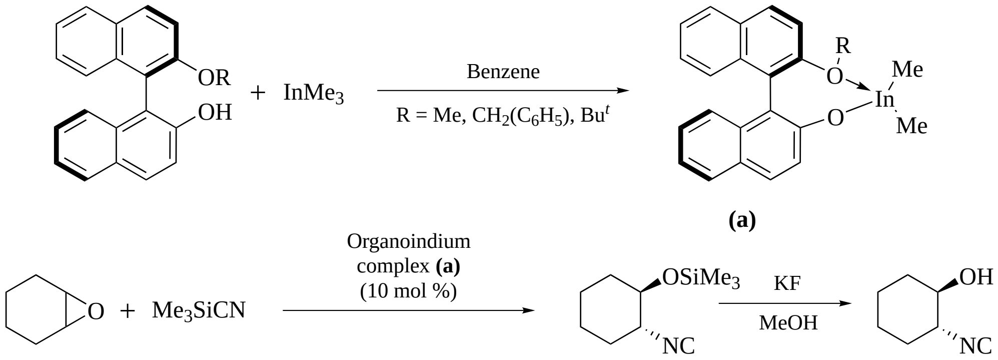
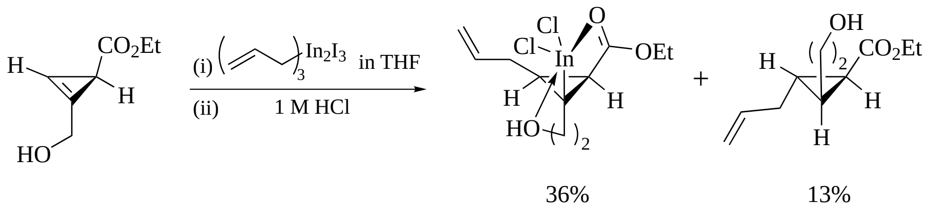


Scheme 10 Use of asymmetric indium catalysts in organic synthesis



Scheme 11 Allylindation of cyclopropenes using allylindium reagents

10% to 95% depending on the nature of the epoxide and the catalyst used. Although the gallium complexes were found to give better enantioselectivities, they gave lower yields than indium complexes (Scheme 10).[191]

Hydroxy-bearing cyclopropenes have been shown to react with allylindium reagents to undergo clean allylindation, in which the chelation of the hydroxyl group to indium plays the central role. The regio- and stereoselectivity is regulated both by the location of the hydroxyl group in the cyclopropenes and the reaction solvent. In particular, the allylindation in water shows marked differences from that in organic solvents.[192] Consequently, hydrolysis stable cyclopropylindium derivatives have been isolated from the reaction of 1-(ω-hydroxyalkyl)cyclopropenes and the structure for 3-Allyl-2-ethoxycarbonyl-1-(2-hydroxyethyl)]cyclopropylindium dichloride has been resolved by X-ray crystallography.[192] Allylindation of these cyclopropenes was conducted with allylindium reagents prepared *in situ* (Grignard-type reaction) or, more conveniently, by mixing allyl halides, indium, and the cyclopropenes together (Barbier-type reaction) with both methods giving almost identical results (Scheme 11).

5.1 Synthesis

The preparation of the organoindium chalcogenides resembles that outlined for the organoindium pnictogens. In general, by elimination of gaseous molecules[144,174,178,195–198] (e.g. cyclopentadiene,[121,195] equation 27), which can be cross-defined as alcoholysis, or by reacting organoindium halides with lithium chalogenides,[57,199,200]

$$\mathrm{In(C_5H_5)_3 + HOBu^t \longrightarrow \tfrac{1}{2}[(C_5H_5)_2InOBu^t]_2 + C_5H_6} \qquad (27)$$

The cyclopentadiene elimination reaction has proven extremely useful for the synthesis of organoindium(III) chalcogenide derivatives. Products of the types R_2InLR ($R = Me, CH_2CMe_3$; $L = O, S$) have been formed in nearly quantitative yields and in excellent purity.[121,195] Interestingly, although $R_2In(C_5H_5)$ incorporates two different organic ligands, only the cyclopentadiene is preferentially eliminated over the more thermodynamically stable compounds, CH_4 or CMe_4, (equation 28). Thus, it is believed that the cyclopentadiene elimination reaction must be controlled by kinetic rather than thermodynamic factors.[195]

$$\mathrm{R_2In(C_5H_5) + H\text{-}LR \longrightarrow \tfrac{1}{2}[R_2In - LR]_2 + C_5H_6} \qquad (28)$$

Attempts to prepare the heteroleptic cyclopentadienide-indium-diketonate derivatives $[(C_5H_5)_{3-x}In(acac)_x]$ (acac = $CH_3COCH_2COCH_3$; $x = 1,2$) products via cyclopentadiene elimination reactions from $[In(C_5H_5)_3]$ and acac fail to yield the expected products, since both $[(C_5H_5)_2In(acac)]$ and $[(C_5H_5)In(acac)_2]$ are unstable and undergo ligand redistribution reactions to form $[In(C_5H_5)_3]$ and $[In(acac)_3]$, respectively.[121]

The preparation of organoindium Schiff base derivatives also encompasses the mechanistic pathway of hydrocarbon

elimination and has received a renewed interest in part owing to their low costs and ease of ligand synthesis. Furthermore, the ligands can be readily engineered to cause change in both steric and electronic properties by directed functionalization. This area has recently been comprehensively reviewed.[176]

The reaction between lithium tetramethylindate $Li[InMe_4]$ and disilanol $[(Ph_2SiOH)_2O]$ yields the rare Lithium indium siloxane $[InMe\{(OPh_2Si)_2O\}_2\text{-}\mu\text{-}\{Li(THF)_2\}_2]$, which can also be synthesized from $Ph_2Si(OH)_2$ and $Li[InMe_4]$ in good yields.[201] The solid-state structure determined by single-crystal X-ray crystallography reveals that the central indium atom is surrounded by four oxygen atoms of the two disilanolate ligands and a methyl group in a square-pyramidal geometry. The InO_4C coordination environment observed is rare among organometallic compounds of indium (Scheme 12).

An example of methane elimination preparation is the reaction between $InMe_3$ with two equivalents of $HO(C_6H_{11})$ in toluene.[177] The reaction was predicted to afford the expected stoichiometric driven product $[MeIn(O(C_6H_{11}))_2]_n$, but instead yielded only the sesquialkoxide $[In\{Me_2In(OCH_2Ph)_2\}_3]$, which can be described also as $[\{Me_2In(O(C_6H_{11}))\}_2\{\text{-}MeIn(O(C_6H_{11}))_2\}_2]$ (Scheme 13).

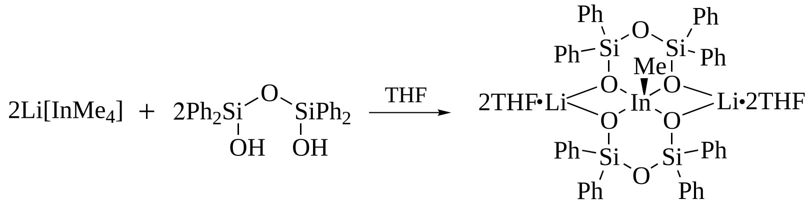
Only a limited number of S, Se, or Te organoindium derivatives are known, the majority of which have been prepared and isolated with large sterically demanding ligands. The supermesityl ligand (Mes* = 2,4,6-$Bu^t_3(C_6H_2)$) and mesityl ligand (Mes = 2,4,6-$Me_3(C_6H_2)$) have been effectively used to prepare several stabilized organoindium derivatives owing to the kinetic stabilization effect these ligands have on the metal center. $[Mes^*In(SePh)_2]$ has been prepared via Grignard synthesis and isolated as a monomer and base-free ligand.[62] The reaction of $In(Mes)_3$ with diselenides R_2Se_2 (R = Me, Ph) at room temperature yields $[Mes_2In(\mu\text{-}SeR)]_2$ (R = Me, Ph) and $[Mes_2In(\mu\text{-}SeMes)]_2$ can be synthesized by the reaction of $In(Mes)_3$ with elemental Se in refluxing toluene. However, under similar conditions, the reaction of $InMe_3$ with Ph_2Se_2 failed to give the target product, but afforded the rearranged product $[MeIn(\mu\text{-}SePh)(SePh)]_n$. Single-crystal analysis of the structures revealed that both $[Mes_2In(\mu\text{-}SePh)]_2$ and $[Mes_2In(\mu\text{-}SeMes)]_2$ were dimeric with planar $(In\text{-}Se)_2$ rings,[62] (see Table 3).

The analogous organotellurolates $[Mes_2In(\mu\text{-}TePr)]_2$ and $[Mes_2In(\mu\text{-}TePh)]_2$ can also be prepared via a similar reaction using the ditellurides (Pr_2Te_2) and Ph_2Te_2 as starting reagents. Like their Se congeners, the organotellurolates have a dimeric configuration with a planar $(InTe)_2$ ring. An advantage of this synthetic route is that it avoids the requirement of organochalcogenide protic compounds (REH), which is generally unstable, thus providing a simple synthetic pathway to binary single-source precursors capable of delivering III-VI materials upon pyrolysis.[62]

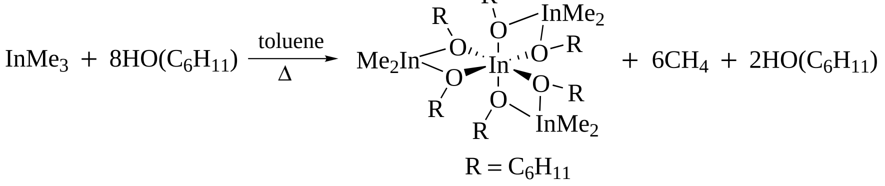
5.2 Structures

The organoindium chalcogenides also exhibit extended ring, cage, and cluster-like structures as is commonly found for III-V derivatives. For example, intra-dative coordination is demonstrated by $[Me_2InCH_2SMe)_2]$, which adopts conformations where the S-bound Me groups are placed in equatorial positions of the chair-like six-membered ring systems.[95]

Cage structures are exemplified by the first reported polyhedral indium siloxanes synthesized when $RSi(OH)_3$ (R = 1,3-$Pr^i_2C_6H_3$) is reacted with $InMe_3$ in a 1:2 ratio via partial elimination of the CH_3 groups, leading to a drum-shaped indium siloxane.[198] Complete elimination of all



Scheme 12 Indium siloxane $[InMe\{(OPh_2Si)_2O\}_2\text{-}\mu\text{-}\{Li(THF)_2\}_2]$



Scheme 13 Sesquialkoxide $[In\{Me_2In(OCH_2Ph)_2\}_3]$

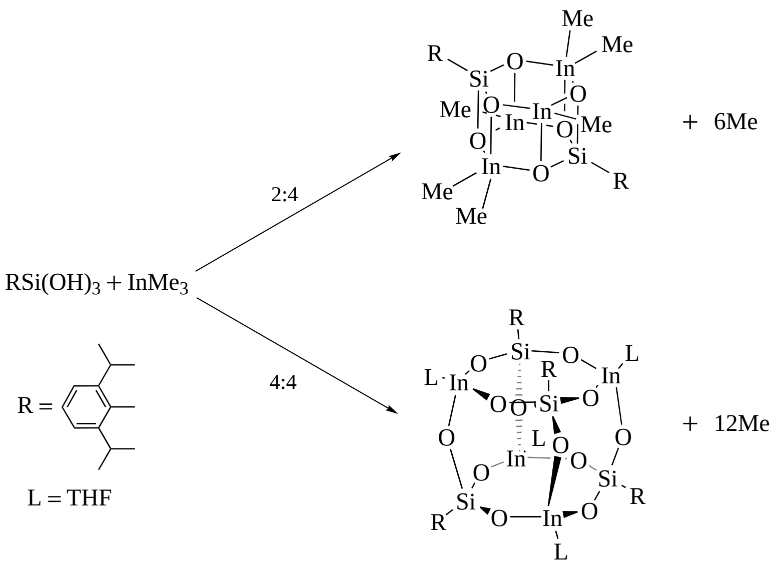


Scheme 14 Synthesis of indium siloxanes

the CH_3 groups can also be performed when the reaction is carried out in a 1:1 ratio, affording the cube shaped indium siloxane (Scheme 14). These indium siloxanes are considered to be important catalysts in the reduction of nitrogen oxides.

A detailed computational study using density functional theory has been used to examine the structural properties of a combination of group 13 and group 16 chalcogenide heterocubanes $[RM(\mu_3\text{-}E)]_4$ (R = H, CH_3; M = Al, Ga, In; E = O, S, Se, Te). Geometries and thermodynamic properties were computed at the B3LYP/SRLC level and all structures were found to be true minima with at most a deviation of 0.08 Å and 2.5° in bond lengths and angles respectively from the experimental geometries reported in Table 3. The M_4E_4 core for each structure proved to be insensitive to ligand choice for the group 13–16 heterocubanes. Density functional theory also suggested that the difficulty for the preparation and isolation of earlier group 13 derivatives $[RM(\mu_3\text{-}O)]_4$ can be attributed to the synthesis being favored by enthalpy but disfavored by entropy; thus, the products might be achievable when prepared at low temperatures.[202]

6 ORGANOINDIUM HYDRIDES

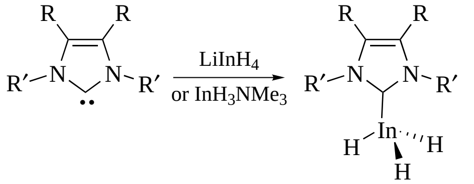
Only an exclusive number of organoindium hydrides are known owing to the inherently weak In–H bond, thus making their synthesis and isolation difficult. Two groups of organoindium hydrides have been characterized, bridging (C-In-H-In) and terminal (C-In-H). The reaction of either $InMe_3{\cdot}Et_2O$ or $InMe_2Cl$ with an excess of LiH at reduced temperatures followed by treatment with TMEDA affords the bridged hydride derivative $[Li(TMEDA)_2][Me_3In(H)InMe_3]$.[208] The compound is stable in solution or solid state for extended periods when kept below 0 °C, above which it auto catalytically decomposes to $[Li(TMEDA)_2][InMe_4]$, indium metal, and gaseous byproducts, (equation 29).

$$InMe_3{\cdot}Et_2O + \text{xs LiH} \xrightarrow[\text{tmeda}]{0\,°C,\ 16\,h} [Li(tmeda)_2]^+[Me_3In\text{-}H\text{-}InMe_3]^- \xrightarrow{>0\,°C} [Li(tmeda)_2]^+[InMe_4]^- + In + \text{byproducts} \quad (29)$$

An interesting feature of $[Li(TMEDA)_2][Me_3In(H)InMe_3]$ as determined from its crystallographic structure is the presence of a bent hydride bridge formation, this is in contrast to its aluminum analogue, which possesses a linear structure.[208] Examples of organoindium with terminal hydride have been pioneered recently by the use of bulky carbene ligands such as $\{:CN(Mes)C_2H_2N(Mes)\}$ or $\{:CN(Pr^i)C_2(R)_2CN(Pr^i)\}$, where R = Me, H, these have been described as ''Arduengo-type'' carbenes[209–212] (Scheme 15).

The organoindium carbene hydrides are synthesized by reacting either $LiInH_4$ or $[InH_3(NMe_3)]$ with the Arduengo-type carbene $\{:CN(R')C_2(R)_2CN(R')\}$ at low temperatures, to afford the indium trihydride complexes $[InH_3\{CN(R')C_2(R)_2N(R')\}]$. The thermal stability of these derivatives can be tailored via the substituents on the ring system. In the case of $[InH_3\{CN(Pr^i)C_2Me_2CN(Pr^i)\}]$, the compound decomposes in the solid state at temperatures $>-5\,°C$ and in solution at $>-20\,°C$.[210] In contrast, in the use of the more sterically demanding groups where $R' = Mes = C_6H_2Me_3$-2,4,6, the indium hydride has exceptionally solid-state stability (dec. $>115\,°C$).[209] Additionally, its decomposition in solution was found to be solvent dependent. For example, in toluene decomposition results in liberation of the free carbene and precipitation of In metal, whilst in THF, H transfer occurs to give $H_2CN(Mes)C_2H_2N(Mes)$ and In metal. In dichloromethane, chloride abstraction occurs from the solvent to yield the trihalide, $[InCl_3\{CN(Mes)C_2H_2N(Mes)\}]$. In addition, a mixed indium hydride halide complex $[InH_2Cl\{CN(Mes)C_2H_2N(Mes)\}]$ can be prepared by the reaction of the carbene organoindium hydride with HCl·quinuclidine ($C_7H_{13}N·HCl$).

The use of bidentate chelating carbene has also been investigated (Scheme 16); however, in thermal stability studies of the organoindium carbene hydride derivative, the bidentate ligand was found not to enhance stability (dec. 10–12 °C).[212]



Scheme 15 Synthesis of organoindium carbene hydrides

7 ORGANOINDIUM METAL COMPLEXES

Most of the reported intermetallic indium complexes are those where the indium is in low oxidation state and are hence discussed in Section 8. Examples where the indium metal center is in higher oxidation states are given below. The intermetallic *bis*(dialkylaminomethyl)-phenylindium derivative is synthesized via metathesis as outlined in Scheme 17.[213] The compound exists as a distorted trigonal bipyramid since the N–In–N angle of 143.1(2) falls considerably short of an ideal trigonal bipyramid (180°).

In similar investigative studies for bimetallic single-source precursors, an iron indane derivative was synthesized by the reaction $Na[(Cp)(CO)_2Fe]0.5THF$ with $BrIn[(CH_2)_3NMe_2]_2$ in THF (Scheme 18)). The analogous Ni, Co, and Mn intermetallic complexes were also successfully prepared with either cyclopentadiene or carbonyl ligands.[214] Photolysis of the indium-iron derivative $[\{Cp(CO)_2Fe\}_2In(CH_2)_3NMe_2)_2]$

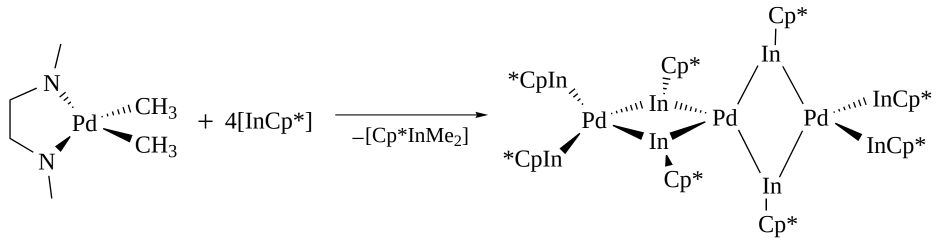


Scheme 19 Formation of low-valent In–M bonds via ligand displacement

in daylight leads to the rearrangement product [(μ-CO) (μ-$In(CH_2)_3NMe_2$){Cp(CO)Fe_2}$_2$].

Attempts to prepare the analogous indium derivative of [$((Me_3)_3SiCH_2)_2$Ga{Co(CO)$_4$}] failed to yield the desired product from the reaction between [$((Me_3)_3SiCH_2)_2$InCl] and Na[$(CO)_3$Co], but instead gave the unexpected indane cobaltate product [{$(CO)_4$Co}$_2$In(CH_2SiMe_3)(THF)].[214] In all cases, these bimetallic compounds were studied to see if they could be viable candidates in CVD process to afford bimetallic thin films.

8 ORGANOINDIUM LOW VALENCY COMPOUNDS

The paucity of organoindium(I) and (II) derivatives is evidenced by the limited number of articles in this area in comparison to those for organoindium(III). This is largely due to the high propensity for In(I) to disproportionate to In(III) and elemental indium.[215] The bulk of low-valent organoindium compounds have been derived with cyclic groups such as Cp, Cp*, etc and functionalized derivatives thereof. The main preparative routes for these species are reduction of InX_3 with alkali salts, controlled reaction of organolithium, or Grignard reagents with of InX, co-condensation of indium vapor with the respective organic moiety and matrix isolation. The area of lower oxidation state indium derivatives has been extensively reviewed, and their synthesis, reactivity, and properties examined;[215] thus, this section will be an overview with recent additions. Again the two areas which have perpetuated the increase for organoindium(I) derivatives are the semiconductor industry and the search for intermetallic precursors to thin films and nanocrystallites,[216–218] and organic synthesis, which reported an organoindium(I) derivative (InCp) as an effective reagent for the preparation of highly functionalized organic cyclopentadienes in aqueous media, thus paving the way for a new role for organoindium(I) derivatives.[219]

8.1 Intermetallic Organoindium Derivatives

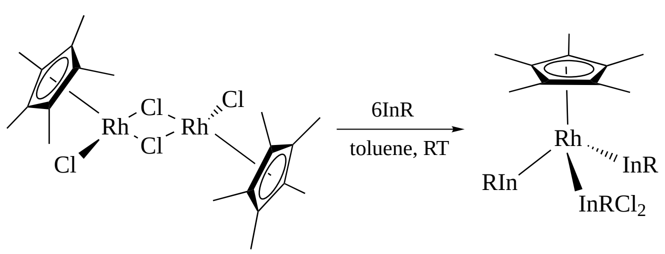
The most common synthetic pathway for the formation of low-valent In–M bonds is the replacement of labile ligands on the incoming metal with InR.[112,220–225] For example, the labile COD ligands in [Pt(COD)$_2$] and [Ni(COD)$_2$] are readily replaced by InC($SiMe_3$)$_3$, InCp* and other group 13 derivatives (i.e. GaCp*, GaC($SiMe_3$)$_3$), yielding monomeric complexes of the type [M(InR)$_4$] (M = Pt, Ni) (equation 30). Elimination reactions have also been employed to prepare novel In-M derivatives (Scheme 19).[221]

$$[\mathrm{Pt(COD)_2}] + \mathrm{InL} \xrightarrow{-2\mathrm{COD}} [\mathrm{Pt(InL)_4}] \qquad (30)$$

Another successful synthetic route to indium-metal species is via insertion of organoindium(I) compounds into metal-halide or metal–metal bonds.[225–227] The organo indium subhalide [R(Cl)In-In(Cl)R]$_2$ [R=C($SiMe_3$)$_3$] reacts with Na_2[$Fe_2(CO)_8$] to form an iron-indium coordination compound, which is isolated as the NaCl adduct [Na$(THF)_4Fe_2(CO)_6$(μ-CO)(μ-InR)$_2$Cl].[226] The iron atoms are bridged by a CO ligand and two InR groups, and the indium atoms are further connected by the μ^2-bridging chlorine atom. Similarly, the insertion of InR (R = Cp*, C($SiMe_3$)$_3$ into the Rh–Cl bond of [(Cp*RhCl$_2$)$_2$] affords the intermetallic derivatives [(Cp*Rh{InCp*}$_3$Cl$_2$] and [(Cp*Rh(μ^2-Cl$_2$){In-C($SiMe_3$)$_3$}$_3$] (Scheme 20).[227]

A very interesting feature determined from the single-crystal structure for [(Cp*Rh{InCp*}$_3$Cl$_2$] is the difference in bonding of the Cp* rings to indium, varying from a sigma bonded mode (InCp*Cl$_2$) to a hapticity of η^5, and one between η^{2-3}, Figure 5.

As is the case for most indium-metallic derivatives in solution, rapid fluxional exchanges are prevalent as can be



Scheme 20 Synthetic route to [(Cp*Rh{InCp*}$_3$Cl$_2$] and [(Cp*Rh(μ^2-Cl$_2$){In-C($SiMe_3$)$_3$}$_3$]

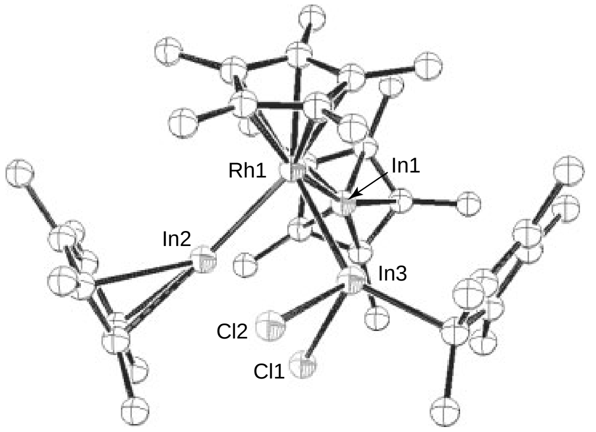


Figure 5 Single-crystal structure for [(Cp*Rh{InCp*}$_3$Cl$_2$]

observed by NMR spectroscopic studies. In the case of both the In-Rh derivatives, ^{1}H-NMR of both complexes shows chemical shifts for only one InR entity and not the three as expected; thus, rapid exchange between the chloride and the In(I) and In(III) centers is occurring.[227]

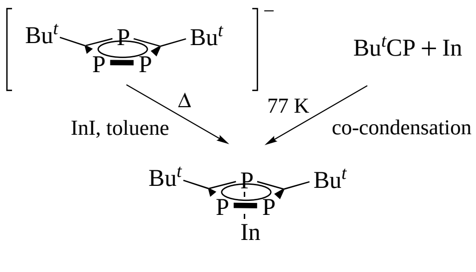
8.2 In(0), In(I) and In(II) Organo Derivatives

Matrix isolation provides a unique insight into otherwise unattainable compounds by isolating the trapped molecule in a rigid and inert matrix such as argon, which is non-invasive during spectroscopic measurements. This novel technique has been used successfully for the fabrication and spectroscopic study of In(0) derivatives, namely In(CO), In·In(CO), $In(CO)_2$, and $In(CO)_2$·In (Scheme 21).[228] Additionally, InMe and GaMe have been reported via the reaction of the respective group 13 atoms with methane in solid Ar matrix.[229] The products are formed via UV photolysis ($\lambda = 200-400$ nm) to give the alkylmetalhydride followed by photodissociation on broad-band irradiation ($\lambda = 200-800$ nm) to yield MeM(I) derivative.[229,230]

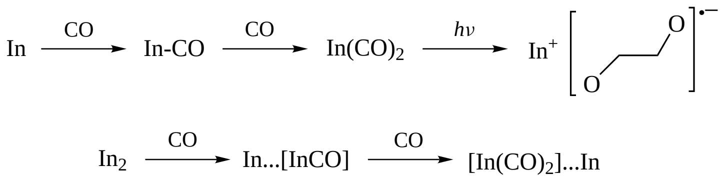
Co-condensation of indium vapor and *tert*-butylphosphaethyne at 77 K yields the volatile In(I) complexes [In(η^5-$P_3C_2Bu^t_2$)] and 1,3-diphosphacyclopentadienyl complex [In(η^5-$P_2C_3Bu^t_3$)].[159] Single-crystal x-ray diffraction studies for [In(η^5-$P_3C_2Bu^t_2$)] reveals a discrete molecular structure, involving half-sandwich coordination of the $P_3C_2Bu^t_2$ ring around the indium center. Cyclization of the Bu^{t}C≡P ligand to afford the cyclic ring is thought to occur by the ‘‘naked’’ indium atoms. The crystal structure of [In(η^5-$P_3C_2Bu^t_2$)] (see Table 2) confirms that the ring is coordinated to the indium metal center with a η^5-hapacity. In contrast to [In(η^5-C_5H_4R)] derivatives, where polymeric zigzag chains are evident, the greater steric bulk of the phosphine substituted ring affords discrete molecular units with no aggregation (intermonomer distance = 3.526 Å).[159] Coincidentally, [In(η^5-$P_3C_2Bu^t_2$)] can also be synthesized in good yields by treating InI with the base-free ligand salt K($P_3C_2Bu^t_2$) (Scheme 22). A study of the molecular and electronic structure of these indium(I) phospholyls including computational modeling has been performed.[231]

Low oxidation state derivatives also have the tendency to be isolated in cage like structures; for example, the tetrahedral derivative $In_4[C(SiMe_3)_3]_4$ is readily prepared from the reaction between InBr and Li[C(SiMe$_3$)$_3$].[232,233] $In_4[C(SiMe_3)_3]_4$ is a highly versatile synthon to many other novel organoindium compounds (Scheme 23). For example, reaction with elemental Se affords the unique In-Se hetrocubane,[232] and halogenation studies of $In_4[C(SiMe_3)_3]_4$ afford novel alkylindium(I) halides,[234,235] while reaction with bimetallic species demonstrates its ability to be inserted into the metal–metal bond.[236] The main by-product from the reaction of InBr with the THF adduct of LiC(SiMe$_3$)$_3$ is $[In_3Br_3\{C(SiMe_3)_3\}_3]^-[Li(THF)_3]^+$ whose geometrical configuration is analogous to that of $In_3I_2[C(SiMe_3)_3]_3$, except the inner In atom is attached to a bromide ion which bridges the In_3 chain and the counterion $[Li(THF)_3]^+$.[237]

A clear example of how ligand steric encumbrance has been implemented to control geometrical conformation for organoindium(I) species from monomeric to aggregated is



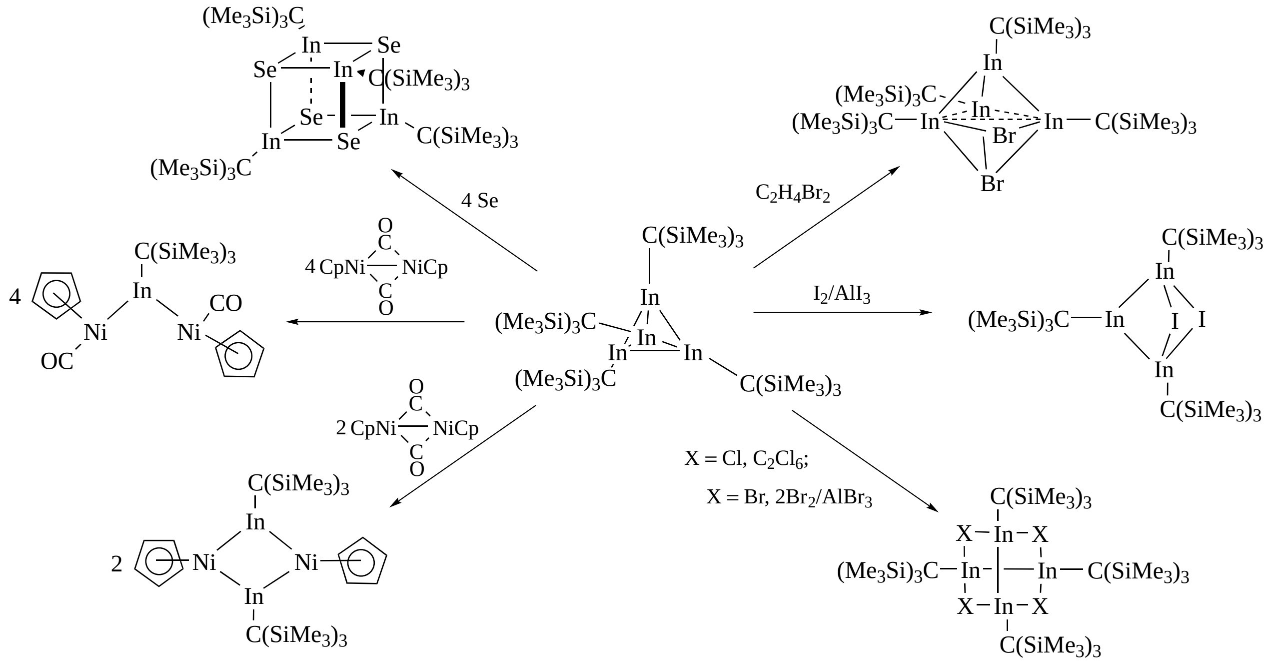
Scheme 22 Preparative routes to these indium(I) phospholyls



Scheme 21 Pathways for matrix reactions of Indium with CO

the reaction of InX with lithium-terphenyls of various sizes. Molecular In(I) derivatives of monodentate ligands of any kind are limited; however, the use of the sterically demanding *o*-terphenyl ligand {–C_6H_3-2,6-$Trip_2$ (Trip = C_6H_2-2,4,6-$Pr^i{}_3$)}, the monomeric compound InC_6H_3-2,6-$Trip_2$, has been prepared and isolated, (Figure 6a).[112] The modified terphenyl ligand –C_6H_3-2,6-$Dipp_2$ (Dipp = C_6H_3-2,6-Pr^i_2) enables the isolation of a stable dimeric group 13 ''dimetallene'' species ArInInAr (Ar = C_6H_3-2,6-$Dipp_2$) (Figure 6b),[238] whereas using the less crowded ligand –C_6H_3-2,6-Mes_2 (Mes = C_6H_2-2,4,6-Me_3) affords the aggregated distorted cubane $In_8(C_6H_3$-2,6-$Mes_2)_4$ (Figure 6c).[239]

A common trait of organoindium(II) complexes is the presence of In–In bonding. The preparation of the first carbene and diazabutadiene In(II) compound has been achieved by the reaction of {:CN(Mes)C_2H_2N(Mes)} with InBr in either a 1:1 or 1:2 ratio, and (($C_6H_3Pr^i_2$-2,6)N=CH$)_2$ with InCl in a 3:2 ratio.[240] Structural characterization reveals In–In bond lengths of 2.7436(7) and 2.7280(9) respectively. A comparison with reported In–In bond distances (Table 4) shows that In–In bond distances fall within the reported range since the In–In bond length is known to vary owing to the steric demand of substituents on the ligands.[98]



Scheme 23 Reaction pathways for $In_4[C(SiMe_3)_3]_4$

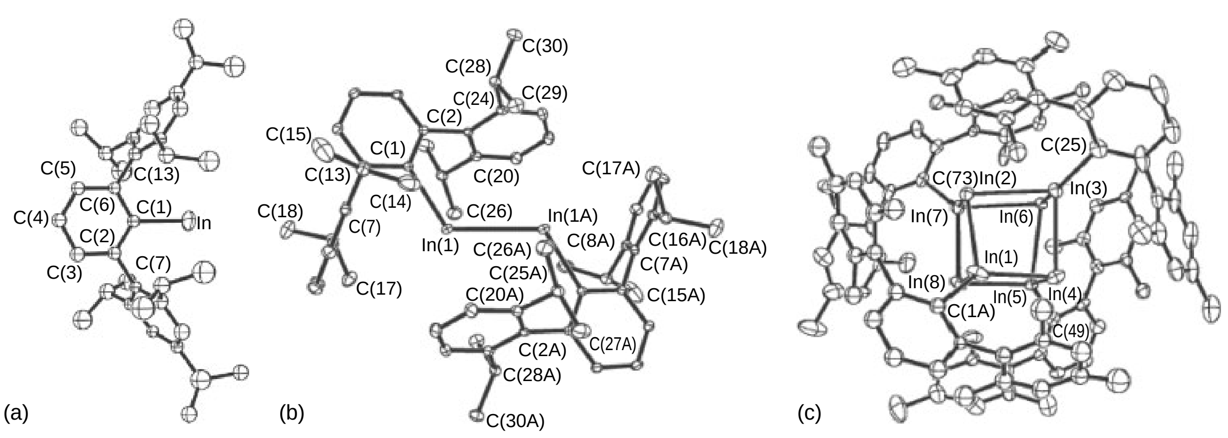


Figure 6 Organoindium-terphenyl complexes

9 ORGANOINDIUM ANIONIC DERIVATIVES

The reaction of organoindium derivatives with alkali metals[54,244,245] results in the isolation of the appropriate tetraorgano anionic complex $M[InR_4]$ (M = K, Rb, Cs; R = Me and M = Li, Na, K, Rb, Cs; R = Ph) (equation 31), and they prove to be valuable synthons for the preparation of indium compounds.

$$3M + 4R_3In \longrightarrow 3M[InR_4] + In \quad (31)$$

$$[(Bu^tCH_2)_3In] \xrightarrow{\text{xs KH}} K[(Bu^tCH_2)_3InH] \quad (32)$$

$$[(Bu^tCH_2)_3In] + K[(Bu^tCH_2)_3InH] \longrightarrow K[\{(Bu^tCH_2)_3In\}_2H] \quad (33)$$

$$R_3In + [NR'_4]X \longrightarrow [NR'_4][R_3InX] \quad (34)$$

$$2R_3In + [NR'_4]X \longrightarrow [NR'_4][R_3InXInR_3] \quad (35)$$

Organoindium anionic compounds in which indium coordinates to both alkyl and hydride ligands have been synthesized via the reaction of R_3In with KH (equation 32); the product, however, combines with unreacted trialkyl to give $K[\{(t\text{-}BuCH_2)_3In\}_2H]$ (equation 33).[54] Complexes in which indium coordinates to both alkyl and halide ligands can be prepared by the reaction of R_3In with $[NR'_4]X$ (X = F, Cl, Br) (equation 34). If two equivalents of R_3In are used, the products are dimeric with bridging halides (equation 35).

An example of a novel synthesis to triple stacked InCp cations is via the reaction of $[InCp^*]_6$ with an equimolar mixture of $B(C_6F_5)_3$ and $H_2O\cdot B(C_6F_5)_3$ in toluene to afford $[(\eta^6\text{-}C_7H_8)In(\mu\text{-}\eta^5\text{-}C_5Me_5)In(\eta^6\text{-}C_7H_8)]^+[(C_6F_5)_3BO(H)B(C_6F_5)_3]^-$.[246] Given the very long indium-ring-centroid distances of 3.490(4) and 3.325(4) Å in conjunction with molecular orbital calculations, the authors view the molecule as an inverse sandwich cation.[247] Ionic cage structures are exemplified by an extension to the first reported polyhedral indium siloxanes[198] when $RSi(OH)_3$ (R = 1,3-$Pr^i_2C_6H_3$) is reacted with $M[InMe_4]$ (M = Li, Na) in a 4:4 ratio via elimination of the CH_3 groups, leading to a ionic poly-organoindium siloxane (Scheme 24).[198]

In another example, the reaction of CsF with organoindium compounds in acetonitrile provides a novel route to the respective cesium organoindium heterocubane in high yields (Figure 7).[248,249] In contrast to $Cs[InMe_4]$, no short intra- and intermolecular Cs···C contacts are noted for $[Cs\{Pr^i_3In\}]_4$, thus indicating that there are no significant intermolecular interactions between the heterocubane units.

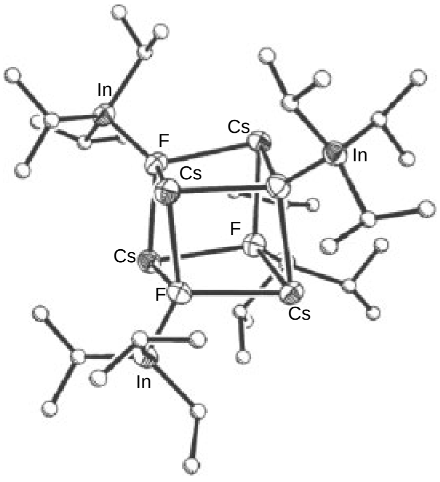

Figure 7 Single-crystal structure of the ionic heterocubane $[Cs\{Pr^i_3In\}]_4$

Glossary

Electron precise: refers to an atom or fragment that possesses the same number of valence functions and valence electrons
Exo- and endo-: define cluster regions lying outside and inside respectively, the sphere defined by the cluster core atoms
Orbitally rich: refers to an atom or fragment that possesses more valence functions than valence electrons
't_{2g}' levels: three metal-based d-functions in a transition metal fragment that are often considered to be nonbonding with respect to a cluster network

Abbreviations

Cp = η^5-C_5H_5; Cp* = η^5-C_5Me_5; triphos = MeC($CH_2PPh_2)_2$; etriphos = MeC($CH_2PEt_2)_2$.

1 INTRODUCTION

Inorganic chemistry can be usefully approached from a number of points of view. One can take an element orientation, for example, boron chemistry;[1] a phase orientation, for example, solid-state chemistry;[2] a function orientation, for example, bioinorganic chemistry;[3] a technique orientation, for example, photochemistry;[4] a mechanistic orientation, for example, electron transfer reactions;[5] a bond-type orientation, for example, quadruple bond chemistry;[6] or even a practical orientation, for example, materials chemistry.[7] All these views of inorganic chemistry are interwoven in a number of ways and are far from mutually exclusive. In the case of this chapter, there is both an element orientation (transition metal and main group elements) and a bonding orientation (clusters containing bonding between transition metal and main group elements).

The rationale for this choice is straightforward. The development of organometallic chemistry, which is essentially the study of the chemistry of the metal–carbon bond, into a full discipline of chemistry is well documented. A substantial subsection of organometallic chemistry is cluster chemistry (*see* ***Polynuclear Organometallic Cluster Complexes***). Carbon, however, is only one of the p-block elements that form covalent bonds to transition metals, and this chapter is concerned with a substantial part of the 'otherside' of organometallic chemistry. This chemistry associated with the transition metal–main group element bond (excluding carbon) has been called *Inorganometallic Chemistry*[8] in order to emphasize similarities to organometallic chemistry without neglecting the differences. Herein, we restrict ourselves to that part of inorganometallic chemistry found in clusters – three-dimensional element catenation. The intercomparison of this chemistry with the analogous organometallic chemistry provides a better understanding of both systems.

This chapter is divided into two parts that are complementary but sufficiently self-contained to be consulted separately if desired. First, in Sections 2 and 3, the essential aspects of cluster structure and bonding using inorganometallic examples are presented and illustrated with real clusters. This primarily serves to outline the possibilities of an area that is rapidly developing. The second part (Sections 4 and 5) contains a more complete description of the structural and reaction chemistry of selected cluster types. Emphasis is placed on the possibilities generated by element variation within a structure type. Sufficient information now exists to show that this not only permits rational variation of structure but also provides access to reactivity types not seen in the homonuclear cluster systems. The goal is to illustrate the possibilities and there is no attempt to be complete either globally or specifically. This is an introduction to a developing area and references to more general sources of information will be found at appropriate points.

2 HETERONUCLEAR CLUSTER BONDING

Mixed transition metal–main group element clusters are ultimately related to either homonuclear metal or main group element clusters.[9] Although there are similarities between the bonding within these two limiting types of clusters, there are also significant differences. It is these differences in the mixed

systems, which can give rise to major changes in both structural aspects as well as properties. In a situation in which a main group fragment cannot mimic a transition metal fragment or, conversely, where a transition metal fragment cannot mimic a main group fragment, what are the consequences in structure and reactivity? Before this question can be sensibly addressed, it is necessary to have a clear understanding of cluster bonding (*see* ***Electronic Structure of Clusters***) as well as the ways in which transition metal and main group fragments combine to generate cluster systems.

2.1 Geometric Considerations

Homonuclear cluster formation, a form of catenation, reflects intrinsic properties of the fragments that make up the compound (*see* ***Boron Hydrides*** and ***Boron: Polyhedral Carboranes***). In a 'leggo' or 'tinkertoy' style approach, it is easily seen that chains and rings can form from two-connect units, whereas clusters can only form from units that can make three or more connections. Thus, a simple geometric definition of a cluster is a three-dimensional array of units in which each is bonded to three or more nearest neighbors. This is a more logical, albeit more limiting, definition than is sometimes used, that is, trinuclear metal systems have been described as clusters, whereas here we consider them as three-member rings.[10]

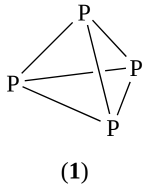
2.2 Electronic Considerations

Geometric and electronic structures are inseparable. The heavy, slow nuclei are easier to deal with, and the first source of information on the distribution of electrons on a nuclear framework is the lowest energy geometry of this framework. With the advent of routine single crystal X-ray structure determinations, measured geometric parameters serve as a rich source of information on cluster bonding – an elementary description of electronic structure that partitions electron density on a nuclear framework to account for the stability of a set of atoms in the observed geometry. Rationalization of observed cluster geometry as a function of composition leads to a bonding model, which, in turn, is used to make predictions, that is, an experimental composition permits a limited set of structures to be postulated, which can then be tested against spectroscopic observations. Models used range from the qualitative (usually simple and often of some generality), for example, electron counting, to the quantitative (usually complex and more specific), for example, quantum chemical calculations. In an impressive advance, the latter approach permits the definition of geometries by the comparison of calculated NMR shifts with observed shifts;[11,12] thus, for compounds not amenable to X-ray determination, for example, intermediates in reactions, good structures are determined and structural controversies in the literature can be resolved. Presently, this technique is restricted to main group cages; however, when the capability to calculate systems with multiple metal atoms of similar accuracy becomes generally available, fruitful application to metal cluster systems is anticipated.

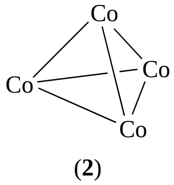
2.2.1 Electron-precise Clusters

Two limiting types of cluster bonding can be distinguished and are presented. In electron-precise clusters, each edge of the polyhedron-defining cluster geometry corresponds to a two-center two-electron bond and the 18- or 8-electron rule (*see* ***Electronic Structure of Clusters*** and ***Electronic Structure of Organometallic Compounds***) is often satisfied for the transition metal and main group atoms, respectively.[13] The shapes exhibited are constructed with three-connect vertices. For example, P_4 (**1**) and $Co_4(CO)_{12}$ (**2**) are examples of main group and transition metal clusters of this type. $Co_3(CO)_9P$ (**3**) is an inorganometallic example in which both geometry (tetrahedron) and bonding structure are analogous to those in the homonuclear example. For (**3**), the reader can easily verify that the 8-electron rule for the main group center and the 18-electron rule for the transition metal centers are both satisfied. Although the bonding may be analogous (two-center two-electron bond on each edge of the tetrahedron), compound properties depend on more than the type of bonding within the cluster core – the external ligand bonds as well as the high-lying partially filled d orbitals on the metal centers play a significant role.

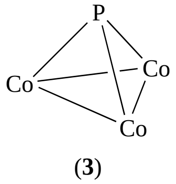
Note that for clarity as well as emphasis, only the cluster geometry and cluster core composition are shown in the structural drawings. The ligands, if any, associated with the transition metal and main group atoms should be clear from the molecular formula for any given compound. The structural abbreviation can be seen in the comparison of the full structural drawing given for (**3**) versus the shorthand one. The reader should note that these ancillary ligands do affect cluster properties via the bonding properties of the main group or metal fragment. On the other hand, endo-cluster hydrogens and interstitial atoms (see below) are shown in the drawings,



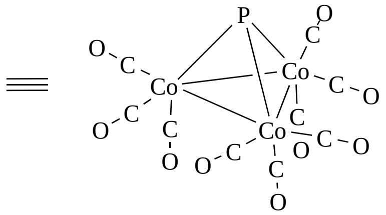
(**1**)



(**2**)



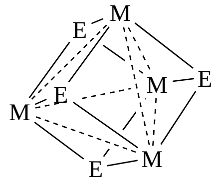
(**3**)



as they are considered essential parts of the cluster network bonding.

Electron-precise cluster systems can be seen to be a more complex version (three-connect units) of chains (one-connect units) and rings (two-connect units), leading up to an extended solid (four-connect units, e.g. the diamond structure). This is most easily appreciated for homonuclear examples, for example, (**1**) and (**2**). For the mixed systems like (**3**), two distinct descriptions are possible – as a 4-atom cluster or as a trinuclear metal complex with a μ_3-P cap. In many cases, the difference is of little consequence; however, in others, proper choice of description can lead to analyses of significant conceptual value.

The $L_{4n}M_4E_4$, M = transition metal, E = p-block element, cluster systems (**4**) provide an example. The elegant experimental work of Dahl and coworkers generated M_4E_4 clusters in which the M_4 unit changed smoothly from a fully bonded tetrahedron with capping E fragments to a fully nonbonding tetrahedron in which the M and E fragments occupy nonadjacent vertices of a cube.[14] Dahl described the bonding and the related spin multiplicities using a molecular orbital model based on fragmenting a given cubane cluster into a M_4E_4 unit to which the external ligands are then appended at the metal sites (*see* ***Paramagnetic Organometallic Complexes***). Harris later showed that an equivalent description is one in which four E_3 ML_n fragments of characteristic coordination geometry condense into $L_{4n}M_4E_4$ by elimination of 8 E moieties.[15] Although equivalent, the latter description has the added conceptual benefit that the basics of the electronic structure follows easily from that of mononuclear Werner complexes, a topic of undergraduate chemistry. (*see* ***Coordination & Organometallic Chemistry: Principles***) A transparent 'back of the envelope' analysis connects Werner models to cubane structure, readily suggesting new variations for synthesis.



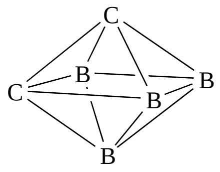
(**4**)

A valuable corollary results from the Harris treatment. Although the cluster bonding is electron precise (two-center two-electron bonds), the electronic structure possesses intrinsic complexity due to the metal centers that constitute part of the cluster framework fragments. Werner complexes need not obey the 18-electron rule; thus, these clusters need not do so either, thereby qualitatively accounting for their interesting metal bond orders and paramagnetism. This example again emphasizes the fact that bridging ligands (E) can be considered as ligands or cluster fragments. In Dahl's picture, they constitute part of the cubane-like cluster even for the fully bonded tetrahedron, whereas in Harris's picture, the focus is exclusively on the metal atoms. The same ambiguity arises for an intrinsically different type of cluster described in the following section.

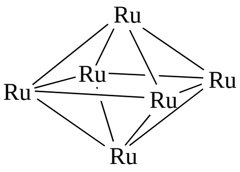
2.2.2 *Orbitally Rich Clusters*

In the second type of cluster, there are insufficient skeletal bonding electrons (electrons formally assigned to cluster bonding, e.g. after accounting for lone pairs, electrons involved in bonding terminal H atoms or other ligands external to the cluster, the electrons that remain are assigned to cluster bonding) to allow two-center two-electron bonds on all of the edges of the cluster polyhedron. Consequently, the 8- or 18-electron rules are not obeyed in any simple fashion, and localized bonding models are inadequate. Attempts to use them in the past resulted in such bizarre structures (as seen with hindsight) such as 'no-bond' resonance structures. Multicenter bonding, for example, three-center two-electron bonds, of some type is required (*see* ***Molecular Orbital Theory***).

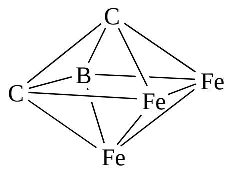
The shapes adopted possess at least one vertex of connectivity four. For example, 1,2-$C_2B_4H_6$ (**5**), $[Ru_6(CO)_{18}]^{2-}$ (**6**), and $C(Me)CHBHFe_3(CO)_9$ (**7**), all have octahedral structures with vertices of connectivity four and 12 equivalent edges – if one is bonding they all are. After localized exo-cluster bonding and the six electrons associated with the nonbonding 't_{2g}' orbitals on the metal centers are accounted for, only seven pairs remain to be distributed between the 12 bonding edges, that is, (**5**) has 26 cluster valence electrons 12 of which are associated with exo-cluster bonding to the hydrogen atoms, leaving 14 for cluster bonding; (**6**) has 86 cluster valence electrons (each CO ligand is counted as 2) 72 of which are associated with exo-cluster bonding or nonbonding electrons at the metal center (36 for 18 CO's, 36 for 6 Fe's), leaving 14 for cluster bonding; whereas (**7**) has 56 cluster valence electrons 42 of which are associated with exo-cluster bonding or nonbonding electrons at the metal centers (18 for 9 CO's,



(**5**)



(**6**)



(**7**)

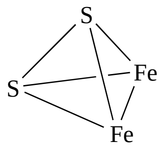
18 for 3 Fe's, 1 for Me, 2 for terminal H, 2 for cluster C atoms, and 1 for cluster B atom), leaving 14 for cluster bonding.

Note that for each metal vertex replaced by a main group atom, the total number of cluster valence electrons decreases by 10. In this counting scheme (Mingos),[13,16,17] the valence electron count associated with a given shape depends on the main group/transition metal numbers, whereas the number of electrons associated with cluster bonding (Wade)[18–20] remains the same. These counting methodologies are to orbitally rich clusters as the 8-, 18-electron rules are to chains, rings, and electron-precise clusters. As it connects the composition to structure in a simple way, the method can both rationalize known compounds and predict cluster shape. The approach is formalized in the empirical skeletal electron counting rules of Wade and Mingos (*see* ***Electronic Structure of Clusters***). A theoretical derivation of these rules for spherical clusters of p-block elements has been presented by Stone.[21]

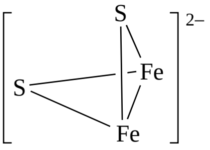
These counting rules follow from a single essential hypothesis that is correct for a spherical cluster. For a closed deltahedral structure with n vertices, the number of skeletal bonding electron pairs (SEP) associated with cluster is $n + 1$. Thus, clusters (**5**)– (**7**) have closed (all vertices occupied) 6-vertex deltahedral structures (often called closo) with seven sep associated with delocalized cluster-bonding orbitals (see below for further examples). An important caveat is that, contrary to the σ/π separation employed in organic aromatic systems, the separation of cluster-bonding orbitals from the rest is never one that is derived from the symmetry of the cluster. This is true even for the high-symmetry octahedral $[B_6H_6]^{2-}$, where mixing of exo-B–H bonding with endo-B–B bonding orbitals of the same point group symmetry is large.

2.2.3 Cluster Reduction

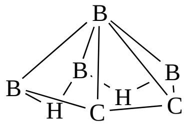
For either cluster type, the addition of electrons, either by ligand addition to the cluster or by a change in cluster composition, changes the cluster valence electron count and sep. On the basis of the electron counting rules, a change in shape is required. The electron-precise tetrahedral $Fe_2(CO)_6S_2$ (**8**), with six pairs for the six cluster edges, exhibits an opened 'butterfly' shape when it is reduced to $[Fe_2(CO)_6S_2]^{2-}$ (**9**) with seven pairs.[22] The seventh pair enters a S–S antibonding orbital and the edge bond between the S atoms is ruptured. On the other hand, addition of a pair of electrons to clusters (**5**)– (**7**) yields eight sep clusters and a pentagonal bipyramidal shape (the geometry is based on a closed 7-vertex deltahedron). As there are only six cluster fragments, one vertex must remain empty. Thus, for example, *nido* 2,3-$C_2B_4H_8$ (**10**) exhibits a pentagonal pyramidal shape. Usually, it is assumed that the vertex of highest connectivity is removed in forming a nido structure from its closo parent. However, recently, a pair of noninterconverting metallacarboranes isomers, which differ only in the vertex removed from the parent pentagonal bipyramid, have been isolated from two different routes.[23] This suggests that the balance in energies between the two different shapes is less than that previously considered, at least for clusters containing transition metals.



(**8**)



(**9**)



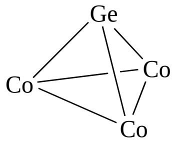
(**10**)

Alternatively, (**10**) formally arises by the addition of 2H to octahedral (**5**), thereby causing it to open. Continued cluster reduction will result in the generation of rings or chains. It should be clear that the overall process is conceptually more difficult to represent than that for the electron-precise cluster. In both electron-precise and orbitally rich clusters, the average connectivity of the cluster decreases on sep increase. There is a difference in that in the latter more than a single bonding edge is ruptured, for example, in going from an octahedron to a pentagonal pyramid, the number of bonded edges goes from 12 to 10. The principles involved have been discussed by Mingos in the context of cluster rearrangements, which require cluster opening in the transition state or high energy intermediate.[13] The barrier for positional isomerization depends on cluster shape, which implies significant differences in the rigidity of the various cluster shapes. With metal clusters, a complex distortion of cluster geometry is a possible alternative to edge bond rupture.[24]

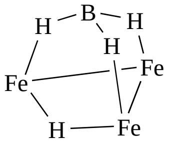
It is worthwhile pointing out that the electron counting rules can lead to apparent ambiguities. Thus, closed (**8**) can be viewed as a nido-cluster (six cluster pairs with a structure based on a trigonal bipyramid with an axial vertex unoccupied) and (**9**) can be viewed as an arachno cluster (seven cluster pairs with a structure based on an octahedron, with two adjacent vertices unoccupied). Little profit is gained in debating which view is 'right,' and most ambiguities of this type cause little problem. Finally, clusters without external ligands,[25] as well as clusters formed from elements with fewer than four valence functions,[26] present interesting variations not discussed here.

2.2.4 Role of Hydrogen Ligands

Two types of hydrogen atoms can be distinguished in clusters. Terminal hydrogens (*see* ***Hydride Complexes of the Transition Metals***) are considered external to the cluster bonding, whereas hydrogens that lie on, or within, the surface defined by the cluster core atoms, that is, bridging hydrogens, are considered to contribute their electrons to cluster bonding. On the other hand, the hydrogen positions are not counted as cluster vertices. This holds true for transition metal, main group, and mixed element clusters. For example, like (**1**)– (**3**), both $Co_3(CO)_9GeR$ (**11**) and $HFe_3(CO)_9(\mu\text{-}H)_3BH$ (**12**) have six electron pairs associated with cluster bonding.



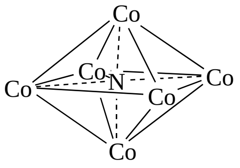
(**11**)



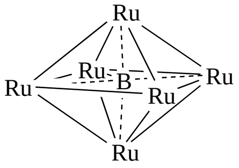
(**12**)

2.2.5 Role of Interstitial Atoms

There is a related complicating factor found only to date in transition metal cluster systems. Because of the larger size of transition metal clusters, a main group or transition metal atom may be found within the interstitial space of the cluster.[27] These interstitial atoms are considered to contribute all their valence electrons to cluster bonding but, like bridging hydrogen atoms, they are not considered as occupying a cluster vertex. For example, as with (**5**) and (**6**), $[Co_6(CO)_{13}N]^-$ (**13**) and $HRu_6(CO)_{17}B$ (**14**) are considered to be 6-vertex closed clusters with seven pairs of electrons associated with cluster bonding with the N and B atoms contributing five and three electrons respectively.



(**13**)



(**14**)

2.3 Role of Element Properties

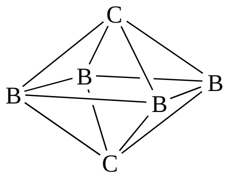
Superimposed on these fundamental cluster-bonding principles are the valence properties of the main group and transition metal elements and fragments that make up the compound. Just as the polarity changes for the 10 valence electron diatomics, N_2, CO, and BF, so too does the charge distribution within a cluster framework change with composition as well as shape.

2.3.1 Main Group Elements

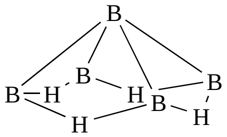
First, the number of valence functions (or frontier orbitals) and valence electrons (frontier orbital occupancy) determines the tendency toward cluster bonding. It is instructive to recall that the structural motif in elemental boron is the icosahedron with six-connected boron atoms (*see* ***Borides: Solid-state Chemistry***); it is the tetrahedral carbon atom in the diamond form of elemental carbon with four-connected carbon atoms; and it is three-connected phosphorus atoms in the sheets of elemental black phosphorus (*see* ***Phosphides: Solid-state Chemistry***). Boron has more valence orbitals than valence electrons, naturally leading to orbitally rich cluster formation; for example, BH has three orbitals and two electrons and forms the very stable $[B_{12}H_{12}]^{2-}$ ion with an icosahedral structure and 13 skeletal bonding pairs. Carbon has the same number of valence orbitals as valence electrons, leading naturally to three-connect units that form electron-precise clusters, for example, CR is found in tetrahedrane, R_4C_4. With a lone pair, a phosphorus atom also constitutes a three-connect unit and P_4 (**1**) is analogous to tetrahedrane.

This does not mean that CH or P units are not found in orbitally rich clusters or that boron is not found in electron-precise clusters, for example, (**7**) and (**12**). Electron-precise clusters will tend to form from three orbital (three-connect) atoms or fragments when the average number of electrons per fragment is three. Likewise, there will be a tendency for orbitally rich clusters when the average number of electron pairs per fragment approaches $(n + 1)/n$, where n is the number of fragments in the cluster. An example is instructive. (**15**), an isomer of (**5**), possesses 7 cluster-bonding pairs (exactly the $(n + 1)/n$ limit) for the octahedral shape it exhibits. The only reasonable description of the cluster bonding is via bonding orbitals delocalized over all of the six cluster atoms.

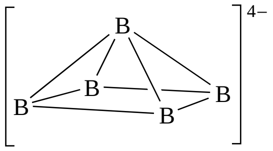
On the other hand, B_5H_9 (**16**) also has 7 skeletal bonding electron pairs and, in accord with the electron counting rules, the cluster geometry is based on an octahedron but with one vertex unoccupied. Consequently, the average number of electrons per vertex is higher and B_5H_9 can be viewed as a hybrid of the two cluster types, that is, one can consider B_5H_9 as derived from $[B_5H_5]^{4-}$ (**17**) and use four of the skeletal pairs to bond the four basal edges of the square pyramid with two-center two-electron bonds. This leaves three pairs in delocalized orbitals bonding the apical vertex to the square base. Likewise, B_4H_{10} can be derived from $[B_4H_4]^{6-}$. Once the six BH bonds are taken care of, five pairs remain to bond the five edges of the butterfly structure generated by removing two adjacent vertices from the parent octahedron. The more electrons added to an orbitally rich cluster, the closer the bonding approaches that of electron-precise systems.[28]



(**15**)



(**16**)



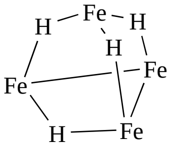
(**17**)

2.3.2 Transition Metal Elements

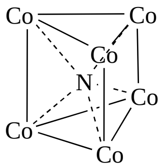
The transition metal elements also have partially filled valence levels but now fragments formed from a metal atom and one or more ligands need be considered. The isolobal principle[29] provides a transparent method for applying the ideas developed from the p-block elements above to fragments derived from d-block elements. Thus, $Mn(CO)_5$ (17 electron), $Fe(CO)_4$ (16 electron), and $Co(CO)_3$ (15 electron) fragments are isolobal with CH_3 (7 electron), CH_2 (6 electron), and CH (5 electron) fragments respectively.[30] It follows, then, that metal fragments with three frontier functions and three electrons will have a tendency to form electron-precise clusters, for example, four $Co(CO)_3$ fragments yield (**2**). Likewise, fragments with three orbitals and less than three electrons will tend to form orbitally rich clusters, for example, $Fe(CO)_3$ and CpCo are isolobal with BH (Figure 1). Thus, with six $Ru(CO)_3$ fragments and a charge of 2^-, (**5**) is analogous to $[B_6H_6]^{2-}$.

Recall that bridging hydrogens and interstitial atoms provide a means of increasing the average number of electrons per vertex. Thus, $H_4Fe_4(CO)_{12}$ (**18**) is analogous to (**2**). Note that in contrast to hydrogen, a CO ligand can be bridging or terminal with no consequence in terms of counting cluster electrons or vertices.

Similar to the main group clusters, the addition of electrons to metal clusters causes a transition from orbitally rich cluster bonding toward electron-precise bonding. $[Co_6(CO)_{15}N]-$ (**19**) has two more skeletal electron pairs than (**6**) and the structure adopted has a three-connect trigonal prismatic geometry rather than four-connect octahedral geometry. Although the number of skeletal pairs matches the number of edges of the trigonal prismatic geometry, it would be misleading to consider this completely as an electron-precise cluster as the phosphorus atom is certainly strongly involved in the cluster bonding even though it is not considered a cluster vertex.



(**18**)



(**19**)

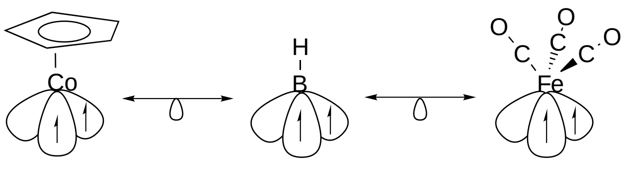


Figure 1 Schematic drawings indicating the isolobal relationship between η^5-C_5H_5Co, BH, and $Fe(CO)_3$ fragments

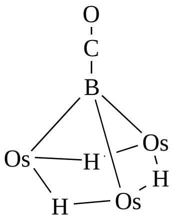
2.4 Variation in External Ligands

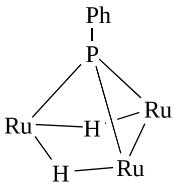
Valence properties of the transition metal or main group element fragments can be changed by variation of element identity and by changing the external ligands.

2.4.1 Main Group Elements

Variation of the external ligand on the main group element changes the number of electrons contributed by the fragment to cluster bonding. For example, contrast BH in $HFe_3(CO)_9(\mu$-$H)_3BH$ (**12**) with BCO in $H_3Os_3(CO)_9BCO$ (**20**) and P in $Co_3(CO)_9P$ (**3**) with PPh in $H_2Ru_3(CO)_9PPh$ (**21**). Replacing the terminal H on B with CO makes BCO a three-electron fragment (as opposed to two for BH), whereas adding a one-electron ligand to P makes PR a four-electron fragment (as opposed to three for P).



(**20**)

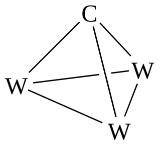


(**21**)

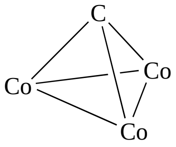
2.4.2 Transition Metal Elements

External ligand variation is more commonly observed for the transition metal fragments. $HRu_6(CO)_{17}B$ (**14**) might be considered to be made up of five $Ru(CO)_3$ fragments (10 electrons) and one $Ru(CO)_2$ fragment (zero electrons) with the interstitial boron and bridging hydrogen providing the four additional electrons needed. Changing from a $Fe(CO)_3$ to a CpFe fragment, for example, also reduces the number of electrons contributed to cluster bonding. In this case, it follows from Figure 1 that the latter fragment will be a three-orbital one-electron fragment.

Group 18 and 19 metals are often found in clusters as carbonyl and Cp derivatives. With these π-acceptor ligands, the 't_{2g}' levels in the fragment are sufficiently stabilized such that they are effectively nonbonding with respect to the cluster. An interesting development in organometallic cluster chemistry is the observation that π-donor ligands such as alkoxy ligands change the role of the 't_{2g}' levels.[31] The p-donor ligands destabilize the 't_{2g}' levels and push them into the valence region. Thus, the $W(OR)_3$ fragment in $W_3(OR)_9CR$ (**22**) has three valence 't_{2g}' orbitals containing three electrons, and is considered to be analogous to the $Co(CO)_3$ fragment in $Co_3(CO)_9CR$ (**23**). $Co(CO)_3$ and $W(OR)_3$ can be considered to be isolobal (surrogates for CH) even though they are not isoelectronic.



(**22**)



(**23**)

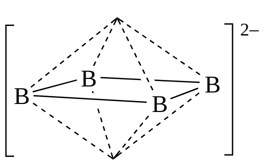
The group 10 metals also provide an interesting complication. The increasing gap between the *n*d band and $(n+1)$p band that gives rise to the observation of stable 16 electron complexes leads, for example, to $Pt(PPh_3)_2$ fragments that can behave in an isolobal manner to CH_2, BH, or $[CH]^-$.[13] Clearly, ligand variation on the transition metal in terms of number and geometric arrangement, as well as the transition metal itself, permits a metal fragment to mimic a range of main group fragments.

2.5 Structural Role of Bridging Hydrogens

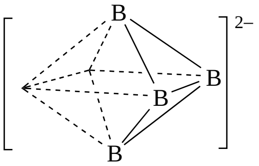
As noted several times, bridging hydrogens are found in all types of clusters. Thus far, they have been considered as of no consequence structurally as far as the cluster bonding is concerned. The experimental evidence suggests that this is an oversimplified view.

2.5.1 Main Group Elements

There is evidence from quantum chemical calculations that bridging hydrogens play a structural role in main group clusters.[32] For example, if $[B_4H_4]^{6-}$ is considered as a 7 skeletal pair arachno cluster with a structure based on an octahedron with two unoccupied vertices, then the electron counting rules allow two isomeric forms, (**24**) and (**25**). Calculations suggest that the planar isomer is the lower energy form, and that the observation that B_4H_{10} adopts the second less stable isomeric form results from a real structural role for the bridging hydrogens.[33] Note also that $[B_6H_6]^{2-}$ decomposes on protonation and calculations suggest that protonation leads to destabilization of the octahedral cluster bonding network.[34] Only face bridging hydrogens are possible on an octahedron and these have only been observed in metal or metallaborane cluster systems. In the latter case, only triangular faces containing a metal atom or atoms are found to be capped.



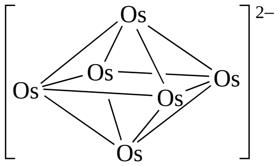
(**24**)



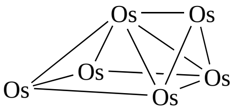
(**25**)

2.5.2 Transition Metal Elements

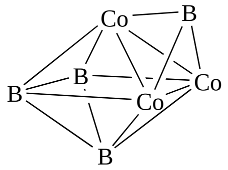
In transition metal systems, bridging hydrogens play an experimentally defined structural role. Two factors permit this behavior. First, the hydrogen ligand occupies space. Second, the metal–metal interactions are weaker than the metal–ligand interactions. Thus, protonation of an anion can lead to observable cluster structure rearrangement as illustrated by (**26**) and (**27**).[35] Capped structures have the same skeletal count as the parent cluster (*see* ***Electronic Structure of Clusters***) and, consequently, the two structures are cluster geometric isomers. Such capped structures do not appear viable for purely main group clusters but they are observed in the mixed main group–transition metal systems, for example, $Co_3Cp_3B_4H_4$ (**28**).



(**26**)



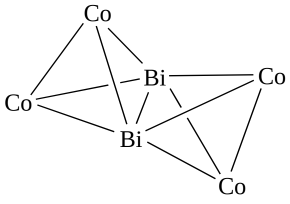
(**27**)



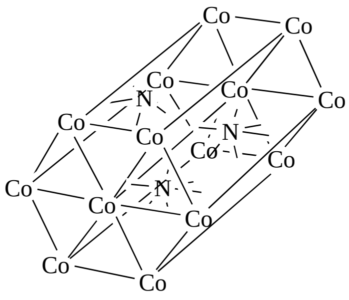
(**28**)

2.6 Fused Clusters

Larger clusters can be formed from two or more cluster fragments by sharing one or more cluster atoms in common. For example, $Co_4(CO)_{11}Bi_2$ (**29**) can be considered as two Co_4Bi_2 tetrahedra sharing a common Bi–Bi edge. Likewise, the condensation of $[Co_6(CO)_{13}N]^-$ (**19**) to give $[Co_{14}(CO)_{26}N_3]^-$ (**30**) can be viewed as the fusion of three trigonal prismatic Co_6N clusters.

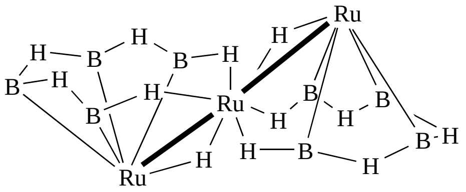


(**29**)



(**30**)

A generalization of the electron counting rules for clusters to accommodate various types of fused cluster structures with common cluster vertices has appeared.[36] The wide variety of examples already known illustrates a richness of cluster structure greatly exceeding that of the single cluster (*see* ***Electronic Structure of Clusters***). Indeed, these ideas provide new insight into the structures of elemental boron in which complex fused cages are observed, and one can see that cluster versions of, for example, metal chains (**31**), are possible.[37]



(**31**)

2.7 Hydrogen Analogs

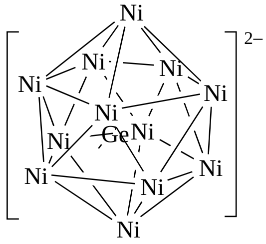
Metal hydrides can often be replaced with the $AuPR_3$ fragment and the $[AuPR_3]^+$ fragment is considered isolobal with a proton (*see* ***Gold: Organometallic Chemistry***). However, the gold fragments need not occupy the same positions as the protons they replace and, depending on the phosphine used, are subject to disproportionation reactions. Pure gold clusters have a characteristic structural chemistry that obeys modified cluster counting rules as the orbital contribution of such a fragment to cluster bonding is no longer three.[13]

3 TRANSITION METAL VERSUS MAIN GROUP ELEMENTS IN A CLUSTER ENVIRONMENT

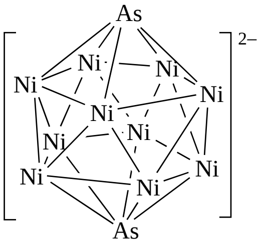
The significant differences in the cluster bonding tendencies of main group and transition metal elements give rise to distinct behaviors that compete in the mixed clusters.

3.1 Differences in Coordination Number

Geometrically, the main group element tends to retain a tetrahedral nearest neighbor environment, whereas the transition metal element tends to retain an octahedral environment. As a consequence, transition metal clusters with more than six metal atoms have a tendency toward ligand loss, leading to the formation of condensed clusters (multiple interstitial metal atoms). This leads eventually to close-packed structures that mimic bulk metal structures (*see* ***Polynuclear Organometallic Cluster Complexes***). On the contrary, the premier cluster-forming element, boron, tends to form single cages without interstitial atoms. In the absence of metal atoms, 12 was the limit of single-cluster nuclearity until recently, even though theoretical evidence of stability beyond 12 vertices has been put forward more than once in the past. A breakthrough this year resulted in the isolation of a single-cage 13-vertex carborane, which resulted from a clever synthetic strategy.[38] Although rare, clusters containing many transition metals can be found in an icosahedral geometry. With the addition of an interstitial atom or main group fragment of appropriate size, icosahedral transition metal clusters have been characterized, for example, $[Ni_{12}(CO)_{22}Ge]^{2-}$ (**32**) and $[Ni_{10}(CO)_{18}(AsR)_2]^{2-}$ (**33**) with 13 skeletal pairs each as expected.



(**32**)



(**33**)

3.2 Steric Interactions

Because metal fragments in general have more than one ancillary ligand, the space demanded by the exo-cluster ligands limits the scope of clusters that are viable. For example, the icosahedral metal clusters just discussed involve a late transition metal that minimizes the number of CO ligands and, hence, intramolecular steric interactions. Even though the $Ni(CO)_2$ and $Fe(CO)_3$ fragments are equivalent in terms of electrons contributed to cluster bonding, it is unlikely that an icosahedral $[Fe_{12}(CO)_{34}Ge]^{2-}$ cluster could be prepared. The concept of a cluster fragment cone angle is useful in estimating possible cluster geometries for a given metal fragment.[39] As the main group fragment usually has a single small ligand or no ligand, steric considerations are a less-important consideration. On the other hand, bulky ligands are important in some instances such as for the isolation of icosahedral $[Al_{12}({}^tBu)_{12}]^{2-}$ (*see* ***Aluminum: Inorganic Chemistry***; ***Aluminum: Organometallic Chemistry***).[40]

3.3 Relative Electronegativities

An important factor in the bonding and reactivity of clusters, as well as all chemical entities, is the effective electronegativity of the atoms or fragments that make up the cluster.[41] In terms of assembling a cluster from a set of fragments, electronegativity differences affect the mutual compatibility of the frontier orbitals of fragment types, that is, if the fragment orbitals are poorly matched in terms of

energy or spatial extent, any covalent interaction will be weakened and the polarity of the cluster will be increased. This is important in considerations of reactivity as well as in the spatial distribution of cluster bridging hydrogens.[42] Note that it is fragment electronegativity that is important and that the ligands on the main group or transition element fragment play a large, albeit difficult to measure, role in determining the value of this parameter.

3.4 Variation of the Transition Metal/Main Group Element Ratio in a Cluster Environment

Consider two examples in which there is a continuous variation in E/M (E, M = main group and transition metal element, respectively) ratio. The first is a series of clusters beginning with a main group element cluster and proceeding via the mixed element clusters to a transition metal cluster. A four-atom cluster system, the E_nM_{4-n} cluster is chosen because examples of all of the possible members of the series for E = B and M = Fe are known.[43] The clusters and their structures are schematically illustrated in Figure 2. For $n = 4$ and 3, clusters with 7 skeletal pairs have been characterized, whereas for $n = 2$–0, clusters with 6 skeletal pairs are known. Examples of clusters with 6 skeletal pairs for the former or 7 skeletal pairs for the latter are not presently known. However, there is evidence for B_4H_8 as a transient intermediate, and the other compounds may well be identified once suitable routes to their formation are discovered. Even so, the change in cluster behavior in going from one to two metals in the cluster is real and illustrates competition between the different structural tendencies of main group and transition metal fragments. Thus, hybrid behavior even in gross structure should not be

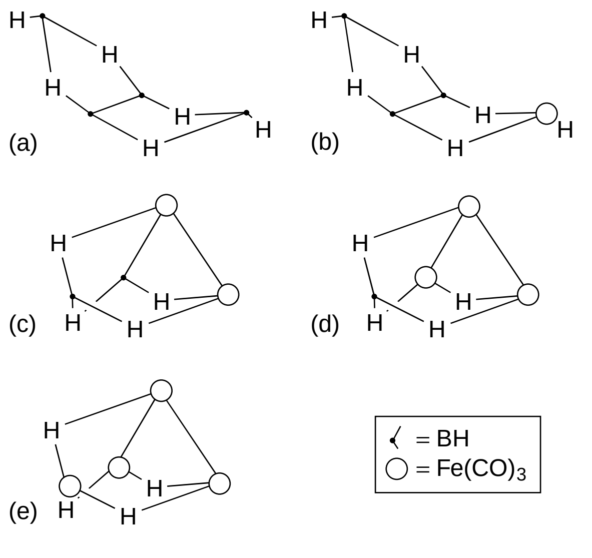


Figure 2 The observed structures of series of clusters B_nFe_{4-n}, (a) $n = 4$, (b) 3, (c) 2, (d) 1, and (e) 0, which run from the boron hydride to the metal hydride

unexpected for mixed transition metal–main group element clusters.

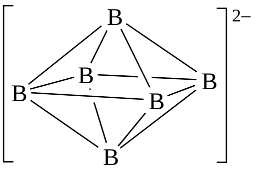
The second example comes from solid-state chemistry, and the connection with cluster chemistry is less obvious. Despite this, it is an excellent example of how E/M variation can lead to systematic variation in structure and, consequently, to properties. Although the example is taken from solid-state metal borides, the silicides (*see* ***Silicon: Inorganic Chemistry***) and phosphides (*see* ***Phosphides: Solid-state Chemistry***) could have been used.

Examples of metal borides (*see* ***Borides: Solid-state Chemistry***) with B/M ratios ranging from large to small have been characterized, although not for the same metal.[44] The boron-rich borides often exhibit boron polyhedra in their structures. In these compounds, the preferred bonding motif of boron is dominant. One view of such compounds is a cluster network with metal ions in the network holes. Indeed, it was a consideration of the electronic structure of these borides that led to the early calculations on $[B_{12}H_{12}]$ and the famous prediction of the stability of this species as a dianion.[45] This prediction was later confirmed experimentally, and these observations eventually gave rise to the cluster electron counting rules. The relationship of CaB_6, which contains a network of octahedral B_6 clusters with intercluster B–B bonds from each vertex, and $[B_6H_6]^{2-}$ (**34**) is clear. Each H on the latter is replaced by a single bond to another B_6 cage, and the net 2− charge required for cluster bonding is derived from the s-block metal, that is, CaB_6 is viewed as a Zintl salt $[Ca^{2+}][B_6{}^{2-}]$.

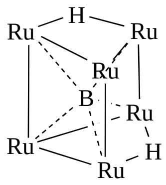
Going to the opposite extreme, the metal-rich borides have structures most easily identified with close-packed metal structures. Now it is the boron atoms that are found in the interstitial holes. Clearly, it is the requirements of the transition metal atoms that are first met. Often, the holes in which the boron atoms reside have a trigonal prismatic geometry defined by the metal atoms. The same type of geometry is found in the cluster, $[H_2Ru_6(CO)_{18}B]^-$ (**35**).[46] However, there is no simple way of relating the solid state and discrete cluster structures. On the other hand, for an E/M = 1 boride, just such a relationship has been described.[47] Thus, for FeB and CrB, the solid-state structures have been described in terms of the packing of chains of M_2B_2 tetrahedra. It is interesting to note, then, that a distorted chain of this type containing four boron atoms is found in the compound $B_4H_8Fe_4(CO)_{12}$ (**36**) containing equal numbers of metal and main group atoms.

3.5 The Main Group Element Fragment as a Ligand

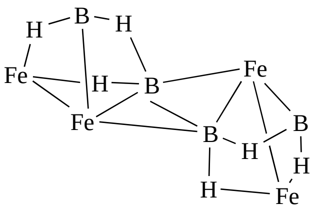
For completeness, it is necessary to briefly mention a popular competing view of a transition metal–main group element cluster. This description will certainly be encountered if the topic is pursued in the literature and, indeed, has already been mentioned in Section 2.2.1. The main group element fragment can be viewed as a ligand, albeit often an exotic one, coordinated to the transition metal center or centers.[48]



(**34**)

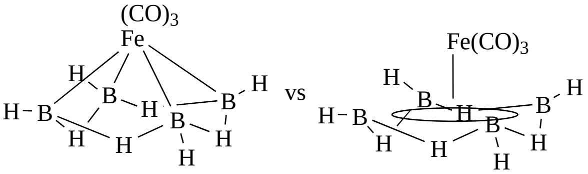


(**35**)

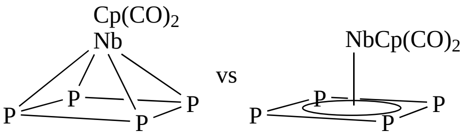


(**36**)

This view is favored by practitioners who have entered the area with a background in transition metal chemistry and can be a more useful approach in some instances. Contrasting the two views with examples highlights the differences. Thus, $Fe(CO)_3B_4H_8$ (**37**) and $CpNb(CO)_2P_4$ (**38**) can be viewed as either clusters (structure drawing at the left) or as metal complexes (structure drawing on the right).



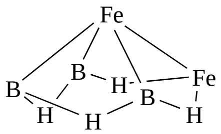
(**37**)



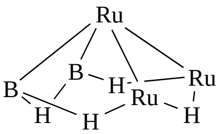
(**38**)

The cluster view is as a 7 skeletal pair, 5 fragment skeleton based on an octahedron, whereas the metal–ligand complex view is as a dianionic η^4-ligand donating six electrons to the metal center in the same manner as η^4-$[C_4H_4]^{2-}$. In the second representation, the compounds are not considered as clusters and would not be classified as such unless the ligand itself is a cluster, for example, the η^5-$[C_2B_9H_{11}]^{2-}$ open cage is a ligand analog of η^5-$[C_5H_5]^{2-}$ (*see* ***Boron: Metallacarbaboranes*** and ***Boron: Polyhedral Carboranes***). Alternatively, the metal fragment can have a nuclearity greater than one, for example, $HFe_3(CO)_9(\mu\text{-}H)_3BH$ (**12**) can be considered as a trimetallic ring with a μ_3-bridging $[BH_4]^-$ ligand. In the examples given, both views are equally useful.

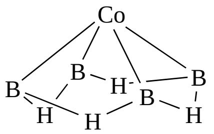
For $CpNb(CO)_2P_4$ (**38**), the ligand view is more realistic because of the greater difference in electronegativities between the transition metal and main group elements. On the other hand, viewing the borane fragment in $Fe(CO)_3B_4H_8$ (**37**) as an η^4-ligand hides its close relationship to $Fe_2(CO)_6B_3H_7$ (**39**) and $Ru_3(CO)_9B_2H_6$ (**40**). All three are 7 skeletal pair, 5 fragment clusters whose main group element parent is B_5H_9 (**16**) or $[B_5H_5]^{4-}$ (**15**). Further, although the $[B_3H_7]^{2-}$ ligand in $Fe_2(CO)_6B_3H_7$ (**39**) is isoelectronic with the allyl ligand, the geometry and bonding in the compound do not correspond to any known allyl metal complex.[49] This makes the ligand view an artificial one. Finally, the ligand view hides the possibility of structural isomerism. Thus, 1-$CpCoB_4H_8$ (**41**) is reasonably considered analogous to $CpCo(\eta^4\text{-}C_4H_4)$ (**42**) but in fact 2-$CpCoB_4H_8$ (**43**) is also stable – a possibility that an organometallic chemist does not consider for $CpCo(\eta^4\text{-}C_4H_4)$. Indeed, the barrier for the conversion of the hypothetical 2-isomer to the 1-isomer is calculated to be very low and even if formed would not be isolated. This is not the case for the boron analog.



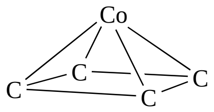
(**39**)



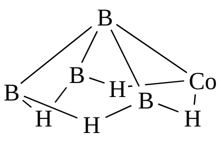
(**40**)



(**41**)



(**42**)



(**43**)

The relationship between the metallaborane structural isomers is clear in the cluster view but less so in the ligand view. In summary, the ligand view will be most useful for compounds containing one, or perhaps two, metal atoms bound to a contiguous main group fragment possessing a substantially higher effective electronegativity than the metals.

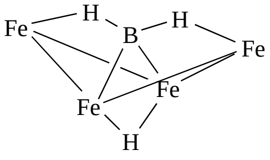
3.6 Element Substitution

In main group chemistry, element substitution constitutes a major perturbation, for example, C_2H_6 to B_2H_6 have very different structures and properties. The latter is more closely related to C_2H_4, that is, in order to draw a parallel between

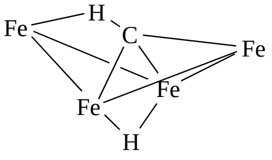
the E–E interactions, the number and/or type of ligands on the main group framework need to be changed. In transition metal chemistry, the perturbation is still significant but potentially a more subtle one. Thus, $[CpMo(CO)_2]_2$ and $[CpFe(CO)_2]_2$ have the same composition but very different M–M interactions: the former has a triple bond and the latter a single bond.[50] This is possible because 10 metal atom valence functions versus four main group atom valence functions permits changes in the metal–metal interaction to accommodate differing numbers of metal valence electrons for the same ligand set. Similar comparisons in inorganometallic complexes become interesting in the sense of exactly how this plays out in a cluster bonding environment.

3.6.1 Variation in Main Group Identity

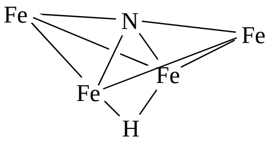
Early examples of inorganometallic compounds benefited greatly from comparison with known organometallic complexes or clusters. Thus, $HFe_2(CO)_{12}EH_n$, $E = B$, $n = 2$; C, $n = 1$; N, $n = 0$, (**44–46**) provide three isoelectronic compounds that are isostructural if one ignores the hydrogen atoms associated with the main group atom. They are analogous in the same sense as ethylene and diborane.[27]



(**44**)



(**45**)



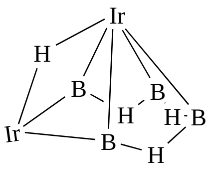
(**46**)

More examples of this type are known,[51] and each structural relationship found generates curiosity concerning the reaction chemistries. The latter is largely unrealized for inorganometallic compounds where identification and structural characterization remain the focus of the vast majority of studies. But much of the impetus behind the study of Inorganometallic Chemistry lies in the possibilities of structural and reaction chemistry that differs from that of organometallic analogs. It was already pointed out above that inorganometallic analogs of organometallic compounds, particularly metallaboranes, exhibit a more varied structural chemistry for a given composition than the organometallic analog. For example, the bridged dimetal compounds $(CO)_6Fe_2(E_2H_n)$, $E = B$, $n = 3$; $E = P$, $n = 1$ (^{t}Bu not H); $E = S$, $n = 0$ all exist, but the carbon compound, $E = C$, $n = 2$, has not been reported.

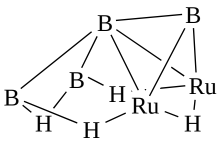
An example illustrating the possibility of significantly different reactivity is pertinent here (see also Section 5). A comparison of the photon driven reaction of alkynes with $(CO)_3Fe(\eta^4\text{-}E_4H_4)$, $E = C$, BH (**39**) has been reported.[52] The former yields substituted benzenes, whereas the latter generates predominantly carbon-rich carboranes, $C_nH_nB_4H_4$, $n = 2$, 4, 9, where the tetracarbon carborane is the primary product.

3.6.2 Variation in Transition Metal Identity

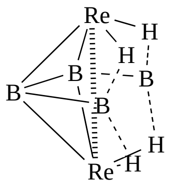
Two series are illustrative. It is important to note that this kind of comparison has only become possible recently because of progress in the synthesis of inorganometallic clusters of boron. The development of the reaction of monocyclopentadienyl metal hydrides with monoboranes has permitted metallaboranes to be generated containing Cp*M fragments of transition metals ranging from groups 5 to 9. For groups 6 and 9, metallaboranes representing all three rows are accessible. In several cases, series with constant or near-constant stoichiometry have been synthesized and characterized, thereby permitting the role of the metal atom in cluster structure to be explicitly defined. The series $Cp^*_2M_2B_4H_8$ for M = Ir, Ru, Cr, Re (**47–50**) is particularly interesting.[53]



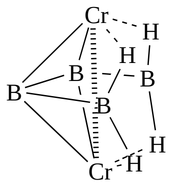
(**47**)



(**48**)



(**49**)



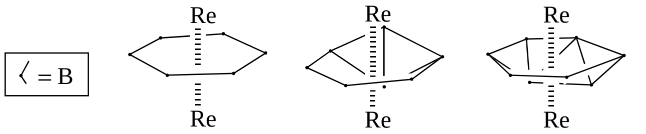
(**50**)

Formally, these compounds contain 8, 7, 6, and 5 cluster bonding pairs. In agreement with the electron counting rules, the structure of the Ir compound is based on a 7-vertex deltahedron with an axial vertex vacant (pentagonal pyramid). For Ru, the structure predicted is an octahedron; however, an alternative structure possible when there are at least two metals in the cluster, namely, a capped square pyramid, is the observed structure. Continuing the capping motif, the Re compound is considered as a bicapped tetrahedron requiring six pairs. The Cr compound appears to possess the same structure as that for Re and, thus, is not in conformance with the counting rules.[54] A detailed examination of its electronic structure shows the compound to be electronically unsaturated.

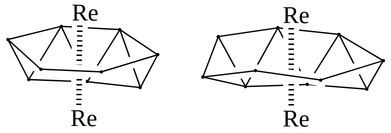
Unlike $[CpMo(CO)_2]_2$ in which unsaturation generates localized metal–metal multiple bonding, here the unsaturation is spread out over the entire six-atom cluster system; a conclusion supported by the difference in geometric parameters between the Cr and Re compounds as well as by molecular orbital modeling. Because of the invariant stoichiometry, these observed geometry changes can only be attributed to the change in metal.

3.6.3 Variation in Borane Fragment Size for a Group 7 Metal

A description of an unusual type of cluster bonding results from the synthesis and characterization of the series of closed clusters $Cp^*_2Re_2B_nH_n$, $n = 6–10$, (**51–55**) (Note: The Re–B bonding interactions have been omitted for clarity and for the $n = 6$ member, only the dichloro derivative was isolated).[55] These clusters all exhibit flattened spherical shapes with cross-cluster metal–metal bonding. Formally, they lack 3 cluster bonding electron pairs to satisfy the cluster electron counting rules for closed clusters possessing 8 to 12 vertices. This must be a consequence of the properties of the elements making up the cluster.



(**51**) (**52**) (**53**)



(**54**) (**55**)

Years earlier in the development of metallaborane and metallacarborane cluster chemistry, structures were found in which the electron count was one less than that demanded by the observed shape. Named 'isocloso' (or 'isonido' for more open shapes) by their discoverers, these compounds were shown to possess metals at vertices of higher connectivity than expected on the basis of the shape of the equivalent borane. Two explanations were proffered albeit individually and not as alternatives. The 'iso-' nomenclature was said to reflect the fact that the metal centers were effectively in a higher oxidation state due to a contribution of two additional electrons to cluster bonding over and above those expected on the basis of an isolobal main group fragment (the 'missing' electrons localized at the metal). The competitive explanation produced the prefix 'hyper,' reflecting an explanation in terms of a low electron count, leading to a change in shape ('missing' electrons delocalized throughout the cluster framework).[56,57] Although the number of such compounds continually grew, they were considered by many as exceptions to the electron counting rule.

The series of Re clusters, used to introduce this section, established the fact that for the right transition metal, this qualitative behavior is the rule not the exception. Consider the principal observations. Each compound characterized possesses a structure compressed along the Re–Re axis that has a distance corresponding to a Re–Re single bond. Of necessity, the equator bulges out. Likewise, the metal vertices are of higher connectivity and the boron vertices are of lower average connectivity than those for borane clusters of nuclearity $n + 2$. These differences do not change the overall connectivity for a given nuclearity. The generation of a Re–Re cross cage bond, the reduction of the B–B bonding and increase in Re–B bonding conspire to empty three orbitals that would be filled in the B_{n+2} core. The electronic mechanism to achieve this situation is equivalent to that developed for families of triple-decker complexes of which $Cp^*_2Re_2B_6H_6$ is a member.

Recent work on related Ru clusters suggests that both the 'iso-' or 'hyper-' nomenclature (and associated description of the location of the 'missing' electrons) are too restrictive. A more general nomenclature, 'hypo-electronic' accommodates both possibilities, which, in fact, are known in related solid-state systems.[58] Moreover, this view suggests that the proper origin of the effect is the metal and is an expression of the variation of metal properties with group number. It was only when metallaboranes substantially different from the commonly studied group 9–10 compounds could be synthesized that the role of the metal center could be distinguished from variations due to ancillary ligand differences.[59]

4 CLUSTER COMPOSITION AND STRUCTURE TYPES

4.1 Limiting Factors

The model-based discussion of Sections 2 and 3 suggests two distinct categories of mixed transition metal–main group element clusters. The first includes main group or transition metal atoms or fragments, which do not necessarily form clusters on their own, incorporated into cluster networks. The formation of the cluster is driven by the cluster-forming tendencies of either the transition metal or the main group element fragments. Thus, these clusters will be transition metal–rich in one case and main group element–rich in the other, somewhat analogous to the borides discussed in Section 3.4. The second category consists of compounds that contain equal or nearly equal numbers of transition metal and main group elements both of which usually meet the requirements of cluster bonding. In this section, these

predictions are tested against a range of cluster compositions and isomeric structural forms that have been characterized.

The examples presented illustrate three points already presented in Sections 2 and 3. The formation of a cluster structure containing specified transition metal and main group atoms depends on (1) the skeletal electron count, (2) the identity of the elements chosen, and (3) the number and type of ligands on the cluster atoms. In addition, the following dramatically shows the wide variety of cluster isomers and stoichiometries that remain to be discovered.

4.2 Examples of Cluster Structures

The compilation of transition metal–main group element compounds is given in Table 1, using Figure 3 to define core cluster structure type. To make the discussion tractable, only three types of clusters having core stoichiometries with varying E/M ratio are considered, that is, 4-, 5-, and 6-atom clusters are discussed. Many more cluster types will be found in the literature but similar organization is possible using the examples given here as a guide (see Sections 2 and 3 for selected examples of other cluster types). The first type discussed is electron precise, while the other two are orbitally rich clusters (see Section 2.2). Both fully closed (closo) and partially opened (nido) clusters are included but, again, more open clusters are known.

The examples given have been characterized mainly by crystallographic techniques. Further discussion of many of these compounds, as well as other related compounds, will be found in the book *Inorganometallic Chemistry* along with references to the primary literature.[8] Many of these same structure types have been observed for carbon as the main group element (*see* ***Polynuclear Organometallic Cluster Complexes***), and are so indicated in Figure 3 by an asterisk. The end members of each series (pure transition metal or pure main group element) are not given but several can be found in chapters devoted to specific elements. Note also that although $HRu_6(CO)_{17}B$ (**14**) can be considered as a 7-atom transition metal, main group element cluster system, electronically it is more usefully considered as a 6-atom metal cluster with an interstitial boron atom. Hence, it too provides an all-metal cluster for the closo-6-atom series.

The organization of Table 1 and Figure 3 is best appreciated by means of an example. $Fe_2(CO)_6B_3H_7$ (**39**) will be found in the table as $\{BH\}_3\{Fe(CO)_3\}_2H_4$, emphasizing that the cluster core contains 3 BH fragments and $2Fe(CO)_3$ fragments with 4 H atoms associated with cluster bonding. The skeletal electron count is $(3 \times 2) + (2 \times 2) + 4 = 14$. Thus, the cluster structure is based on a $(14/2) - 1 = 6$ vertex deltahedron (octahedron) with one vertex unoccupied. There is only one possibility: the square pyramidal shape. However, a square pyramidal cluster has three possible ways for the distribution of 3 BH and 3 $Fe(CO)_3$ fragments over the five vertices. Of these three isomeric forms, the one observed for this compound is indicated by reference to Figure 3, that is, structure 5q. But now that many metals may be incorporated into such a framework, examples of all three possible isomers are known for this structure type. Indeed, two have been isolated for Rh, and in this case, the relative stabilities of the two isomers were determined to be 5p > 5q.[60] If one assumes that the isomeric form isolated in the other cases corresponds to the most stable one, then isomer stability is seen to depend on the nature of the metal and its ancillary ligands. The properties of the transition metal are expressed in structure.

The information in Table 1 and Figure 3 defines some interesting trends. More than 100 compounds are listed for just these three cluster types. For the 4-atom electron-precise cluster, at least one example of all possible isomers is known. There are more than 30 examples of the tetrahedral M_3E core, with E from groups 13–16 and M from groups 6–9. The E atom usually has a one-electron ligand (H, R, or a 17-electron metal fragment) but examples with no ligand, a two-electron donor (CO), or a two-electron acceptor (see Section 5.3) are known. The M atom usually has three coordination positions occupied by exo-cluster ligands (3CO or Cp are most common). The number of hydrogens bound to the cluster in edge-bridging positions range from none to four. These observations are completely in accord with the limitations on cluster composition imposed by the requirements of cluster bonding and steric considerations (see Section 2).

The 5- and 6-atom cluster systems shown in Figure 3 and Table 1 have more compositional and isomeric possibilities, but relatively fewer examples are known. Thus, although some structural types are well represented, about half of the possibilities remain to be characterized. If barriers for rearrangement of isomeric forms are low, the isolation of the less stable forms will be very difficult (see Section 5.2). However, the unrepresented structures in Figure 3 are probably due more to lack of appropriate synthetic routes than to any intrinsic factors. Thus, for all three-cluster sizes, it would be dangerous to draw any interpretations from the differences in the numbers of examples for differing E and M core compositions. Certainly, one expects differences but what is required is a comparison of series containing differing numbers of the same E and M atoms (see Section 3.4). The missing compounds constitute attractive synthetic goals for future work.

5 CLUSTER REACTIVITY

The complement of structure is reactivity. Studies of reactivity usually follow advances in synthesis, which, in turn, are often stimulated by serendipitous characterization of novel compounds. Progress in understanding reactivity, even at the most elementary mechanistic level, is very important. New compounds, despite novel and interesting structures, find little use unless their chemical origins and ultimate chemical

[a]Organized according to framework size, skeleton type (see Figure 3), main group atom, and transition metal atom.

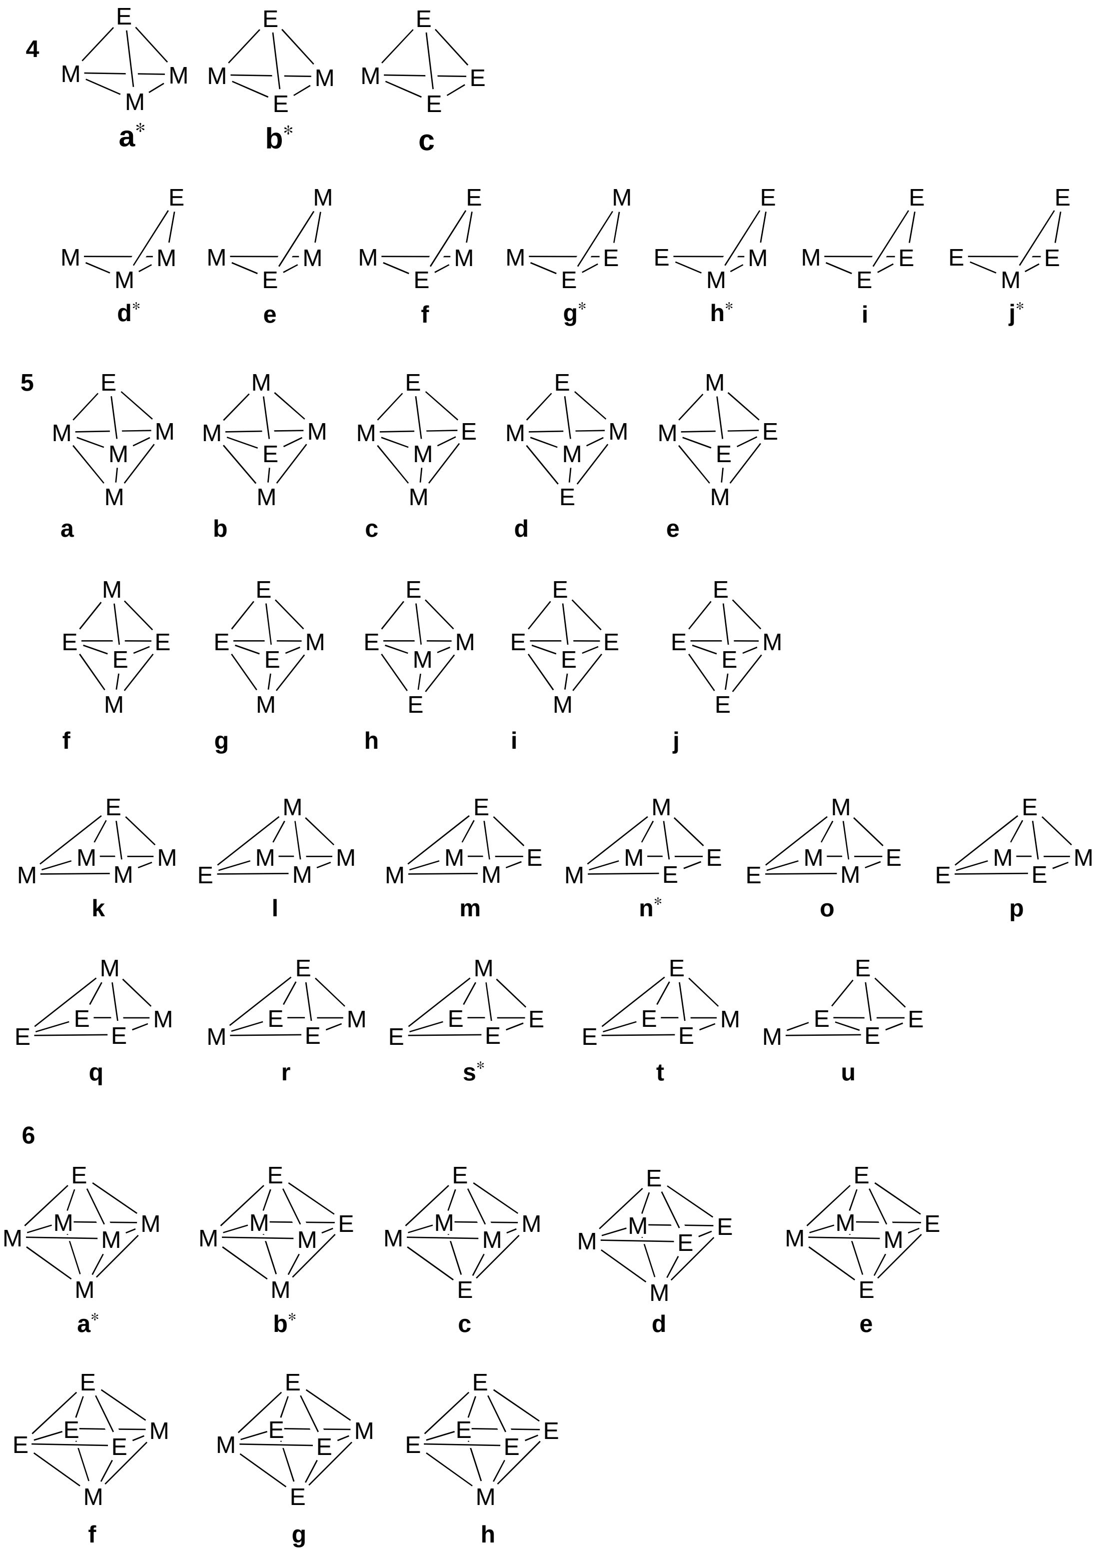

Figure 3 Isomeric possibilities for structures for E_nM_{x-n}, $n = (x - 1) - 1$, $x = 4$–6. Only the geometry of highest total vertex connectivity (usually denoted as closo but note the ambiguity for $x = 4$) and that of next highest (usually denoted as nido) are shown for economy of space. Likewise, only the binary E and M clusters are enumerated. Clearly, many more structures are possible if more open structures are allowed or more than one type of main group or transition metal element is used in the compound

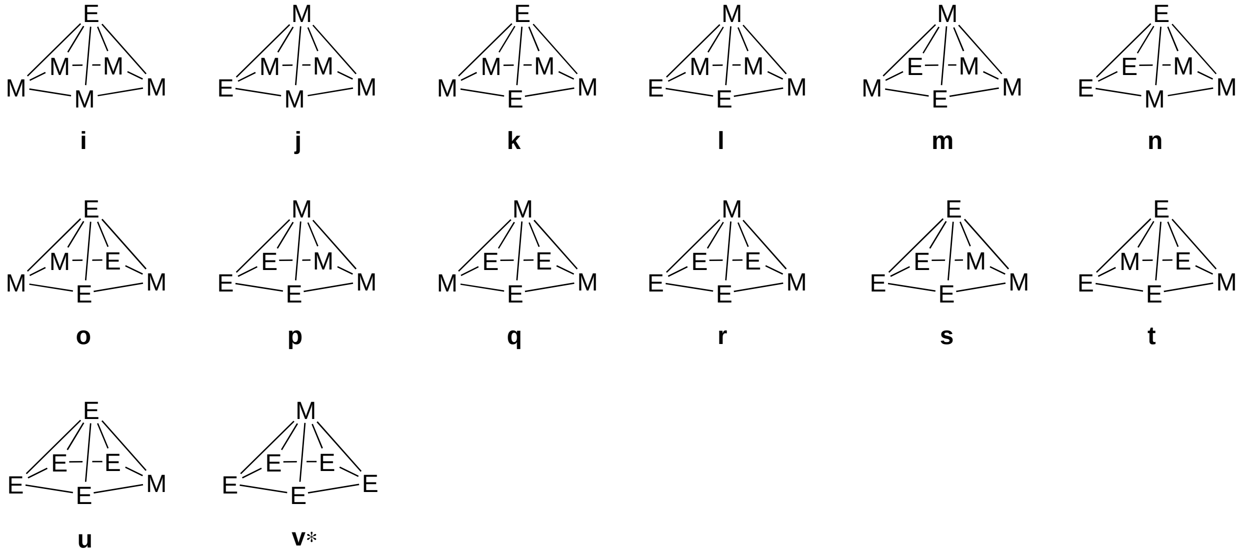

Figure 3 cont'd

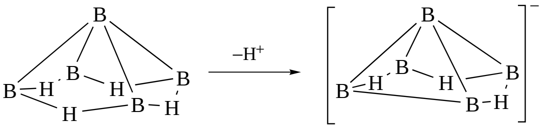
destinations are understood. This information not only aids the development of new synthetic routes but can also lead to applications. Thus, it can be argued that if organometallic chemistry had not developed beyond the bizarre (at the time) structures of ferrocene and olefin π-complexes, it would never have had the large impact already demonstrated. Transition metal–main group cluster chemistry remains rich in structure and poor in reactivity. But progress continues to be made, and a brief introduction to reaction types characteristic of the area is presented. It is highly selective but illustrates the mutual effects of main group and transition elements on reactivity. Of course, element properties are important, but the emphasis in the following is on the reactivity derived from or modified by cluster structure properties. For example, element properties make the hydrogen of a B–H bond hydridic, but when a B–H bonding interaction is found as part of a cluster edge-bridge, it also exhibits protonic character.[61]

5.1 Addition or Loss of a Proton

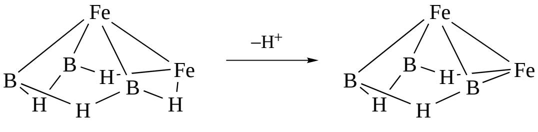
Boron hydride (equation 1)[62] and transition metal clusters (equation 2)[63] containing bridging hydrogens can be deprotonated by bases (*see* ***Boron Hydrides***; ***Boron: Polyhedral Carboranes***; ***Hydride Complexes of the Transition Metals***, and ***Polynuclear Organometallic Cluster Complexes***). The resulting anionic conjugate bases are often nucleophilic in character and more reactive than the neutral clusters (see below). For the boranes, it has been demonstrated that the acidity of a bridging hydrogen increases as the cluster size increases, whereas for transition metal clusters, it is the ligands on the metal atoms that have the dominant effect. In general, the boranes are weaker Brönsted acids than the metal cluster hydrides, and the anions are consequently more reactive. An important factor here is that the metal clusters are much more effective at delocalizing the anionic charge generated on deprotonation, particularly when the metal centers contain carbonyl ligands.



(**16**) (1)

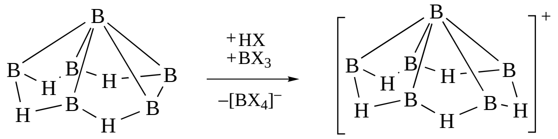
$$(\mu\text{-H})_2Re_3(CO)_{12} \xrightarrow{-H^+} [(\mu\text{-H})_2Re_3(CO)_{12}]^- \quad (2)$$

From this, it follows that transition metal–main group element clusters with bridging hydride ligands will also serve as Brönsted acids but with acidities intermediate between those of the homonuclear clusters of the same structure type. Thus, the isolobal analog of B_5H_9 (**16**), $Fe_2(CO)_6B_3H_7$ (**39**), is more easily deprotonated than B_5H_9 (equation 3), and it is one of the FeHB protons that is lost rather than a BHB proton.[64] Deprotonation of $HFe_3(CO)_9(\mu\text{-H})_3BH$ (**10**) yields $[HFe_3(CO)_9(\mu\text{-H})_2BH]^-$, again with the loss of a B–H–Fe proton. However, the Fe–H–Fe and remaining Fe–H–B hydrogens are fluxional on the NMR timescale and, thus, the difference in proton affinities of the Fe–Fe and Fe–B edges must be small.[65]



(**39**) (3)

The removal of a cluster bridging hydrogen as a proton yields a semilocalized bonding orbital that, in the reverse process, serves as a site of available electron density. It follows that an unbridged edge of neutral clusters is a potential site of protonation provided that there is a high-lying cluster orbital associated predominantly with that edge. Thus, B_6H_{10} and $Os_3(CO)_{12}$ can be protonated (equations 4 and 5) to yield cationic species.[66,67] In both cases, the added proton becomes a bridging 'hydride.' Because cluster bonding is often highly delocalized, cationic clusters like these are rare.



(4)

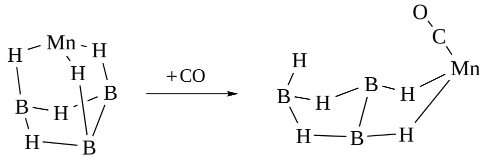
$$Os_3(CO)_{12} \xrightarrow{+H^+} [(\mu\text{-H})Os_3(CO)_{12}]^+ \qquad (5)$$

When there are exo-cluster ligands with lone pairs as well as metal–metal edges, an incoming proton is presented with two possible basic sites with differing proton affinities. Because the metal–metal edges are sterically shielded by the ligands on the metal centers, the exo-cluster lone pair is more accessible. An interesting example of such behavior is shown in equation (6).[68] For our purposes, $[Ru_3(CO)_{10}NO]^-$ can be viewed as the $[Ru_3(CO)_{10}N]^-$ tetrahedral cluster with the lone pair of the N atom coordinated to the Lewis acid oxygen (see Section 5.3). The first product formed is the O protonated product, which then rearranges to the Ru–Ru edge protonated product. Steric control generates the kinetic product but, at least in this case, the greater basicity of the metal site controls the identity of the final product.

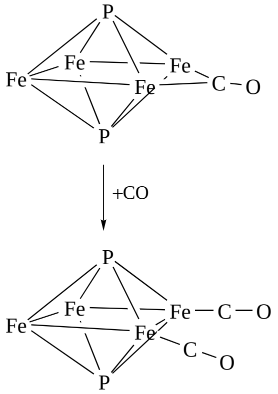
$$[Ru_3(CO)_{10}NO]^- \xrightarrow{+H^+} Ru_3(CO)_{10}NOH \longrightarrow (\mu\text{-H})Ru_3(CO)_{10}NO \qquad (6)$$

5.2 Addition or Loss of a Lewis Base

Clusters, particularly those described in Section 2.2 as orbitally rich, can act as Lewis acids. Addition of a Lewis base formally adds two electrons to the cluster bonding system. For some clusters, this causes an opening of the cluster, for example, closo to nido interconversion of $B_3H_8Mn(CO)_3$ and $B_3H_8Mn(CO)_4$ by the addition and loss of CO (equation 7).[69] If the cluster is formally unsaturated with respect to the electron counting rules, no change in the core structure takes place, for example, the interconversion of $Fe_4(CO)_{11}(PPh)_2$ and $Fe_4(CO)_{12}(PPh)_2$ (equation 8).[70] The base pair may be supplied by a conventional Lewis base (equation 7 or 8), but also can come from bond pairs, for example, H_2 (equation 9).[71] The latter is equivalent to oxidative addition in mononuclear systems (*see* ***Hydride Complexes of the Transition Metals***).



(7)



(8)

$$Os_4(CO)_{11}(\mu_4\text{-S})(\mu_4\text{-HC}_2\text{CO}_2\text{Me}) \xrightarrow{+H_2} Os_4(CO)_{11}(\mu_3\text{-S})(\mu\text{-HC}_2\text{CO}_2\text{Me})(\mu\text{-H})_2 \qquad (9)$$

In transition metal–main group element clusters, there is the possibility of ligand substitution at either type of element center. Displacement of an exo-cluster ligand on one of the metal centers (equation 10) is to be expected (*see* ***Mechanisms of Reaction of Organometallic Complexes***).[72] However, displacement at a main group cluster site has also been observed (equation 11).[73] Indeed, phosphine substitution takes place exclusively at the boron atom, and the osmium-substituted BCO complex can only be prepared by synthesizing it from the phosphine-substituted osmium carbonyl starting material.

It is interesting to note that the base displaced need not be a simple one, that is, dihydrogen is exclusively displaced from $[HFe_3(CO)_9(\mu\text{-H})_2BH]^-$ (equation 10). Indeed, a comparison of equations (10) and (11) demonstrates that cluster composition is important in determining the outcome of a Lewis base displacement reaction on a transition metal–main group element cluster. This implies that control of electronic structure via cluster element composition is a viable means of controlling reactivity.

$$Fe_3(CO)_9(\mu\text{-CO})(\mu_3\text{-HBH})^- \xrightarrow[-CO]{+PR_3} Fe_3(CO)_8(PR_3)(\mu\text{-CO})(\mu_3\text{-HBH})^-$$

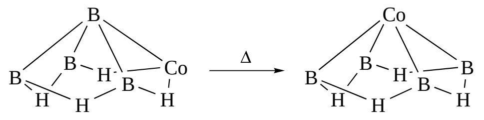
$$(\mu\text{-H})Fe_3(CO)_9(\mu_3\text{-HBH})^- \xrightarrow[-H_2]{+PR_3} Fe_3(CO)_8(PR_3)(\mu\text{-CO})(\mu_3\text{-HBH})^- \qquad (10)$$

$$(\mu\text{-H})_3Os_3(CO)_9(\mu_3\text{-BCO}) \xrightarrow[-CO]{+PR_3} (\mu\text{-H})_3Os_3(CO)_9(\mu_3\text{-BPR}_3) \qquad (11)$$

It should be clear from the discussion of Section 2 that all of these clusters can be unstable with respect to cluster degradation in the presence of Lewis bases with the formation of saturated fragment species (*see* ***Boron Hydrides*** and ***Polynuclear Organometallic Cluster Complexes***). Thus, in the presence of an excess of phosphine, the reaction of $[HFe_3(CO)_9(\mu\text{-}H)_2BH]^-$ changes from that shown in equation (10) to that shown in equation (12). The mononuclear boron and iron products demonstrate that both transition metal and main group element vertices are removed by base and the cluster is degraded.[72]

$$(\mu\text{-H})Fe_3(CO)_9(\mu_3\text{-HBH})^- \xrightarrow{+PR_3\ \text{excess}} BH_3PR_3 + Fe(CO)_3(PR_3)_2 + Fe_3(CO)_9(PR_3)_{2^-} \quad (12)$$

The variety of cluster structure isomers shown in Figure 3 suggest that geometrical isomerization should be a substantial feature of the reaction chemistry of transition metal–main group element clusters. It may well be, but at present there are only a few established examples of isomerization reactions. Consistent with the high main group character of the cluster bonding, the isomerization of 2-$CpCoB_4H_8$ (**40**) (equation 13) requires high temperatures.[74] However, the rearrangement of 1,2-$(Cp^*Rh)_2B_3H_7$ to the 2,3-isomer takes place on mild heating and that of 1-$Cp^*WH_3B_4H_8$ to 2-$Cp^*WH_3B_4H_8$ takes place below 0 °C.[75] As all these clusters have the same square pyramidal geometry, not only is the number of metal fragments important but also the type of metal fragments is important in determining the flexibility of the skeleton toward rearrangement. Cluster geometry can play a role that has been delineated via calculations. Thus, the octahedral cluster system appears to be one that possesses a large barrier for unimolecular rearrangement compared to other less symmetrical cluster geometries.[76] Note, however, that coordination of a Lewis base, thereby opening the structure, can catalyze rearrangement of rigid frameworks under mild conditions.[77]



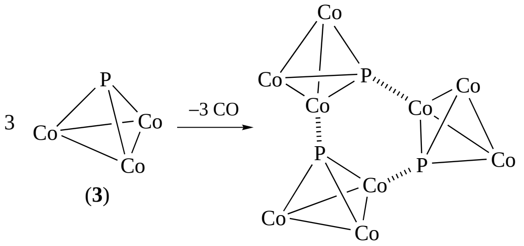
(**43**) (**41**) (13)

5.3 A Cluster as a Lewis Base

The conjugate base of a cluster generated by deprotonation (see Section 5.1) is a Lewis base. Any metal–metal, metal–boron, or boron–boron bond is a potential Lewis base. The former have considerable nucleophilic character if anionic and effectively interact with electrophiles more complex than the proton. As the site of basicity is associated with framework bonding, this reaction type results in cluster building, for example, with metal fragment sources (equation 14).

$$(\mu\text{-H})Fe_3(CO)_9(\mu_3\text{-HBH})^- \xrightarrow{+Fe_2\ (CO)_9} (\mu\text{-H})Fe_4(CO)_{12}(\mu_4\text{-BH})^- \quad (14)$$

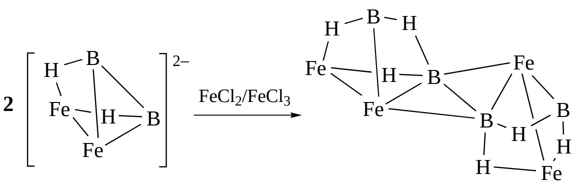
As noted in Section 2, clusters with 'bare' main group atoms possess a lone pair not formally involved in cluster bonding, for example, $Co_3(CO)_9P$ (**3**). Such clusters can act as ligands to main group or metal centers. Thus, for example, loss of CO from (**3**) takes place and leads to the formation of a trimer (equation 15).[78]



(**3**) (15)

The coordination of a cluster to an oxidized metal center is a crucial part of the oxidative fusion reaction, whereby large clusters are generated from smaller ones in a single reaction procedure (equation 16).[79] Recently, this approach has been extended to a metallaborane system as illustrated in equation 17.[80] Although the presumed coordinated Fe^{II} intermediate has not been isolated, the fact that the reaction requires Fe^{2+} strongly suggests its formation.

$$R_2C_2B_4H_4{}^{2-} \xrightarrow{Mn^+} H_xM\{R_2C_2B_4H_4\}_2 \xrightarrow{[O]} R_4C_4B_8H_8 \quad (16)$$



(**36**)

(17)

5.4 Metallacarboranes via Metallaboranes

Metallacarboranes historically have been prepared from carboranes and metal fragment sources. The recent ready availability of metallaboranes permits the generation of metallacarboranes from the reaction of alkynes with metallaboranes. An advantage of such an approach arises from the fact that one forms weaker M–B bonds before stronger B–C bonds, which, in principle, permits milder reaction conditions and more control of reactivity. Indeed, such appears to be the case. For example, the reaction of $(Cp^*RuH)_2B_3H_7$ with MeC≡CMe permits the generation of several previously unprecedented metallacarborane structures.[81] As shown in Figure 4, among other compounds, two isomers of identical

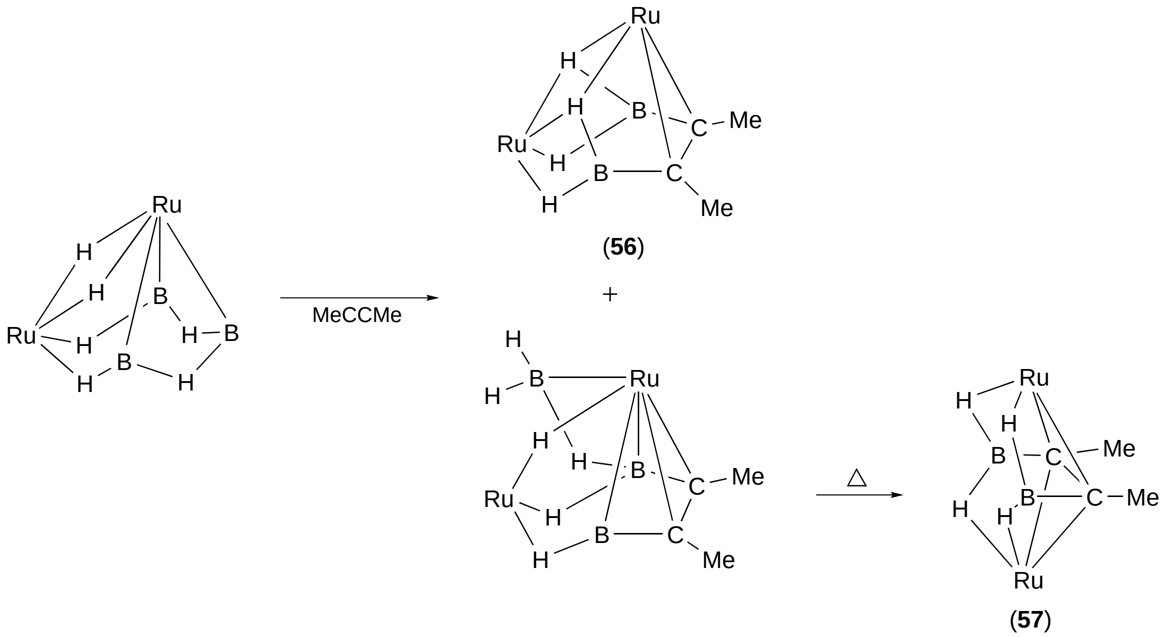


Figure 4 The reaction of a nido-diruthenapentaborane with an alkyne, ultimately generating two clusters of identical composition in which the geometric isomerism is associated with the type of unoccupied vertex in the pentagonal bipyramidal shape upon which both structures are based

composition, (**56**) and (**57**), are produced – isomers in the sense that the observed nido structures are based on the same pentagonal pyramid with either apical (**56**) or basal (**57**) vertices remaining vacant. These two species are to cluster chemistry as cis and trans olefins are to organic chemistry. Also, reminiscent of olefin isomers, the two species do not interconvert readily by thermal activation, showing that access to such species only arises from control of the reaction chemistry. Note that this isomerism is distinctly different from that associated with different distributions of the metal and main group atoms on a given framework geometry. This constitutes one more example that the prospects for the future development of inorganometallic chemistry are excellent.

1 INTRODUCTION

The term 'intercalation' refers to a process whereby a guest molecule or ion is inserted into a host lattice. The structure of the guest–host or intercalation compound is only slightly perturbed from the host structure and the reaction used to form the compound is either chemically or thermally reversible. Other terms such as *Insertion*, inclusion, and *Topotactic* reaction are also often used but fall under this general definition. Intercalation compounds have been known since the last century, but in the last three decades have attracted significant attention from the scientific community. The term intercalation was originally used for reactions of layered host lattices but it has been recognized for some years that structures with other dimensionalities can also fall under the same general definition. The more general approach will be taken here, though detailed coverage of all the guest–host combinations that have been studied is beyond the scope of the article. A more detailed view of the extensive scientific literature that covers a wider range of different host lattices and guest molecules and ions and the many different facets of synthesis, reactivity, and physical properties can be found in the references.[1–8]

Intercalation reactions and intercalation compounds have attracted attention for several reasons. Reactions provide routes for the synthesis of new solids with kinetic rather than thermodynamic stability and permit controlled systematic changes in physical properties, particularly the electronic, magnetic, and optical properties of the host lattice. Chemical properties may also be finely tuned by incremental changes in composition through *Ion Exchange* reactions. The ability to tailor specific properties by intercalation has been one of the major reasons for interest in the area. This 'tunability' makes it possible to design materials for a variety of applications, for example, catalysts, sorbents, solid electrolytes, sensors, electrochromic displays, and batteries.

Intercalation reactions leave the structure of the host lattice largely unchanged and are therefore different from normal solid-state reactions that involve extensive bond breaking and structural reorganization. Host lattices suitable for intercalation are inherently anisotropic in their chemical bonding. One part of the structure has a strongly bonded lattice of atoms that is largely unchanged when guest molecules or ions are inserted. Intercalation of the guest species occurs in other parts of the structure that contain a connected network of vacant lattice sites or of mobile ionic species. Intercalation of a mobile guest species (G) into a host lattice (H) with interconnected vacant lattice sites (□) can be represented by equation (1), and exchange reactions where the host lattice contains a connected network of mobile ions by equation (2).

$$x\mathrm{G} + \square_x[\mathrm{H}] \Longleftrightarrow \mathrm{G}_x[\mathrm{H}] \quad (1)$$

$$x\mathrm{G}'' + \mathrm{G}_x{}'[\mathrm{H}] \Longleftrightarrow \mathrm{G}_x{}'[\mathrm{H}] + x\mathrm{G}'' \quad (2)$$

As indicated, intercalation reactions are usually reversible. In many cases, reactions occur near ambient temperature, but in general the reaction temperature should be high enough to ensure mobility of the guest species but not so high that the strong bonds are broken and the structure of the host lattice is rearranged. Many intercalation compounds are metastable because of the inherent anisotropy in the chemical bonding.

The structural requirement described above places restrictions on the types of host lattices that are suitable for intercalation reactions. Nevertheless, many examples of one-, two-, and three-dimensional structures can be found with suitable properties. Studies of alkali metal reactions with C$_{60}$ (*see* ***Carbon: Fullerenes***) have been discussed in terms of intercalation in a host lattice of effectively zero dimensionality.[9] The different types of host lattice geometry are shown in Figure 1.

In three-dimensional systems, the sizes of the guest species that can access the host lattice are constrained. In lower dimensional systems, no such restriction exists and the strongly bonded components (layers, chains, C$_{60}$ molecules) can adjust their separation freely to accommodate guest species of different sizes. With increasing guest size, the structural correlation between layers or chains is diminished and compounds become more difficult to characterize. In the limiting case, complete separation of single layers or chains occurs in solution, resulting in the formation of colloidal dispersions.

In addition to dimensionality, host lattices can be classified as electronic insulators (*see Insulator*) or conductors. Insulating lattices undergo reactions that involve ion exchange, acid–base chemistry (*see Acids & Acidity*), and solvent exchange. Sorption of neutral molecules from the gas phase is

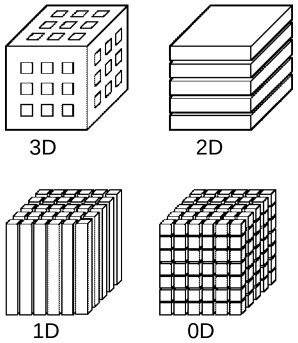

Figure 1 A schematic illustration of different host lattice geometries for intercalation

also an important property, particularly for three-dimensional structures with large pores (e.g. zeolites, *see* ***Zeolites***) and the layered compounds. Sorption of organic molecules forms the basis for the application of these compounds in separations and in catalytic conversions (*see Catalysis*) of hydrocarbons to fuels and chemicals. The major classes of three- and two-dimensional insulating host lattices are listed in Table 1; examples of one-dimensional systems are rare. Most of the examples contain mobile cationic species in negatively charged lattices. The layered double hydroxides, such as $Zn_2Cr(OH)_6Cl{\cdot}2H_2O$, form the only major class of anion exchangers.

The major classes of conducting host lattices are summarized in Table 2. Of these, graphite and the layered transition metal dichalcogenides (*see* ***Chalcogenides: Solid-state Chemistry***) have been investigated in the greatest detail. The conducting host lattices have the feature that the concentration of ionic guest species can be altered by oxidation or reduction of the host lattice. In contrast, in the insulating lattices the concentration of ionic guests is fixed by the chemical composition and remains unchanged throughout subsequent reactions. The chemistry of most of the compound classes in Table 2 involves reduction reactions and cation insertions. The major exception is graphite, which can be both reductively intercalated with cations and oxidized with anion insertion. The two types of reactions can be represented by equations (3) and (4).

$$xG^+ + xe' \text{ to } [H] \Longleftrightarrow G_x{}^+[H]^{x-} \quad (3)$$

$$xG^- + xe' \text{ from } [H] \Longleftrightarrow [H]^{x+}G_x{}^- \quad (4)$$

The simplest model for redox intercalation involves the quantitative transfer of electrons between the intercalating species and the lowest energy level of the host lattice. A rigid band description is generally assumed to give a reasonable account of the variation of the composition and the properties of the intercalation compound. Once an intercalation compound has been formed by a redox process, then ion and solvent exchange reactions of the type observed in insulating lattices are possible. A redox intercalation reaction of a layered compound is shown schematically in Figure 2 for the reaction of lithium with TiS_2. The titanium disulfide layers are reduced and lithium cations diffuse into empty octahedral sites between the sulfur layers. The reaction begins at the crystal edges and the reaction front moves into the center of

the crystal as the reaction proceeds. The intermediate stage shown schematically in Figure 2 is clearly visible in the optical micrograph of a partially reacted crystal (Figure 3).[10]

Electrochemical techniques have been widely used to study redox reactions. They provide important quantitative

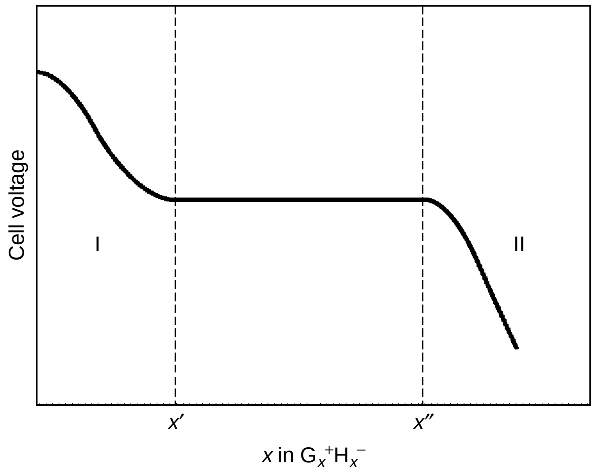

Figure 4 Schematic of the variation of cell voltage with composition for the electrochemical intercalation of a guest ion (G) into a host lattice (H)

information about the extent of total charge transfer and details of phase equilibria. For a reaction expressed by equations (3) and (4) a schematic diagram of the variation of voltage versus charge transferred is shown in Figure 4 for a typical system at equilibrium.[2b] The smooth variations of V versus x in regions I and II are indicative of single phases with varying compositions. The variation in voltage is directly proportional to the partial molar free energy (*see Gibbs Energy*) of solution of the guest species in the host lattice. Regions where the cell voltage is constant with x correspond to regions where two solid phases coexist. For example, in Figure 4, phase I is converted to phase II between x' and x''. Interpretation of such data assumes that equilibrium has been obtained, a situation that can be difficult to achieve at lower temperatures for larger guest species. Apparent plateaux in V versus x data may also be observed in cases where electron transfer involves a region where the density of states is very large.[11]

Chemical reagents can also be used to carry out redox intercalation reactions. Alkali metals in liquid ammonia[12] and organometallic reagents such as n-butyllithium[13] were among the earliest used. Other chemical reagents can be used to provide different effective activities of the alkali metal relative to the pure metal. A convenient summary, developed for comparison of the reduction potentials for some common lithium reagents and common host lattices, is shown in Figure 5.[14]

1.1 Mechanisms of Intercalation

Intercalation is a complex process. Reactions involve adsorption of guest species on host crystals, exchange or insertion at the host surface, the formation of intermediate stages in layered compounds, and transport within the host lattice. Macroscopic effects such as variations in crystal size,

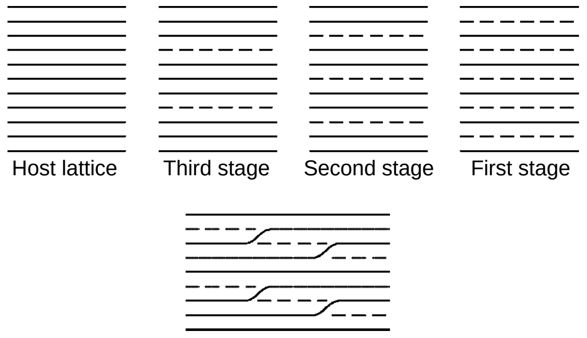

Figure 6 Schematic representation of staging in intercalation compounds. The lower part represents the isolated island or domain model. The continuous line represents the host layer, the dashed line a guest layer

dislocations, stacking faults, and pore mouth blockage can strongly influence the kinetics of intercalation. In layered compounds, interlayer defects (*see* ***Defects in Solids***) such as crosslinks in graphite and interstitial metal atoms in dichalcogenides further complicate the situation. Reaction mechanisms have been studied in some detail for layered structures, but some aspects remain poorly understood. Recent advances in in situ studies using energy dispersive X-ray diffraction with synchrotron radiation have added significantly to our general understanding of intercalation mechanisms.[15]

Redox intercalation reactions of layered host lattices show two extreme kinds of behavior at low guest concentrations where the interlayer sites are only partially occupied. Some reactions proceed by insertion of the guest species into all the interlayers. At intermediate compositions each interlayer has the same concentration of guest species distributed randomly over the available interlayer sites. Two-phase behavior is observed up to some critical concentration of guest species, implying that a minimum energy of reaction is required to open up the van der Waals gap between the layers. Other reactions occur *via* staging, which provides a mechanism to minimize the energy associated with separating the layers. Ideally, staging results in the formation of compounds with alternating sequences of filled or empty interlayer sites, as shown in Figure 6. The facile transformations between odd and even numbered stages that are observed in graphite intercalation compounds are not easily explained with this simple model. Consequently, Daumas and Hérold proposed a model in which the stages are assumed to exist in the crystal in the form of local domains.[16] The existence of staging indicates that at low guest concentrations the energy associated with a homogeneous distribution of cations throughout the interlayer space is higher than when the guests are concentrated in a fraction of the interlayer sites. Communication between layers in staged systems involves deformation of the layers and is most commonly observed in compounds where the layers are flexible. The origin of the effect has been discussed in detail for graphite intercalation compounds.[17] A related phenomenon occurs in ion-exchange reactions of layered compounds with two cations of different sizes. Some synthesis conditions can result in a random distribution of both cations over the interlayer sites. The random distribution is, however, unstable with respect to a distribution in which cations of different sizes are segregated into different interlayers.

Uptake isotherms measured for the intercalation of gaseous species by layered structures generally show the sigmoidal behavior characteristic of a nucleated process. These curves may also show plateaux as a consequence of the formation of intermediate stages. Early experiments by Hooley[18] showed that basal plane adsorption plays a critical role. In a study of the reaction of graphite with bromine, intercalation did not occur when the basal surfaces of a graphite cylinder were isolated from the bromine by glass caps. When the basal surfaces were exposed, intercalation proceeded with the greatest physical expansion of the specimen observed nearest the ends. The experiments were interpreted in terms of basal plane adsorption weakening the interaction between the first two layers and permitting intercalation to occur. Once the process begins, then the effect is transmitted layer to layer.

Involvement of higher stages at the early stages of intercalation has been shown in several experiments. For example, intercalation of ammonia in TaS_2 was shown by in

situ neutron diffraction (*see **Diffraction Methods in Inorganic Chemistry***) of a bulk polycrystalline sample to proceed through the formation of higher stages, which coexist in the powder sample.[19] A single-crystal study of the intercalation of silver in TiS_2 was shown to involve the initial formation of a first stage phase on electrochemical reaction. Analysis of the penetration of silver into the crystal showed that a stage 1 region was formed near to the crystal edge. Further inside the crystal, the stage 1 region transformed into a stage 2 zone that was followed by unintercalated host. When the electrochemical insertion was stopped and the crystal allowed to equilibrate, the stage 1 region rapidly converted to stage 2 without further treatment and the overall reaction front moved further into the crystal. The result supports the Daumas–Hérold model of staging (see Figure 6) and gives for this specific case an estimate of 130 Å for the dimension of the islands.[20] A similar study of lithium intercalation in 2H-TaS_2 by measurement of the ^{181}Ta quadrupole interaction also showed the existence of phase boundaries between regions of different composition, which gradually diffused into the center of the crystal. In this case, three different regions were identified: stage 1, a dilute stage 1 with the composition $Li_{1/3}TaS_2$, and an intermediate improper stage 2 made up of alternating layers of the two first stage compositions.[21] Crystal size plays an important role in all of these experiments. Intercalation of hydrated sodium ions under nonequilibrium conditions carried out either electrochemically or by using sodium dithionite as a chemical reductant, shows the same staging type of behavior as that described above, together with the additional feature that a monolayer hydrate region precedes the stable bilayer configuration into the crystal. In contrast, no staged intermediates are observed with polycrystalline material and the reaction occurs as a simple two-phase process.[22]

As mentioned above, the rigidity of the layers is an important parameter in directing the mechanism of intercalation. The concept of layer rigidity has been quantified by Solin and coworkers.[23] For an intercalation compound with the general composition $G_xG'_{1-x}H$ where G and G′ are either two different guests or a guest and a vacant site, the normalized interlayer separation as a function of the mole fraction x of the guest species can be written as $d_n(x) = 1 - (1-x)^p$ where p is a parameter that characterizes the layer rigidity. The normalized interlayer separation is defined as $d_n(x) = [d(x) - d(0)]/[d(0) - d(1)]$. By measuring the composition dependence of the normalized interlayer separation the rigidity parameter of the host structure can be determined. This technique has been applied to several systems including Cs_xRb_{1-x}-vermiculite ($p = 7$), Li_xTiS_2 ($p = 5$) and Li_xC_6 ($p = 2$). As shown by the values of p, the layer rigidity of vermiculite is higher than that of TiS_2, which in turn is higher than that of graphite. An assumption of the layer rigidity model is that the guest ions do not deform. For hosts such as the layer perovskites, with layers that are even more rigid than those of 2:1 clays, this condition does not hold and an alternative model was developed to account for the observed variation of the interlayer spacing as a function of composition.[24] The rigidity of the layer is an important factor in determining whether or not staging will occur. Layered compounds with rigid layers such as clays and layered perovskites do not show staging behavior unlike the intercalation compounds of graphite and the layered dichalcogenides.

2 INSULATING HOST LATTICES

The major classes of insulating host lattices are given in Table 1. A very diverse range of compositions and structure types is included and it is beyond the scope of this article to describe all the structures and their associated chemistry in any detail. Some general comments concerning a few typical compounds will be made to illustrate the types of intercalation compounds and reactions that are known.

2.1 Three-dimensional Structures

2.1.1 Zeolites[25,26]

Zeolites and the related aluminophosphates form the most extensive class of insulating three-dimensional solids. Zeolites are three-dimensional framework structures with the general composition $M_{x/n}{}^{n+}[Al_xSi_{1-x}O_2]\cdot nH_2O$. The frameworks consist of AlO_4 and SiO_4 tetrahedra (*see Tetrahedral*) linked by corner-sharing oxygen atoms to build open structures illustrated in Figure 7 for two important materials, zeolite A (LTA) and *Faujasite* (FAU, also called zeolite X or Y depending on the Si:Al ratio). The vertices show the positions of the Si or Al (T) atoms; oxygen atoms are not shown. Frameworks are constructed so that there are no Al–O–Al bonds (Lowenstein's Rule[27]) and consequently Si:Al $\geq$ 1.0. The substitution of Al atoms for some Si atoms introduces a net negative charge on the MO_2 framework, which is compensated

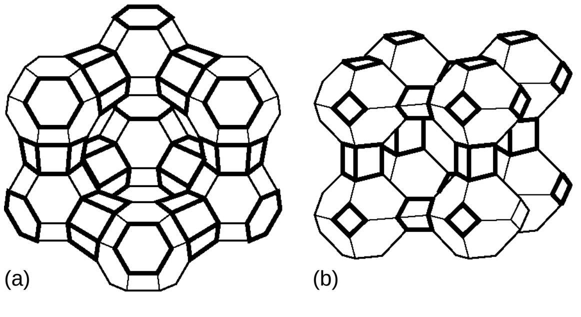

Figure 7 A schematic representation of the frameworks of faujasite (a) and zeolite A (b). The lines connect T atoms (Al or Si) in the framework (the oxygen atoms are omitted for clarity)

by the presence of nonframework cations. Nonframework cations are either solvated or bonded to the framework oxygen atoms when the zeolite is anhydrous. Zeolites are very low density metastable phases. The intracrystalline pore volumes of FAU and zeolite LTA are 0.53 and 0.47 cm^3 liq H_2O/cm^3 crystal, respectively. Consequently, zeolites can adsorb large amounts of gaseous atomic or molecular species. Adsorption isotherms and kinetics and thermodynamics of sorption have been investigated for a wide range of polar and nonpolar molecules. The adsorption of molecules is restricted to those that are smaller than the narrowest free diameter of the channel structure. This diameter is controlled by the topology of the specific zeolite, by the narrowest ring of tetrahedra, and also by the nonframework cations. In LTA, the smallest diameter is defined by eight tetrahedra, whereas FAU contains a 12-ring. The aperture of LTA is large enough to permit access by paraffins, whereas FAU will sorb single ring aromatics. Until the discovery of the $AlPO_4$ family of structures,[28,29] 12-rings were the largest known. Compounds are now known with larger ring sizes, for example, 18 in the aluminum phosphate VPI-5[30] and in the aluminosilicate ECR-34.[31]

The energetics of molecule sorption depend on the guest molecule or atom, the specific cations present in the framework, and the Si:Al ratio. Frameworks with low levels of aluminum substitution and few nonframework cations have relatively low affinities for polar molecules.

In addition to molecule sorption, zeolites also exhibit extensive ion-exchange behavior. Ion mobilities in anhydrous phases are very low, but increase when polar molecules or water are present in the structure. Ion exchange is an important property of zeolites. The ion-exchange capacity is determined by the Si:Al ratio and exchange rates are usually fast. Synthetic zeolite A (Na-LTA) is widely used for water treatment by selective ion exchange of Ca and Mg for Na ions. Ion-exchange reactions also make possible the introduction of a wide range of cations that modify the sorption and catalytic properties. For example, the Na exchanged form of zeolite A (often called zeolite 4A) has an effective pore diameter of 4 Å, whereas in the potassium exchanged form this diameter is reduced to 3 Å. The K-LTA (zeolite 3A) will sorb water but will not sorb larger molecules such as alkanes, and consequently is widely used for drying solvents and gases. Exchange of Na^+ by Ca^{2+} (zeolite 5A) increases the effective pore diameter sufficiently to permit sorption of n-alkanes. Zeolite 5A is used commercially for separating straight chain from branched alkanes.

Zeolites find major applications in catalysis. A form of the zeolite FAU is, for example, an active catalyst component in catalytic cracking of heavy hydrocarbons to produce motor gasoline and diesel. The catalyst activity arises from its Brønsted acidity, which in turn comes from the presence in the structure of protons attached to bridging oxygen atoms. Protons can be introduced by ion exchange of ammonium cations, followed by calcination to remove NH_3 and generate the acid form of the zeolite. The process is more complex in practice because of the instability of the acid form of the zeolite. Some decomposition invariably occurs, resulting in aluminum removal from the framework sites (dealumination).

Zeolite catalysts containing platinum and other precious metals are prepared by ion exchange of species such as $Pt(NH_3)_4{}^{2+}$, for example, the catalyst Pt/zeolite KL that catalyzes hexane aromatization to selectively form benzene.

2.1.2 Other Structures[32–35]

In addition to the zeolites and the $AlPO_4$-*n* structures, many other synthetic materials now are known with pores big enough to permit access of molecules larger than water. These include phosphates of main group elements, such as Ga, In, and Sn, and a number of transition metal phosphates, including systems based upon V, Mo, Fe, Co, and Ni. The nickel phosphate, VSB-5, $Ni_{20}[(OH)_{12}(H_2O)_6][(HPO_4)_8(PO_4)_4]\cdot 12H_2O$, is an example of a framework that is porous, has good thermal stability and catalytic activity for hydrogenation and base-catalyzed reactions.[36] Synthesis of novel microporous materials that have mixed octahedral-tetrahedral frameworks has been extended to include transition metal silicates, particularly those of titanium, vanadium, and copper.[33,34]

In addition to the synthetic materials, several naturally occurring phases formed under hydrothermal conditions are known with very large intracrystalline volumes and pore openings. Examples include cacoxenite, $AlFe_{24}O_6(OH)_{12}(PO_4)_{17}(H_2O)_{17}\cdot 51H_2O$, which has 14.2 Å pores,[37] and wightmanite ('natural drainpipe'), $Mg_5(BO_3)O(OH)_5\cdot nH_2O$, which has elliptical channels with maximum and minimum free diameters of 6.0 and 4.0 Å.[38] Both phases contain octahedrally coordinated cations connected by other units.

The wide range of structural units exhibited by the natural and synthetic phases suggests that many new open frameworks with ion-exchange and sorption properties can be obtained. Exploratory synthesis of novel microporous solids is currently an active research area.

Other three-dimensionally connected oxide structures show ion-exchange chemistry and sorption of small molecules such as water or ammonia. These include oxides with the $A_2B_2O_7$ pyrochlore structure,[39] $KSbO_3$ related phases,[40] and $LiNbO_3$.[41] Compositions with these structure types can be exchanged in mineral acids or in molten salts.

The pyrochlore structure can be described as a three-dimensional connected network of BO_6 octahedra that share all corners (Figure 8). Interpenetrating the B_2O_6 network is a tetrahedral A_2O' lattice oriented so that the A cations are located in rings formed by six oxygen atoms from the B_2O_6 lattice and two O′ oxygen atoms from the A_2O' lattice. The A_2O' lattice is not necessary for the stability of the structure, and defect pyrochlore compositions are known in which all or part of the A_2O' lattice is missing. Examples include $Ca_2Nb_2O_7$, $Tl_2Nb_2O_6$, and $KNbWO_6$.[42,43] The last-named compound is anhydrous when prepared by reaction of

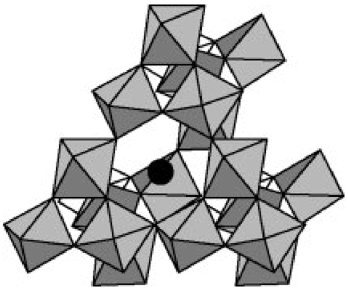

Figure 8 The B_2O_6 framework of pyrochlore represented as BO_6 octahedra sharing corners. The filled circle corresponds to the position of the water molecule in $W_2O_6{\cdot}H_2O$

$KNbO_3$ and WO_3 at high temperature, but readily hydrates in ambient conditions to form $KNbWO_6{\cdot}H_2O$. All three niobates form the corresponding proton exchange forms $H_2Nb_2O_6{\cdot}H_2O$ when ion exchanged in acid with retention of the pyrochlore structure. Recently, the series has been extended to include synthesis of the pyrochlore $W_2O_6{\cdot}H_2O$ by ion exchange of an alkali metal tungstate.[44] The water molecule is only weakly bound in the pyrochlore WO_3 compared with $KNbWO_6$ or zeolitic frameworks where significant interactions with nonframework cations are present.

The $KSbO_3$ structure contains pairs of edge-shared SbO_6 octahedra that share corners to form the cubic network with K^+ ions in three-dimensionally connected channels. The structure was originally investigated as a candidate for fast ion conductivity (*see* ***Ionic Conductors***). The K atoms are readily exchanged in excess molten nitrates to form the phases $MSbO_3$ (M = Li, Na, Rb, Tl, and Ag). The hydronium phase $HSbO_3{\cdot}H_2O$ has been synthesized by acid exchange and found to have lower proton conductivity than the same composition with the pyrochlore structure.[45]

Ion-exchange reactions in aqueous acid of $LiNbO_3$ and $LiTaO_3$ to form $HNbO_3$ and $HTaO_3$ have also been reported. A transformation from the hexagonal close-packed oxygen lattice to the perovskite structure occurs during reaction. The transformation appears surprising at first glance, but can occur by deformation of the lattice without bond breaking. The reverse transformation is observed in lithium intercalation of ReO_3 (see Section 3.6.1). Lithium niobate has important nonlinear optical properties, and ion-exchange reactions have been used to modify the surface of crystals for optical devices.

2.2 Two-dimensional Structures

The sheet silicates or *Clay Minerals* constitute the largest group of the two-dimensional structures in Table 1.[25,46,47] All the two-dimensional materials show ion exchange and sorption of neutral molecules like the three-dimensional structures, but with the added feature that the interlayer separation can adjust freely to accommodate large guest species. Shape selective sorption or molecular sieving is not generally observed except in a special class of materials usually referred to as pillared layered compounds.

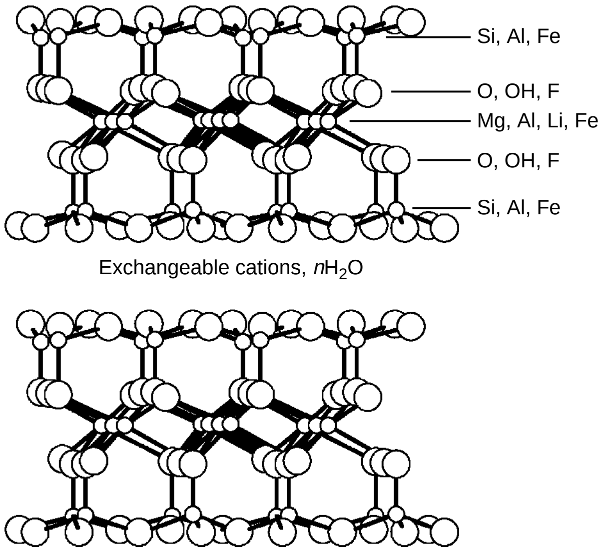

Figure 9 Schematic diagram of the structure of a three-layer silicate

2.2.1 *Clay Minerals*

Clay minerals have structures comprising complex layers made by condensing two types of sublayers. In one type, silicon is tetrahedrally coordinated, $Si_2O_3(OH)_2$, and in the other aluminum is octahedral, $Al(OH)_6$ (see Figure 9). The sublayers are connected to produce two different structure types that are illustrated by kaolinite, which has the ideal composition $Al_2Si_2O_5(OH)_4$ and contains one octahedral and one tetrahedral layer (1:1), and pyrophyllite, $Al_2(Si_4O_{10})(OH)_2$, which has one octahedral and two tetrahedral layers (2:1). Compounds are also known in which three Mg^{2+} cations replace two Al^{3+} cations to give serpentine, $Mg_3Si_2O_5(OH)_4$, or talc, $Mg_3(Si_4O_{10})(OH)_2$.

The compositions of the layers in the ideal end members have no charge and are not reducible. Consequently their intercalation chemistry is very restricted. *Hydrogen Bonding* interactions exist between the layers in kaolinite, and some intercalation reactions occur with guest molecules that can themselves hydrogen bond. For example, kaolinite intercalation compounds are known with urea, formamide, acetamide, and hydrazine. The hydrogen bonding network in the compound of formamide with dickite (a crystallographic modification of kaolinite with the same composition) has been determined by single-crystal *X-Ray Diffraction*. The compound is an unusual example of intercalation of a neutral guest between neutral layers and where the product is sufficiently crystalline for a complete structure determination.

As in zeolites, negative charges on the layers can be introduced by chemical substitution. Substitutions can be made in either the tetrahedral or the octahedral positions

with ions of comparable radii. Thus aluminum may replace silicon in the tetrahedral layers and Li^+ can replace Mg^{2+} or Fe^{2+}/Fe^{3+} can replace Al^{3+} in the octahedral sites. The flexibility that results by substitution with many different cations leads to an extraordinary diversity of phases, beyond the scope of this section.[25,46,47] The micas, with very high layer charges (24 Å^2 per e^-), represent the opposite extreme of behavior to that shown by the neutral layers. Muscovite, $KAl_2(Si_3AlO_{10})(OH)_2$, is the analog of pyrophyllite. One tetrahedral layer silicon atom is substituted by aluminum and K^+ interlayer cations balance the layer charge. Similarly phlogopite, $KMg_3(AlSi_3O_{10})(OH)_2$, is the mica analog of talc. Solvent molecules cannot usually be intercalated into micas because of the strong electrostatic forces between the layers.

In clay chemistry, the layer charge density is often expressed in terms of the cation exchange capacity in milliequivalents per gram of solid (e.g. muscovite 252 meq g^{-1} and phlogopite 240 meq g^{-1}). Pyrophyllite and talc ideally have zero ion-exchange capacities. The interesting intercalation chemistry in the clays occurs in the intermediate range of layer charges (60–165 meq g^{-1}) for compounds described as smectites (60–100 meq g^{-1}) or vermiculites (100–165 meq g^{-1}). Idealized compositions of some examples are given below:

montmorillonite	$Na_x(Al_{2-x}Mg_x)(Si_4O_{10})(OH)_2{\cdot}mH_2O$
Beidellite	$Na_x(Al_2)(Al_xSi_{4-x}O_{10})(OH)_2{\cdot}mH_2O$
hectorite	$Na_x(Mg_{3-x}Li_x)(Si_4O_{10})(OH)_2{\cdot}mH_2O$
vermiculite	$(Na, Ca)Mg_3(Al_xSi_{4-x}O_{10})(OH)_2{\cdot}mH_2O$

Interlayer water molecules that solvate the interlayer alkali or alkaline earth metal are present in all compositions.

The smectites and vermiculites show reversible intercalation behavior with a wide range of neutral molecules. Two features are worth noting. In molecule sorption by zeolites, minimal changes in the framework structure occur. In layered systems, however, energy has to be expended to separate the layers on intercalation, with the consequence that reactions with vapor-phase guests generally have threshold pressures for intercalation and hysteresis is observed on deintercalation. The hysteresis loops are a measure of the energy needed to expand and contract the interlayer spacing. Secondly, when in contact with an electrolyte solution the interlayer separation depends on the solvent activity. As the electrolyte concentration is lowered, the layer separation is increased as increasing numbers of solvent molecules are intercalated. At lower layer charges, this process can ultimately lead to complete delamination (exfoliation) and the formation of colloidal solutions or gels at higher solid concentrations.

Three areas of the intercalation chemistry of clays have received very detailed study and will be described further: (a) intercalation of organic cations and neutral organic molecules; (b) pillaring reactions; and (c) clay–polymer nanocomposites.

Organic Cations. Intercalation reactions of long chain alkylamines and alkanols have been studied in many different classes of insulating host lattices.[48,49] Ordered bilayer structures are formed because of the high van der Waals interaction energies (*see van der Waals Forces*) between the alkyl chains (4.2 kJ per CH_2). The compounds provide model systems for study of structure and phase transitions in ordered bilayers related to lipid layers in biological membranes and ordered monomolecular films on surfaces. In sheet silicates, particularly uniform structures are obtained when ion exchange of the inorganic cations by alkylammonium cations is followed by intercalation of neutral alkanol molecules. When the alkyl chains in the alkylammonium cations and in the alkanol are about the same length, two alkyl groups per Si_4O_{10} unit are intercalated. The stoichiometry corresponds to one polar head group for each hexagonal hole in the layer surface. The ratio of alkylamine to alkanol varies with the layer charge and the packing density is in the range 23–23.5 Å^2 per chain, somewhat less than the value of 19 Å^2 per chain observed in paraffins or polyethylene. At ambient temperature the alkyl chains are perpendicular to the layers and have all trans conformations (see Figure 10). However, as the temperature is raised, decreased interlayer separations are observed corresponding to the conformational changes from trans to gauche. The introduction of regular sequences of trans and gauche bonds produces kinks in the chains, which reduces the interlayer separation in steps of 1.27 Å. The regular decrease in the interlayer spacing implies a concerted rearrangement of the chains in order to fit adjacent chains together. Such packing results in the formation of kink blocks (Figure 10). At higher temperatures, loss of the intercalated alkanol molecules results in a lower packing density of the remaining alkyl chains and a large drop in the interlayer spacing is observed. The changes in interlayer spacing are harder to interpret in this region, but generally involve the formation of gauche blocks.

The formation of different types of ordered arrangements generally correlates with the chain packing density. At high chain packing densities (closest packing $\leq$20 Å^2) the energy required to nucleate a kink is $\geq$30 kJ mol^{-1}, but for 24 Å^2 it is only about 3 kJ mol^{-1}. Consequently, regular kink block structures are favored in the range of 22–25 Å^2 and gauche blocks at packing densities of 33–40 Å^2 per chain. Similar

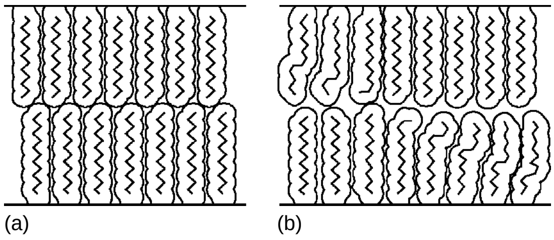

Figure 10 Schematic diagram of organic bilayer structures in layered compounds; all trans conformation (a), kink blocks (b)

results are observed in alkyl chain structures in other insulating layered systems including titanates, niobates, and molybdates.

Pillaring Reactions. In zeolite and other three-dimensional structures, the frameworks remain porous in the absence of guest molecules. In smectites and vermiculites, on the other hand, the layer separation is reduced as intercalated solvent molecules are removed and the materials have no permanent porosity. The introduction of large cations by ion exchange can, however, provide permanent intracrystalline porosity. Organic cations, for example, mono-, di-, tri-, and tetra-alkylammonium cations, were shown to introduce porosity characterized by no additional increase in separation of the layers on sorption of small molecules. Larger molecules produce an increase in interlayer separation and characteristic hysteresis in the sorption isotherms. Dications such as en^{2+} are even more effective, since only half as many are required to neutralize the layer charge. Significant amounts of guest molecules can be intercalated and selective molecule separations characteristic of materials with permanent and well-defined porosity are observed. An interesting example is the separation of benzene and toluene by ethylenediammonium fluorohectorite.[50]

The organic pillared layered compounds are of considerable interest for intercalation chemistry at lower temperatures, but are not stable at the higher temperatures where clays have been used as catalysts. Inorganic pillared clays were studied by Vaughan, Lussier, and Magee[51] with a view to extending the temperature stability range. A large inorganic cation is introduced by ion exchange into the interlamellar space to separate the layers. The inorganic pillars are then fixed in place by calcination to form a stable pillared clay with permanent microporosity.[52] The initial work and many subsequent studies have used the complex aluminum polyoxocations present either in commercially available chlorhydrol solutions or solutions of aluminum chloride partially hydrolyzed with sodium hydroxide. Both reagents have been shown by nuclear magnetic resonance (NMR) to contain the polyoxocation $[Al_{13}O_4(OH)_{24}\cdot 12H_2O]^{7+}$, first identified crystallographically by Johansson.[53] Ion exchange of smectite layers with such solutions produces an interlayer expansion of about 9 Å, consistent with the incorporation of the Al_{13} cation. The amount incorporated depends on the layer charge, but is somewhat variable since the polyoxocation charge may change by further hydrolysis reactions. On heating, the Al_{13} cationic species dehydrates and becomes permanently attached to the silicate layers through the formation of Si–O–Al bonds, producing a permanent microporous solid. The pore size distribution is not as sharp as that observed in crystalline zeolites, but pillared clays do show characteristic molecular sieving properties. Similar pillaring reactions with a variety of other inorganic cations including zirconium, bismuth, silicon, and niobium halide clusters have also been reported.[54]

Clay – Polymer Nanocomposites. Polymer intercalation into layered compounds has become an important route to the synthesis of organic-inorganic hybrid materials and composites. A variety of layered systems have been investigated but much of the work has focused on the sheet silicates, in part because of the discovery of exceptional mechanical properties of clay nanocomposites formed between organocation exchanged montmorillonites and nylon-6 by Toyota researchers.[55–57] In general, these polymer-clay composites can be described as either intercalated or exfoliated. In the former, polymer chains are intercalated into the host lattice to give a well ordered multilayer structure. In contrast, in an exfoliated composite, individual 10 Å thick clay layers are dispersed in a continuous polymer matrix and separated at average distances that depend on the volume fraction of clay. The general synthesis approach to these systems involves preintercalation of a cationic surfactant such as a long chain primary alkylammonium cation, as discussed in Section Organic Cations, in order to make the silicate sufficiently organophilic to intercalate either monomers or polymers in a second step. A wide range of polymer systems including, for example, poly(styrene), poly(isoprene), poly(methyl methacrylate), poly (L-lactic acid), and poly(ethylene oxide) have been studied.

Intercalation of poly(ethylene oxide) into a lithium-ion exchanged clay gives an interesting class of layered silicate nanocomposites that are lithium-ion electrolytes.[58,59] Compounds have been prepared by intercalation from methanol/water solutions and by melt intercalation. Melt intercalation typically gives samples with higher polymer contents than the solution method and with higher lithium-ion conductivity though the conductivity is probably still too low for practical applications.

2.2.2 *Layered Double Hydroxides*[60,61]

The layered double hydroxides are derived by partial substitution of a trivalent cation for a divalent cation in a hydroxide with the $Mg(OH)_2$ brucite structure. The natural mineral hydrotalcite, with the approximate formula $Mg_6Al_2(OH)_{16}CO_3\cdot 4H_2O$, is the best known example. Substitution results in a general composition $M_{1-x}M'_x(OH)_2\cdot A_{x/n}\cdot mH_2O$, where the positive charge introduced into the hydroxide layers is compensated by a solvated interlayer anion (A). Compounds with a wide range of cations, for example, $M^{2+} = $ Mg, Zn, Fe, or Co and $M'^{3+} = $ Cr, Al, Mn, or Fe, can be synthesized by direct precipitation from aqueous solutions with hydroxide or carbonate ions. The precipitates have broad X-ray diffraction patterns, indicating small particles. Crystallinity can be improved by mild hydrothermal treatment. The amount of trivalent cation substituted in the $M(OH)_2$ layer typically corresponds to either $x = 0.25$ or $x = 0.33$. In the Mg–Al and Ni–Al systems, some evidence exists for a more continuous range of composition. One interesting synthesis variant is found for

$Zn_{2/3}Cr_{1/3}(OH)_2 \cdot A_{1/3} \cdot mH_2O$. This phase is formed directly by reaction of 60 °C of ZnO with a solution of $CrCl_3$ at pH = 4.[62] The specific interlayer anion is determined by the synthesis method, but can easily be exchanged after the compound is formed. Ion-exchange isotherms have been determined for several combinations of simple ions (e.g. OH^-–NO_3^-, NO_3^-–X^- (X = F, Cl, Br, I), NO_3^-–SO_4^{2-}, NO_3^-–CO_3^{2-}). Ion selectivities are generally found to be in the order $OH^- > F^- > Cl^- > Br^- > NO_3^- > I^-$.[63]

The layered double hydroxides will also intercalate organic anions such as *n*-alkylsulfates to give phases with large basal spacings that undergo further swelling by intercalation of *n*-alkanols and *n*-alkylamines analogous to the behavior of the layered silicates.[62] Exchange of interlayer ions by aliphatic carboxylate anions with different chain lengths gives intercalation compounds in which the interlayer separation increases regularly with the increase in the number of carbon atoms. In situ X-ray diffraction has been used to study dicarboxylate intercalation reactions in $[LiAl_2(OH)_6]Cl \cdot H_2O$.[61] The reaction proceeds via the formation of a second stage intermediate, which then transforms into a single-phase first stage compound. Intercalation of ammonia in TaS_2 shows similar behavior (see Section 1.1). In situ X-ray diffraction has also been used to study the competition between exchange reactions of terephthalate and phthalate in $[Ca_2Al(OH)_6]NO_3 \cdot 2H_2O$. Exchange of both anions occurs initially but with time the phthalate phase is replaced by the more stable terephthalate intercalation compound.

The layered double hydroxides have been of interest as anion exchangers, basic catalysts, and catalyst precursors. Pillared derivatives of the type discussed earlier for the clays have been synthesized by ion exchange with polyoxometallate anions but have lower thermal stability.[52] Several authors have reported synthesis of layered double hydroxides pillared with the $V_{10}O_{28}^{6-}$ ion by direct ion exchange or by techniques that involve preswelling the layer structure with an organic anion. For example, the terephthalate anion was used in the synthesis of $V_{10}O_{28}^{6-}$ and $Mo_7O_{24}^{6-}$ intercalated phases.

In other recent developments, the intercalation of biologically active materials in layered double hydroxides has been investigated. For example, large biological molecules such as DNA, ATP, and nucleosides were intercalated into $[Mg_2Al(OH)_6]NO_3 \cdot 1.2H_2O$ and shown to remain structurally intact. Similarly, anionic drug molecules have been intercalated into a variety of layered double hydroxides, in order to determine the possible use of these intercalation compounds for controlled drug release.

Somewhat surprisingly, intercalation reactions of certain layered double hydroxides show shape selectivity. For example, a strong preference for 1,5-naphthalenedisulfonate over 2,6-naphthalenedisulfonate is found on intercalation of an equimolar mixture into $[LiAl_2(OH)_6]Cl \cdot H_2O$ at 100 °C. Perhaps even more remarkably, the rate of intercalation into $[Mg_{0.7}Al_{0.3}(OH)_2](Cl)_{0.3}nH_2O$ of L-histidine was shown to be larger than that of D-histidine and that stereoselective intercalation of the L-histidine was achieved by an optically inactive host lattice.[64]

2.2.3 *Tetravalent Acid Phosphates*[52,65]

Because of their selectivity, stability in acid solutions, thermal stability, and resistance to radiation, the acid phosphates, $M^{IV}(HXO_4)_2 \cdot nH_2O$ (X = P, As), have been investigated as ion exchangers for applications where organic ion-exchange resins cannot be used. The layered structures exist in two modifications, α and γ. The structure of α-$Zr(HPO_4)_2 \cdot H_2O$ (α-ZrP), was first determined by Clearfield and Smith (Figure 11).[66] Each layer contains zirconium atoms octahedrally coordinated by oxygen atoms and bridged by the phosphate groups. Three oxygen atoms of each phosphate group are shared by three zirconium atoms. The fourth oxygen atom is directed into the interlayer space and carries a proton. Adjacent layers are displaced relative to each other to form a cavity between the layers that contains the H_2O molecule. Zirconium hydrogen phosphate can be prepared by adding a soluble zirconium salt to concentrated phosphoric acid, and refluxing the mixture before separating the precipitate. Larger crystals can be prepared by slow crystallization from fluoride containing solutions. Other tetravalent metal cations also form the α structure. Examples include Ti, Hf, Ge, Sn, and Pb phosphates and Ti, Zr, and Sn arsenates.

The intercalation chemistry of α-$Zr(HPO_4)_2 \cdot H_2O$ includes ion-exchange reactions, acid–base reactions, and layer derivatization. The protons of the P–OH groups can be partially or completely replaced with counterions by exchange reactions. The exchange reaction equilibrium greatly favors the proton form of the exchanger, so that exchange requires the addition of base. Titration curves for alkali metal hydrogen ion exchange are shown in Figure 12. For exchange with sodium ions, the data show that the exchange proceeds in two steps as OH^- ions are added at constant $[Na^+]$, as in equation (5).

$$\underset{(7.65\text{Å})}{Zr(HPO_4)_2 \cdot H_2O} \longrightarrow \underset{(11.8\text{Å})}{ZrNaH(PO_4)_2 \cdot 5H_2O} \longrightarrow \underset{(9.8\text{Å})}{Zr(NaPO_4)_2 \cdot 3H_2O} \quad (5)$$

The interlayer separation directly depends on the number of water molecules present between the layers. In the anhydrous phases $ZrM(PO_4)_2$ (M = Mg, Ca, Sr, or Ba) and the half exchanged phases $ZrHM(PO_4)_2$ (M = Li, Na, K, Rb, or Cs) the interlayer separation is independent of cation size, indicating that the interlayer cavity, which contains one water molecule in the unexchanged compound, is sufficiently large to accommodate a single cation. In contrast, in the fully exchanged alkali metal ion compositions, the interlayer separation increases with increasing cation radius.

The acid phosphates, as the name suggests, also show acid–base intercalation reactions. For example, ammonia is intercalated from very dilute aqueous solutions to form

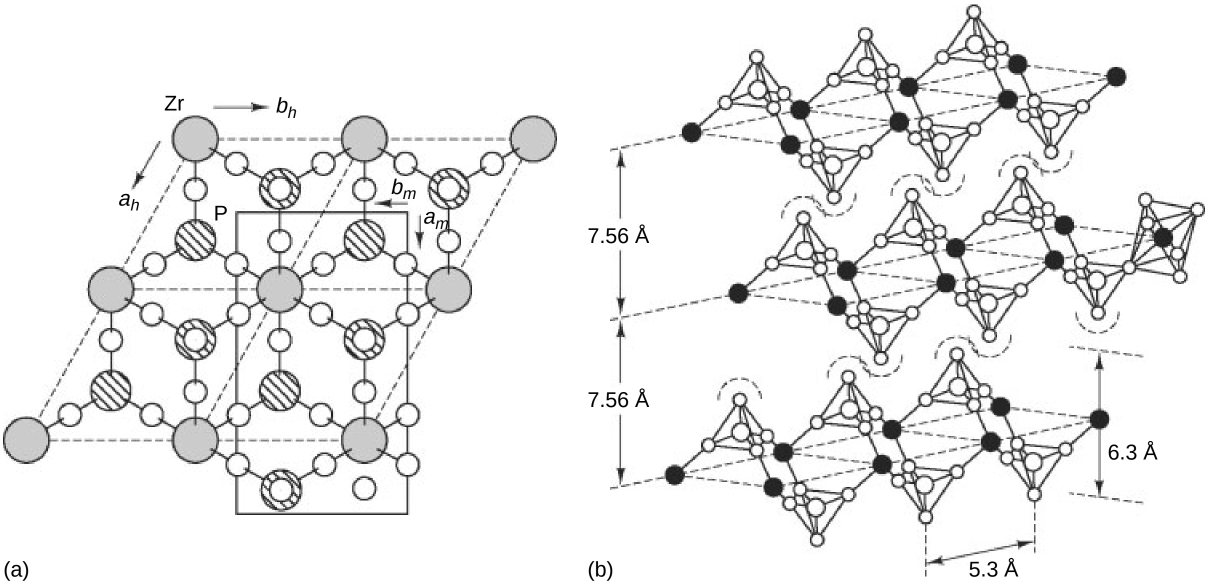

Figure 11 The structure of α-$Zr(HPO_4)_2{\cdot}H_2O$ looking down on the layers (a); edge on (b). (Reprinted with permission from Ref. 65. © 1969 American Chemical Society)

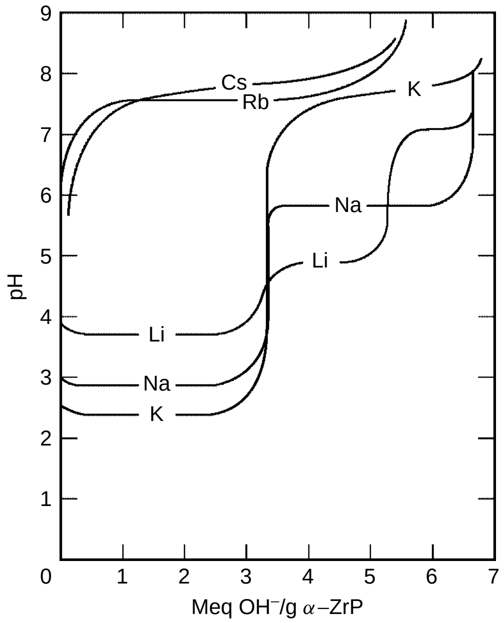

Figure 12 Ion-exchange isotherms for alkali cation exchange with $Zr(HPO_4)_2{\cdot}H_2O$. (Reprinted with permission from Ref. 66. © 1981 American Chemical Society)

$Zr(PO_4NH_4)_2{\cdot}H_2O$. The same compound is formed by ammonium ion exchange with α-$Zr(PO_4)_2K_2{\cdot}H_2O$. Heat treatment of the ammonium exchanged form at 300 °C gives back the hydrogen phosphate. Primary alkylamines react very readily to form bilayer intercalation compounds analogous to those formed by clays (the layer area per proton is 24 Å^2). The chain packing density is not close packed, but falls in the range where regular kink blocks are observed. Diamines and secondary and tertiary n-alkylamines have also been studied.

The mechanism of amine intercalation has been investigated by measuring the change in pH as amine is added to a suspension of α-ZrP. Several intermediate compositions are observed en route to the fully exchanged phase. When n-propylamine is used in this reaction, at a point when about one half of the protons have been titrated, the α-ZrP layers spontaneously exfoliate. Presumably the hydrogen bonding interlayer interactions are reduced and not compensated by interchain van der Waals forces. Addition of more propylamine causes the layers to reflocculate.

In addition to the α form of $Zr(HPO_4)_2{\cdot}H_2O$, a second modification, γ-$Zr(HPO_4)_2{\cdot}2H_2O$, is also known. The γ phase contains an additional water molecule and has a correspondingly larger interlayer separation (9.5 Å vs. 7.65 Å). Similar ion-exchange and intercalation chemistry of amines and polar molecules is observed, though the layer charge density is apparently 30% higher than that in the α phase. The formation of organic derivatives of ZrP using the γ form was investigated by Yamanaka and coworkers.[67] They showed that reactions with ethylene and propylene oxide resulted in simultaneous intercalation and reaction with P–OH groups to form P–O–C ester linkages on the internal surfaces of the layers. Compounds are formed with compositions illustrated by γ-$Zr(HOCH_2CH_2OPO_3)_2{\cdot}H_2O$. A large number of organic derivatives with the general composition $Zr(RPO_3)_2$ can be synthesized by direct reaction of a zirconium source with an organophosphonic acid. The organic R group can be an alkyl or an aryl group and may itself be functionalized with, for example, SO_3H, CO_2H, or NMe_3Cl. Reaction chemistry of

the organic groups attached to the layer has been studied. Compounds analogous to amine intercalation compounds are obtained by the reaction shown in equation (6), where X = NH or O, and R = n-alkyl; the alkyl group is attached to the layers through a covalent bond.[68]

$$Zr(O_3PCH_2CH_2COCl)_2 + 2HXR \longrightarrow Zr(O_3PCH_2CH_2COXR)_2 + 2HCl \qquad (6)$$

The development of organic derivatives of zirconium phosphate has led to wide interest in other examples of layered metal organophosphonates. For example, VO^{2+}, M^{2+}, and M^{3+} phases have been synthesized with a variety of different layer connectivities and interlayer chemistry.[69]

2.2.4 *Intercalation and delamination of layered oxides*

Many high-temperature ternary oxides are known that have structures made up of layers of transition metal–oxygen atom octahedra separated by large alkali metal cations or layers of composition $Bi_2O_2^{2+}$. These layered oxides often can undergo ion-exchange reactions in molten salts and sometimes in aqueous solutions. The relationship between the ionic conductivity, structure, and ion-exchange properties has been discussed.[70] Of particular interest are the ion-exchange reactions in aqueous acids that generate the protonic or hydronium forms of the oxides. The proton exchanged forms are good starting materials both for the synthesis of other cationic exchange forms and for the synthesis of novel oxides by dehydration–dehydroxylation. The proton exchange forms can be intercalated by organic bases and under appropriate conditions complete exfoliation of the layers can be induced.

Alkali Metal Titanates and Niobates.[71,72] The structures of the titanates and titanium niobates with the general formula $A_mM_nO_{2n+1}$, where A is the interlayer cation and M is the transition metal atom, contain double chains of edge-shared octahedra, which are joined by corner sharing to form puckered layers; n describes the number of edge-sharing octahedra in each chain. The end member of this series has the layer composition MO_3 and the structure is that of MoO_3. The structures of some examples of the alkali metal-containing phases synthesized at high temperature are shown in Figure 13. The proton exchanged forms of the oxides dehydroxylate on heating above 300–350 °C to form metastable oxides with structures that bear a strong relationship to the original layers. For example, $HTiNbO_5$ dehydroxylates to $Ti_2Nb_2O_9$, a tunnel structure formed by crosslinking the starting layers. Similarly on dehydroxylation, $H_2Ti_4O_9$ first forms $H_2Ti_6O_{17}$ and then, at higher temperatures, TiO_2(B). The second transformation is not topotactic because TiO_2(B) is also obtained on heating $H_2Ti_3O_7$ and $H_2Ti_5O_{11}$.

The proton exchanged form of the titanates and titanium niobates are Brønsted acids and intercalate bases in the same way as described above for zirconium hydrogen phosphate. All compounds intercalate strong bases such as primary amines. The titanium niobates, however, are somewhat stronger acids than the pure titanates. Thus $HTiNbO_5$ will intercalate bases with pK_a values greater than 6, whereas pK_a values greater than 9 are required for bases to intercalate $H_2Ti_4O_9$. It is interesting to note that $HTiNbO_5$, like $Zr(HPO_4)\cdot H_2O$, exfoliates when treated with short chain primary alkylamines.

Compounds Containing Perovskite Layers. A second class of layered oxides have structures related to the three-dimensional perovskite lattice and include the Aurivillius phases,[73] the Ruddlesden–Popper phases[74] and the Dion–Jacobson phases.[75,76] The general composition can be written $M_a[A_{n-1}B_nO_{3n+1}]$ where A is an alkaline or rare earth metal, and B is niobium or titanium. In the Aurivillius phases $M_a = Bi_2O_2^{2+}$, whereas M is an alkali metal cation in the ion-exchangeable Ruddlesden–Popper ($a = 2$) and Dion–Jacobson ($a = 1$) phases. The relationships between the three structure types is shown in Figure 14. The intercalation chemistry of the Dion – Jacobson phases was the first to be studied.

The first examples with $n = 3$ were synthesized by Dion *et al.*[75] and later extended to compounds with $n = 7$.[75,76] The ion-exchange properties and intercalation chemistry are generally similar to the titanium niobates (above) and have been discussed in detail by Jacobson.[77] Ion exchange is facile in molten alkali metal nitrates and the proton containing phases are formed by reaction in mineral acids. The proton exchanged phases are much stronger Brønsted acids and will intercalate bases as weak as pyridine. One of the most unusual features of the layered perovskites is that the layers are extremely thick and are presumably very rigid. Layer thicknesses range from 10 to 30 Å for compounds with $n = 1$ to 7, though this apparently has little effect on the general features of the intercalation chemistry.

The earlier studies of the Dion–Jacobson phases have been extended to the other layered perovskites.[78] Specifically, Ruddlesden-Popper phases with interlayer alkali metal cations have been synthesized, for example, $K_2La_2Ti_3O_{10}$, $K_2CaNaTa_3O_{10}$ ($n = 3$) and $K_2SrTa_2O_7$ ($n = 2$). The interlayer alkali metal cations in these compounds can be exchanged for protons. The protonated compounds are particularly interesting because they undergo topochemical dehydration to form three-dimensional perovskites. Thus on heating $H_2La_2Ti_3O_{10}$ at 350 and 500 °C, water is lost and the structure collapses to form the three-dimensional perovskite $La_2Ti_3O_9$. The perovskite has 1/3 of the A sites vacant and preserves the original A site distribution so that the A site cations (La) and vacancies (V) are ordered in the sequence La-La-V. This reaction does not occur for the Dion-Jacobson phases that contain only half of the number of interlayer protons. Aurivillius phases can also be converted to the proton form of the corresponding Ruddlesden–Popper phase by selectively dissolving the interlayer bismuth oxide in acid.

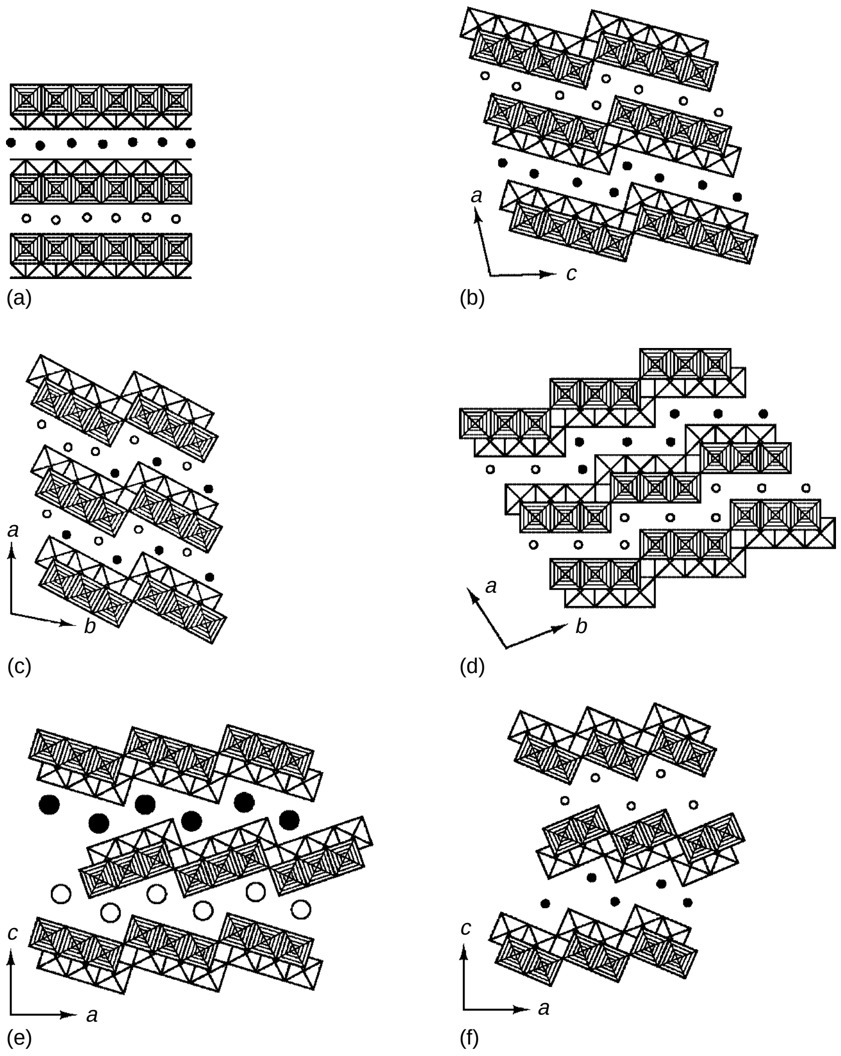

Figure 13 Schematic representations of the layer structures of (a) $A_xTi_{2-x}M_xO_4$, (b) $Tl_2Ti_4O_9$, (c) $Na_2Ti_3O_7$, (d) $K_3Ti_5NbO_{14}$, (e) $CsTi_2NbO_7$, (f) $KTiNbO_5$[72]

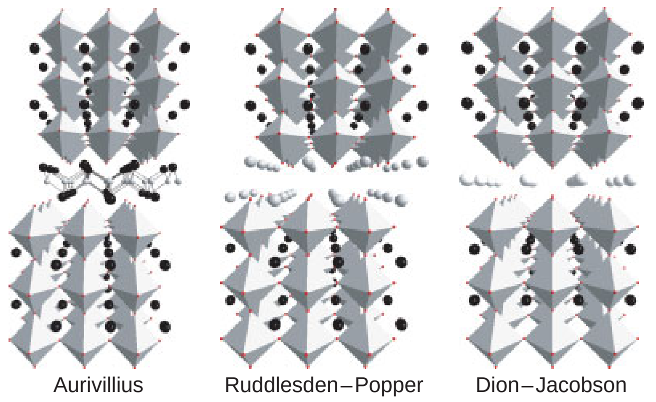

Figure 14 The triple layer structures of the Aurivilius, Ruddlesden–Popper, and Dion–Jacobson perovskite phases

For example, the Aurivillius phase $Bi_2O_2[SrNaNb_3O_{10}]$ reacts with HCl with removal of the interlayer $Bi_2O_2^{2+}$ forming the Ruddlesden–Popper phase $H_2SrNaNb_3O_{10}$. The protonated Ruddlesden–Popper compounds in general do not intercalate organic bases though some exceptions have been found. Specifically, $H_2SrNaNb_3O_{10}$ reacts with n-butylamine and n-octylamine and some tantalates such as $H_2CaNaTa_3O_{10}$ and $H_2Ca_2Ta_2TiO_{10}$ also intercalate alkylamines. A new series of layered oxyhalide perovskites were prepared by reaction of the Dion–Jacobson phases ($ALaNb_2O_7$, A = Li, Na, K, or Rb) with anhydrous metal halides under mild reaction conditions (<400 °C).[79] The compounds have the composition $(MCl)LaNb_2O_7$ (M = Cr, Mn, Fe, Co, Cu). The reaction is topochemical and results in the formation of a two dimensional metal halide sheet in the perovskite interlayer in which MO_2X_4 octahedra corner-share with NbO_6 octahedra from the perovskite slab and edge-share with each other

along all four equatorial edges. The interrelation of all of the ion exchange, amine intercalation and dehydration reactions of this family of oxides has been reviewed by Schaak and Mallouk.[80]

Exfoliation of the perovskite related layer structures is more difficult than for the clays and acid phosphates discussed earlier but can be achieved by intercalation of large bulky amines. Treacy *et al.* reported that the layered perovskite $HCa_2Nb_3O_{10}$ could be made to form unilamellar sheets by first intercalation of an amine polyether.[81,82] Spontaneous exfoliation of the layers occurs on subsequent exposure of the intercalated phase to a suitable solvent. Exfoliation techniques have been extended to other systems using tetra(n-butyl)-ammonium hydroxide (TBAOH) by Mallouk and others.[78] A number of examples of the protonated layered perovskite phases that intercalate bases have been exfoliated. The Dion–Jacobson phases typically exfoliate to form plates but others including Ruddlesden–Popper tantalates curl to form tubular ‘scrolls’. Part of the interest in these single layer dispersions arises from their use as building blocks in the layer-by-layer self-assembly of thin films. Single layers derived from exfoliated perovskites can be attached to or alternately stacked with polycationic layers to produce thin films. Tiled monolayer structures and multilayer perovskite heterostructures result from the self-assembly.

3 CONDUCTING HOST LATTICES

Conducting host lattices have been intensively investigated since graphite intercalation attracted the attention of physicists and chemists in the 1950s and dichalcogenide intercalation reactions were discovered in 1969. Intercalation chemistry in layered structures has received the most attention and will be described first. A summary of the analogous chemistry for the smaller number of one and three-dimensional compounds will be given for comparison.

3.1 Graphite Intercalation

Graphite is the simplest of the two-dimensional structures that show intercalation chemistry. The formation of the earliest reported intercalation compound, graphite sulfate, was described by Schauffaütl in 1841[83] as resulting from the reaction of single-crystal graphite flakes in H_2SO_4/HNO_3 mixtures. Since then detailed studies have been made both of the intercalation chemistry of a variety of guest species and of the physics (structure, dynamics, transport, and electronic properties) of graphite intercalation compounds. The physics and chemistry of graphite intercalation are described in several review articles and in a comprehensive survey edited by Zabel and Solin.[84] The focus of this section is on the chemistry of graphite intercalation.

Graphite intercalation compounds have received widespread interest for two main reasons. First, intercalation results in compounds that have metallic conductivity. The electrical conductivity can approach that of copper metal and is highly anisotropic: ratios of the conductivity in-plane to that along the c axis can be six orders of magnitude at room temperature. Secondly, graphite is a unique host lattice in that intercalation compounds can be formed with either electron donors or electron acceptors as guest species.

3.1.1 Structure

Graphite is structurally the simplest host lattice (Figure 15). The stable hexagonal form is obtained by stacking planar sheets of carbon atoms in an ABAB arrangement. Adjacent sheets are separated by a van der Waals gap of 3.35 Å. Each individual sheet is a regular hexagonal network of sp^2 hybridized carbon atoms. The p_z orbitals perpendicular to the sheets overlap to form a filled *Valence Band* (bonding π orbitals) and an empty *Conduction Band* (*Antibonding*) π orbitals, (*see* π*-Bond*). The C–C bond length is 1.42 Å, longer than in benzene (1.39 Å) because each p_z orbital interacts with three rather than two neighbors. For an isolated graphite sheet the *Band Gap* would be exactly zero, but in the three-dimensional structure some interaction between adjacent sheets results in a small overlap (0.04 eV) of the valence and conduction bands. A small number of electrons in the conduction band and holes in the valence band result and the pristine material has significant conductivity.

Intercalation studies of graphite have used a variety of different types of material with different degrees of perfection.

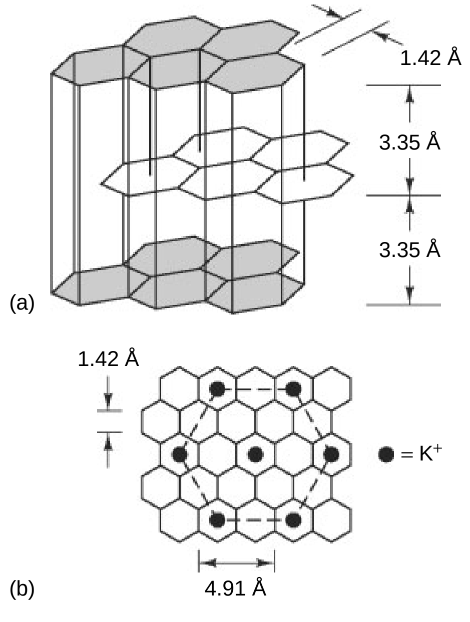

Figure 15 Layer structure of graphite (a) and the arrangement of alkali metal atoms in MC_8 (b)

Some studies have used single crystals obtained naturally from coal or lead mines or synthetic (Kish) graphite. Most work has, however, been carried out using highly oriented pyrolytic graphite, which is a textured polycrystalline material. The *ab* orientation of the graphite layers is random, but the *c* axis is well defined. Intercalation reactions of graphite commonly lead to staging (see Section 1.1). Adjacent carbon layers present in higher stages are stacked in the same way as in graphite but graphite layers containing a guest species are usually eclipsed. A shorthand description of a stage 2 intercalation compound where the guest species is represented by/is then given by – A/AB/BC/CA–. This simple description of staging was modified by Daumas and Hérold,[16] who proposed the isolated island (domain) model to account for transformations between odd and even numbered stages (see Figure 6). Direct experimental evidence for the existence of islands has been obtained by high-resolution *Transmission Electron Microscopy* studies of $FeCl_3$ intercalation compounds.

Within a domain, several different arrangements of the guest species have been identified. The guest species may form an ordered structure that is commensurate with the graphite lattice. This may result in an ideal composition in which the carbon:guest ratio is a rational fraction, such as LiC_6 or KC_8. Incommensurate ordered arrangements with more complex compositions, where the lattice formed by the guest species and the graphite lattice are not simply related, are also known. At higher temperatures, the intercalated layers have two-dimensional liquid structures.

3.1.2 Intercalation with Graphite Reduction

Donor intercalation compounds, where charge is transferred from the guest to the graphite layers, include the alkali metal, alkaline earth metal, and rare earth metal phases. The compounds with K, Rb, or Cs are the easiest to prepare and can be obtained by reaction with the elements in sealed tubes at 200 °C. Formation of compounds with Li, Na, the alkaline earth metals (Ca, Sr, Ba), and rare earth metals (Sm, Eu, Yb, Tm) requires higher reaction temperatures (500–600 °C) and is complicated by side reactions that lead to the formation of carbides. The first stage compounds of K, Rb, and Cs have compositions MC_8 and higher stages MC_{12n}, where n is the stage number. The other metals form first stage compounds MC_6, but higher stage compounds are not well defined. Figure 15 shows the in-plane ordered arrangement of alkali metal atoms observed for KC_8 and RbC_8 relative to the graphite lattice. Table 3 shows structural and conductivity data for several different alkali metal phases.

Table 3 Graphite–alkali metal intercalation compounds

Compound	Stage	Color	Interlayer separation (Å)	σ ($S\,cm^{-1} \times 10^4$)	r
C_8K	1	Gold	5.41	11, 9	2.06
$C_{24}K$	2	Blue	8.77	12	2.07
$C_{36}K$	3	Blue	12.15	17	2.07
C_8Rb	1	Gold	5.65	8	2.30
$C_{24}Rb$	2	Blue	8.97	–	2.27
C_8Cs	1	Gold	5.94	11, 8	2.59
$C_{24}Cs$	2	Blue	9.25	12	2.55

Intercalation compounds containing two metals can be prepared by reaction of binary alloys of K, Rb, and Cs and also with alloys of metals that intercalate easily combined with those that do not. For example, Billaud and Hérold[85] prepared a compound Na_2BaC_8 by reaction with a NaBa alloy. The interlayer separation implies a sandwich structure comprising a layer of barium atoms with layers of sodium on either side. Triple layer structures for $KHgC_4$ and more complex compositions containing Tl and Bi have been described by Lagrange.[86,86] Several of these phases show ***Superconductivity*** in the range 1–4 K, significantly higher than observed in the ambient pressure binary phases (e.g. KC_8; $T_c = 0.13$ K).

Intercalation compounds containing solvated cations are also well known and are obtained from metal ammonia solutions, alkali metal naphthalides, or by electrochemical intercalation.

3.1.3 Intercalation with Graphite Oxidation

Intercalation compounds with electron acceptors form a large class of compounds with several distinct types of guest, including anions of strong acids, halogens and halides, and oxides.

Graphite intercalation compounds can be synthesized with guest anions of strong inorganic and organic acids. Direct intercalation reactions occur with oxidizing acids (HNO_3, $HClO_4$), but generally electrochemical oxidation of graphite has been used. Electrochemical synthesis is necessary for nonoxidizing systems. Some examples of stage 1 compounds include (interlayer separation in parentheses) $C_{24}(HSO_4)(H_2SO_4)_2$ (7.98 Å), $C_{21}SO_3F(HSO_3F)_2$ (7.73 Å), $C_{24}ClO_4(HClO_4)_2$ (7.85 Å), and $C_{25.8}NO_3(HNO_3)_5$ (7.8 Å). The interlayer separation for the tetrahedral anions implies a double layer of oxygen atoms between graphite layers. The maximum packing density would correspond to two close-packed oxygen layers, but lower density packings can be envisaged, for example, with the C_2 axis of the tetrahedron perpendicular to the graphite layers. The interlayer separation of the nitrate intercalation compound is consistent with a bilayer of nitrate groups with their C_3 axes along c or a monolayer with C_3 parallel to the graphite planes.

Bromine readily reacts with graphite from the vapor phase at ambient temperature to form a second stage phase with composition C_8Br. Higher stage compositions are formed by reaction above 50 °C. Several studies show that complete charge transfer from graphite to bromine does not occur, but that polybromide species, Br_n^-, are present in the interlayer. The oxidizing power of bromine, even with the additional

stabilization provided by the formation of polybromide species, is insufficient for stage 1 formation. Chlorine intercalation compounds have lower stability and iodine compounds do not form. However, intercalation compounds with ICl and IBr are known, presumably owing to additional stabilization provided by the formation of ICl_2^- and IBr_2^- species in the interlayers. Intercalation compounds are not formed with fluorine, which reacts with graphite to form either black C_2F (at temperatures in the range 350–450 °C) or white CF (near 600 °C).

Metal and nonmetal halides also form acceptor intercalation compounds with graphite. Compounds fall into several classes: halides that are strong enough electron acceptors to oxidize graphite; halides that undergo *Disproportionation* reactions; and halides that can only intercalate in the presence of a separate oxidizing agent. Bartlett and McQuillan[1] have reviewed direct intercalation of metal hexafluorides and shown that spontaneous reaction requires an *Electron Affinity* greater than 108 kcal mol^{-1}. The hexafluorides, MF_6 (M = Os, Ir, Pt, Mo, U), all meet this criterion and form first stage compounds with compositions in the range C_8–C_{12}. Higher stages are formed with the composition $C_{12n}MF_6$ at higher temperatures and pressures.

Other metal fluoride intercalation compounds can be formed in the presence of fluorine, where the formation of MF_{n+1}^- complexes from MF_n adds to the overall stability. Examples include the intercalation of WF_6 and ReF_6 in the presence of F_2 via formation of MF_7^- guest species, C_8MF_6 (M = P, As), and C_nBF_4 compounds. Direct intercalation of AsF_5 occurs by a different mechanism (see below). Metal chlorides react similarly. Thus $AlCl_3$ and $NiCl_2$ can form intercalation compounds in the presence of Cl_2 through formation of the complex anions $AlCl_4^-$, $NiCl_3^-$, or $NiCl_4^{2-}$.

Molecular halides (e.g. AsF_5, SbF_5, and $SbCl_5$) can also form intercalation compounds by *Disproportionation* reactions. Intercalation of AsF_5 has been extensively studied, because of the high electrical conductivity of the resulting compound. Early studies indicated conductivities at room temperature comparable to that of copper, but subsequent measurements have indicated lower values more comparable to aluminum metal. The direct reaction with AsF_5 proceeds via disproportionation of the neutral fluoride according to equation (7), and both hexafluoride and trifluoride species are present in the interlayer. The composition corresponds to C_8AsF_5 for the first stage compound. The AsF_3 component can be removed by vacuum and reintroduced into the lattice from the gas phase without any change in the stage or significant change in conductivity. The AsF_3 species can be replaced by AsF_5 by repeated exposure to AsF_5 and evacuation. The composition is gradually modified to form C_8AsF_6 analogous to the low conductivity phase prepared from AsF_5/F_2.

$$2e^- + 3AsF_5 \longrightarrow 2AsF_6^- + AsF_3 \quad (7)$$

Several oxides and oxyhalide intercalation compounds have been reported, but detailed reaction mechanisms and stoichiometries are available in only a few cases. Reactions with N_2O_5, Cl_2O_7, and SO_3 proceed with evolution of NO_2, Cl_2O_6, and SO_2 respectively. These species are both strong oxidants and Lewis acids and intercalate by the reactions shown in equations (8) and (9). In the case of SO_3, the formation of polymeric guest species based on corner-shared chains of tetrahedral SO_4 terminated with SO_4^{2-} anions has been proposed.

$$N_2O_5 + e^-(\text{graphite}) \longrightarrow NO_3^- + NO_2 \quad (8)$$

$$2Cl_2O_7 + 2e^-(\text{graphite}) \longrightarrow 2ClO_4^- + Cl_2O_6 \quad (9)$$

The disproportionation reactions with graphite of oxidants that are also strong Lewis acids parallel the intercalation of molecular species into the layered dichalcogenides, which are reductants and Lewis bases (see Section 3.2.1).

3.1.4 *Alkali Metal Intercalation in C_{60}*

The molecule C_{60} was first observed in the mass spectrum of laser evaporated carbon by Kroto *et al.*,[87] who proposed the now familiar ‘soccer ball’ structure. Subsequently, macroscopic quantities were synthesized.[88] In the solid state, C_{60} adopts a face-centered cubic (fcc) structure, which can be considered to be based on the close packing of spheres with a radius of 5 Å. Two tetrahedral sites and one octahedral site with radii 1.12 and 2.06 Å are present in the structure. The availability of these empty sites and the electronegativity of C_{60} make it a suitable host lattice for reductive intercalation by electropositive cations such as the alkali metals. The octahedral site is larger than any of the alkali cations, but the tetrahedral site is about the same size as Na^+. The discovery of ***Superconductivity*** in K_xC_{60} ($T_c = 18$ K) has focused considerable interest on these materials. Intercalation compounds can be prepared by direct reaction of the alkali metal with C_{60} to form compositions A_xC_{60} ($x = 2$, 3, 4, or 6) depending on the specific A cation. Direct reaction of C_{60} with the alkali metals is the most convenient route to the A_6C_{60} phases; other compositions can be prepared by use of the appropriate stoichiometry or by reaction of A_6C_{60} with C_{60}. Other alkali metal reagents such as Na_5Hg_2 and NaH have also been used.[89]

The structures of the alkali metal fullerides may be considered to be intercalation compounds of the fcc lattice of the C_{60} host formed by filling the interstitial sites. Superconductivity has been investigated in detail for the alkali metal and mixed alkali metal phases of composition A_3C_{60} where the conduction band is half filled. Critical temperatures as high as 31.3 K (in Rb_2CsC_{60}) have been observed. A clear correlation between unit cell size and T_c is observed, and it has been suggested that the conduction bandwidth controlled by the separation between the molecules is the dominant factor in determining T_c.

It is interesting to compare the intercalation chemistries of C_{60} and graphite. The different electronic structures produce

quite different intercalation chemistry. As discussed above graphite is a *Semimetal* and is amphoteric (*see Amphoterism*), forming both acceptor and donor intercalation compounds. In contrast, C_{60} is more electronegative than graphite, and forms much more stable intercalation compounds with alkali metals. No stable acceptor compounds are formed by C_{60}, $(I_2)_2C_{60}$ being the closest example. Addition reactions occur with more oxidizing halogens, analogous to the formation of C_2F and CF in reactions of graphite with fluorine.

3.1.5 *Intercalation Chemistry of Single-walled Carbon Nanotubes*

Single-walled carbon nanotubes comprise rolled sheets of sp^2 graphene carbon, which form well-defined cylinders with diameters in the range 1 to 2 nm. The diameter depends on the synthesis conditions as does the orientation of the six-membered carbon rings with respect to the nanotube axis. Achiral zigzag, achiral armchair, or chiral nanotubes can be obtained as illustrated in Figure 16.[90]

Single-walled carbon nanotubes self-assemble during growth into partially ordered two-dimensional bundles, or 'ropes', which consist of 100 to 500 nanotubes in a two-dimensional triangular lattice with a lattice spacing of 17 Å.[92]

Intercalation reactions can occur either by insertion of guest species into the channels between the tubes[93,94] or by insertion into individual tube after the ends have been open by oxidation.[91,95,96] Intercalation reactions of species between the tubes are accompanied by charge exchange between host and guest and are similar to those observed for graphite and C_{60} host lattices. Both oxidative intercalation with bromine and iodine and reductive intercalation with the alkali metals can occur. Reaction with alkali metals vapors give intercalation compounds with the composition MC_8 (M = K, Rb, Cs) comparable to those observed for the corresponding graphite intercalation compounds (Table 3). Intercalation leads to expansion of the two-dimensional lattice of the nanotubes

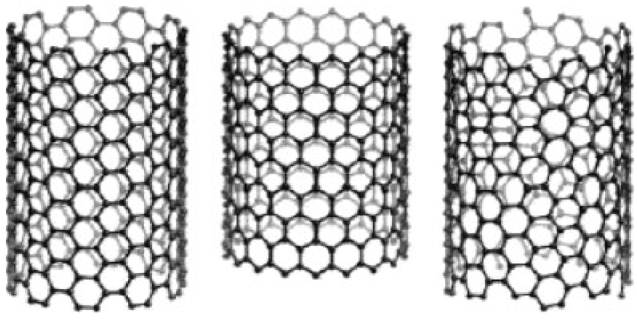

Figure 16 Schematic representation of (a) armchair, (b) zigzag and (c) chiral single-walled nanotubes. (Reprinted with permission from Ref. 91. © 2002 American Chemical Society)

so that the alkali metals are intercalated in between the tubes within the bundles. Disordered lattices are observed after intercalation of Rb and Cs ions. Simulations of the X-ray powder data for potassium intercalation compounds indicate that three K ions occupy the triangular cavities between the tubes. Various physical measurements including in situ measurements of the resistivity show a large drop in the resistance on intercalation and the temperature dependence suggests metallic behavior.

Carbon nanotube bundles can also be intercalated electrochemically in nonaqueous cells. Intercalation of lithium ions has been investigated in some detail because of the possible use of carbon nanotubes as anodes in reversible lithium batteries. On electrochemical intercalation of lithium ions, the composition approaches LiC_6 and a significant amount of the intercalated lithium can be removed on reoxidation though there is also a large irreversible component. No well-defined redox potential for lithium insertion or removal in the nanotube lattice is observed in galvanostatic charge-discharge and the loss in crystallinity that is observed by in situ X-ray diffraction suggests that solvent molecules are cointercalated.

In the second class of intercalation reaction, guest species are encapsulated inside individual single-walled nanotubes rather than between them. Guest compounds are introduced into the nanotubes by capillary filling with molten salts and crystals are formed that have structures typically with different coordination environments compared to the bulk. Metal halides have been studied in most detail though several examples of inorganic oxides have also been reported.

Confining either halides or oxides inside nanotubes leads to structures that are strongly influenced by the restricted dimensionality. As an example, the structure of a 2×2 KI crystal formed within a 1.4 nm-diameter carbon nanotube is shown in Figure 17. Electron microscopy shows pairs of identical dark spots along the axis of the tube, each representing an individual KI column viewed in projection. All of the ions in this 2×2 structure have a 4:4 coordination environment that is reduced from the 6:6 coordination found in the bulk crystal. The KI lattice is also expanded across the tube relative to the bulk. Single-walled nanotubes can also be filled with C_{60} molecules to give so-called 'peapod' structures.[96] Further intercalation reactions of the peapods using both donor (K) and acceptor ($FeCl_3$) guest species have been studied.

3.2 Transition Metal Dichalcogenides[1–8,97–100]

3.2.1 *Structures*

The transition metal dichalcogenides of groups 14, 15, and 16 have layered structures in which the transition metal (M) occupies either octahedral (trigonal antiprismatic, TAP) or trigonal prismatic (*see Trigonal Prism*) sites between two layers of chalcogen atoms (X). Each chalcogen layer

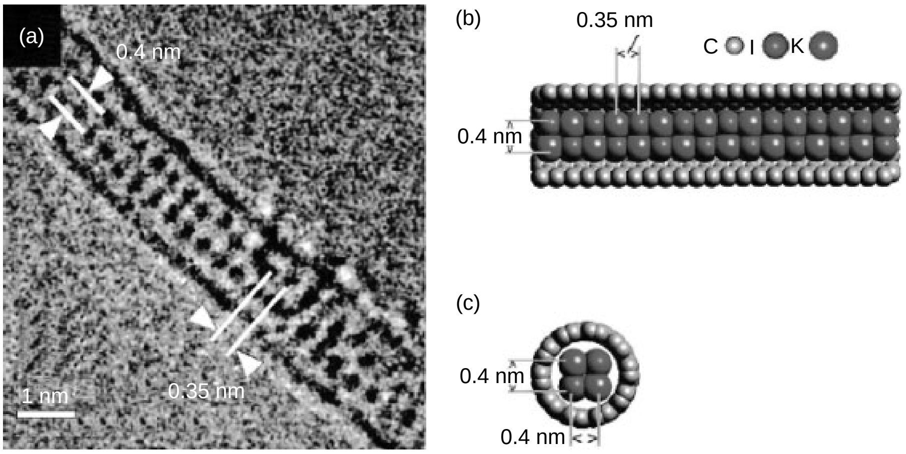

Figure 17 (a) High-resolution electron micrograph of a 2 × 2 KI crystal inside a single-walled carbon nanotube; (b,c) side and end views of the 2 × 2 KI crystal showing the lattice dimensions. (Reprinted with permission from Ref. 91. © 2002 American Chemical Society)

is close packed and the X–M–X sandwiches are stacked in a direction perpendicular to the chalcogen layers to complete the structure. Bonding within a layer is strong whereas, the van der Waals interactions between layers are weak. Different combinations of octahedral and trigonal prismatic coordination for M and different stacking sequences of the layers give rise to a variety of polymorphs (*see Polymorph*) and polytypes. Several commonly occurring stacking arrangements are shown in Figure 18, and a summary of examples of different stacking sequences and different transition metal coordinations is given in Table 4. In general, the group 14 metals and vanadium are octahedrally coordinated, whereas trigonal prismatic sites are occupied by the group 16 elements. Niobium and tantalum are found in both coordinations and the number of possible structures for the dichalcogenides of these elements is greatly increased by the possibility of alternating octahedral and trigonal prismatic layers. An example of a mixed layer sequence, 4Hb, which is observed for both TaS_2 and $TaSe_2$ is shown in Figure 18.

In an intercalation reaction, guest species are inserted into the octahedral, tetrahedral, or trigonal prismatic sites between the chalcogenide layers. Intercalation often produces a change in the layer stacking sequence.

3.2.2 *Alkali Metal Intercalation*

Intercalation reactions of the dichalcogenides with alkali metals are redox reactions in which the host lattice is reduced by electron transfer from the alkali metal. Lithium and sodium intercalation reactions, for example, have been studied using cells of the type $Li/LiClO_4$–dioxolane/MX_2 and Na/NaI–propylene carbonate/MX_2. The reactions proceed spontaneously to form the intercalation compound if the cell is short circuited; alternatively, a reverse potential can be applied to control the composition of the final product. Apart from their application in synthesis, such electrochemical cells can be used to obtain detailed thermodynamic information and to establish phase relations by measuring the dependence of the equilibrium cell voltage on composition (see Figure 4).

A variety of chemical reagents may also be used to form alkali metal intercalation compounds. The first compounds of the dichalcogenides were prepared by Rüdorff,[12] who reacted the host lattices with liquid ammonia solutions of the alkali

Table 4 Structure of layered dichalcogenides[a]

Designation[b]	Sequence	Space group	Examples	M coordination[b]
1T	AbC|	*P3m1*	MX_2 (M = Ti, Zr, Hf, V; X = S, Se, Te)	TAP
2Ha	BaB|CaC	$P6_3/mmc$	MX_2 (M = Ta, Nb; X = S, Se)	TP
2Hb	BaB|CbC	$P6m2$	$TaSe_2$, $NbSe_2$	TP
2Hc	BcB|CbC	$P6_3/mmc$	MX_2 (M = Mo, W; X = S, Se), $MoTe_2$	TP
3R	BcB|CaC|AbA	*R3m*	MX_2 (M = Ta, Nb, Mo; X = S, Se), WS_2	TP
4Hb	aB|CaC|BaC|BaB|Ca	$P6_3/mmc$	TaS_2, $TaSe_2$	TP, TAP

[a]In the notation used, A, B, C and a, b refer to chalcogen and transition metal layers, respectively. The layers are stacked at (0, 0, 0), (2/3, 1/3, *z*), and (1/3, 2/3, *z*) and, for example, AbA and AbC represent trigonal and octahedral sites. [b]T = trigonal, H = hexagonal, R = rhombohedral, TAP = trigonal antiprismatic (octahedral), TP = trigonal prismatic.

metals. The compounds formed by this procedure contain cointercalated ammonia molecules that are difficult to remove completely and the high thermodynamic activity of the alkali metal can lead to destructive side reactions. However, the method is applicable to all of the alkali metals and has been used successfully for the synthesis of a variety of compounds including the low stability A_xMoS_2 phases (A = K, Rb, Cs).

Other chemical reagents that give lower alkali metal activities, for example, sodium and potassium naphthalide and benzophenone solutions in tetrahydrofuran (THF), have been used Examples of lithium reagents with different activities are shown in Figure 5.

The phase relations for the alkali metal–TiS_2 and –ZrS_2 systems (Figure 19) illustrate most of the general features of alkali metal dichalcogenide systems. The simplest system is Li_xTiS_2, which is a single phase over the entire composition range as indicated by the smooth variation of the c axis lattice parameter with composition and by the equilibrium electrochemical data.[100] The intercalation reaction leads to occupation of the octahedral interlayer sites and the final product, $LiTiS_2$, is isostructural with the high-temperature phases $LiVS_2$ and $LiCrS_2$. The intercalation compounds formed by the other alkali metals are more complex and show two-phase behavior up to some low value of x, implying that a minimum energy of reaction is required to open up the van der Waals gap. Staging can provide a mechanism to minimize this energy and is observed for all of the alkali metal compounds at low x values except for those of lithium. In the TiS_2 systems, second stage compounds are formed for all alkali metals except lithium, and fourth stage phases occur with K, Rb, and Cs (see Figure 19).

The structures of the first stage compounds (I, Ia, Ib) illustrate how the dichalcogenide layers are restacked to optimize the guest coordination and the interlayer interactions. Structure I is observed for $LiTiS_2$ and has the same hexagonal sulfur stacking as TiS_2. Structure type Ia, in contrast, involves a restacking such that the chalcogen layers become cubic close packed. The alkali metals in Ia are in octahedral interlayer sites. Structure Ib is also restacked but in this case the rearrangement results in trigonal prismatic coordination for the alkali cations.

The alkali metal coordination depends on its ionic radius and also on the particular composition and the ionicity of the specific host lattice. Chalcogen–chalcogen repulsions destabilize trigonal prismatic coordination and are larger at higher layer charges and greater *Ionic Character* in the transition metal–chalcogen bond. Consequently, the alkali cation coordination generally changes from trigonal to octahedral as the layer charge increases.

The alkali metal intercalation compounds of the dichalcogenides readily form hydrated phases on exposure to water (equation 10). The value of x varies with host lattice, and depends on the reducing power of the intercalated host relative to water. For example, approximate x values of 0.5, 0.33, and 0.1 are found for hydration of the sodium intercalation compounds of TiS_2, TaS_2, and MoS_2, respectively. Hydrated phases may be prepared by several other procedures, including electrochemical reduction in the corresponding aqueous electrolyte and chemical reduction using aqueous reducing agents such as sulfide, borohydride, and dithionite.

$$\mathrm{AMX_2 + H_2O \longrightarrow A_x(H_2O)_yMX_2 + (1-x)A^+ + (1-x)OH^- + \tfrac{1}{2}(1-x)H_2} \quad (10)$$

The water content (y) depends on the ambient water pressure and on the hydration energy of the interlayer cation. At low water partial pressures or for cations with low hydration energies (small charge/radius ratio) a monolayer of water molecules is present between the chalcogen layers. At higher pressures or at a higher cation charge:radius ratio, a bilayer structure is observed.

In solvents with high dielectric constants, for example, N-methylformamide (NMF), the application of weak shear forces to solvated alkali metal systems results in complete dispersion of the solid intercalation compound and the formation of homogeneous dispersions or colloidal solutions of negatively charged dichalcogenide layers. Colloidal dispersions can be reflocculated by addition of electrolyte solutions of other cations. Ion exchange occurs at the same time. The reaction provides a good way of circumventing problems with the ion-exchange kinetics of large guest species. For example, an intercalation compound of the large cluster cation $[Fe_6S_8(PEt_3)_6]^{2+}$ was synthesized by flocculation of a colloidal solution of $Na_{1/3}TaS_2$ in NMF/H_2O.[101]

3.2.3 Molecular Guests

Intercalation compounds of the dichalcogenides can be formed with organic guest molecules under strictly anhydrous conditions by direct reaction at temperatures up to about 200 °C. Early studies of the transition metal dichalcogenides largely focused on this type of reaction after the initial discovery of amide intercalation in TiS_2[102] and the subsequent observation of the increase in the superconducting transition temperature of 2H-TaS_2 on intercalation of primary organic amines.[103] Since the early work, a large number of compounds with several different general classes of organic molecule (amines, phosphines, amides, and N-heterocycles) have been synthesized. Several studies of the physical properties of organic intercalation compounds such as optical spectra and magnetic susceptibilities have established charge transfer from the organic guest to the host layers. The charge transfer in most cases occurs through redox chemistry involving reactions of the guest molecules.[104] Ammonia, for example, may be intercalated into TaS_2 or the other dichalcogenides by direct reaction at ambient temperature. The reaction proceeds to a limiting composition NH_3MX_2, which is a first stage compound. The first stage composition is not very stable and readily converts to a second stage phase of composition $(NH_3)_{0.5}MX_2$ under vacuum at room temperature.

The ammonia molecules occupy trigonal prismatic sites between the dichalcogen layers and NMR measurements show that they are oriented with the threefold axis parallel to the dichalcogenide layers, indicating only weak *Lone Pair* interactions with the layers. Careful study of the reaction stoichiometry, prompted by this observation, led to the conclusion that ammonia oxidation was involved and that the overall mechanism of reaction could be summarized by equation (11). The reaction product has x in the range 0.1–0.3 and contains ammonium ions solvated by neutral ammonia molecules.

$$\left(1+\frac{x}{3}\right)\mathrm{NH_3 + TaS_2 \longrightarrow (NH_4)_x(NH_3)_{1-x}TaS_2} + \frac{x}{6}\mathrm{N_2} \quad (11)$$

While ammonia can be taken as a model system for intercalation of primary organic amines, pyridine represents the simplest N-heterocyclic Lewis base. The general chemistry is closely analogous to that shown by ammonia. Direct reaction of the dichalcogenide, for example, 2H-TaS_2, with pyridine at elevated temperature (200 °C) leads to the formation of a first stage intercalation compound with limiting composition $(py)_{0.5}TaS_2$. Structural measurements have shown that pyridine is oriented with the long C–N axis, and hence the nitrogen lone pair, parallel to the layers. Chemical studies established that intercalation involved redox chemistry of the guest molecules, leading to the formation of bipyridines. The oxidation of pyridine by TaS_2 is analogous to the oxidation of ammonia, and the product of the reaction contains pyridine and pyridinium cations.

A second class of molecular intercalation compounds that can be prepared by direct reaction with the dichalcogenides are those formed with certain organometallic molecules. Compounds with *Chromocene* and *Cobaltocene* were the first examples.[105] All of the organometallic molecules known to form intercalation compounds are good reducing agents and form stable cations. Compounds may be prepared by direct reaction with a solution of the organometallic molecule or alternatively by electrochemical or ion-exchange methods. Electrochemical intercalation of $Co(\eta\text{-}C_5H_5)_2^+$ into TaS_2 gives a compound with the same stoichiometry as that obtained for the compound prepared by direct reaction with neutral cobaltocene and confirms the redox nature of the process. The *Magnetic Susceptibility* of $[Co(\eta\text{-}C_5H_5)_2]_{1/4}TaS_2$ and of $[Cr(\eta\text{-}C_5H_5)_2]_{1/4}TaS_2$ are also consistent with complete electron transfer to the TaS_2 layers. The electron transfer mechanism accounts for the correlation that exists between the reducing power of the organometallic (measured in a relative way by its first ionization potential, IP) and its ability

to intercalate specific host lattices. For example, $Co(\eta\text{-}C_5H_5)_2$ with an IP of 5.56 eV will intercalate both TaS_2 and FeOCl, but *Ferrocene*, which is less reducing (IP is 6.88 eV), will only intercalate the more oxidizing host lattice, FeOCl (see Section 3.4).

3.3 Metal Phosphorus Trisulfides[106]

The metal phosphorus trisulfide phases, MPS_3, form layered structures with M = Mg, V, Mn, Fe, Co, Ni, Zn, Pd, and Cd. All of the first transition series sulfides adopt the $FePS_3$ structure that is based on a cubic close-packed anion array with alternate layers of cation sites vacant. Within a layer, the cation sites are occupied by M^{2+} cations and P_2 pairs, as shown in Figure 20. The two different types of octahedra are ordered so that each P_2S_6 octahedron is surrounded by six MS_6 octahedra and each MS_6 octahedron has three each of MS_6 and P_2S_6 neighbors. To emphasize the structural relationship to the dichalcogenides, the composition can be written $M_{2/3}(P_2)_{1/3}S_2$.

The MPS_3 host lattices are ***Semiconductors*** or insulators, and the transition metal compounds have magnetic properties characteristic of high-spin octahedral cations (*see High-spin & Low-spin Compounds*). At low temperatures, antiferromagnetic order (*see Antiferromagnetism*) is observed but the susceptibility maxima are broad, indicative of the strong two-dimensional nature of the magnetic interactions.

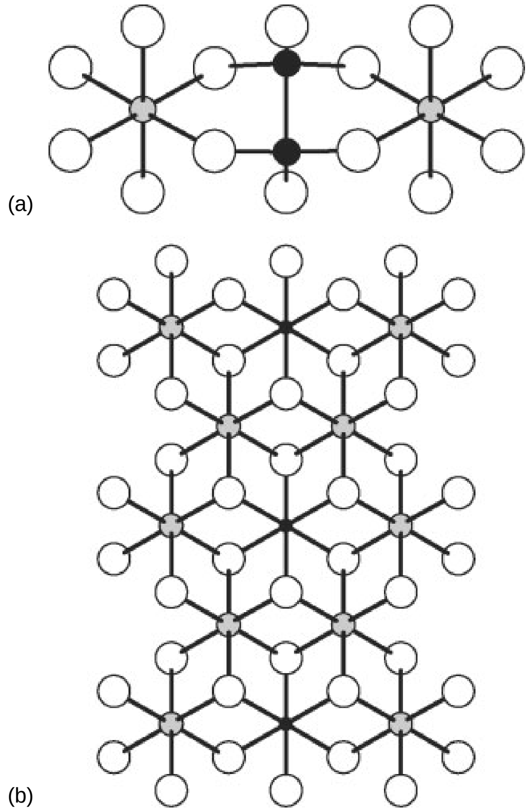

Figure 20 The iron phosphorus trisulfide structure showing the connection of P_2S_6 and FeS_6 octahedra (a) and the ordered arrangement within a single layer (b). The speckled circles are iron and the filled circles phosphorus

Redox intercalation reactions analogous to those of the dichalcogenides are observed for the MPS_3 phases with lower band gaps, that is, MPS_3 (Fe, 1.5 eV; Ni, 1.6 eV) and $FePSe_3$ (1.3 eV). Most work has focused on reactions of the MPS_3 (particularly $NiPS_3$) compounds with lithium because of interest in the application of the materials as cathodes in secondary batteries. The intercalation reactions are significantly more complex than those of the dichalcogenides. The reaction of $NiPS_3$, for example, with excess n-butyllithium in hexane results in compositions Li_xNiPS_3, with $x \leq 3$. Complete occupation of the interlayer sites corresponds to a maximum value of $x = 1.5$, indicating that degradation of the host lattice occurs with the formation of lithium sulfide. Irreversible behavior beyond $x = 1.5$ is confirmed by electrochemical intercalation of lithium in $NiPS_3$. Detailed studies using physical techniques (e.g. NMR and *Extended X-ray Absorption Fine Structure*) and theoretical calculations have led to an understanding of the reaction mechanism and the nature of the host acceptor levels.

Both $FePS_3$ and $NiPS_3$ react with toluene solutions of cobaltocene to give intercalation compounds that are similar in compositions and interlayer separations to the corresponding phases formed by the transition metal dichalcogenides. However, in studies of the direct intercalation reaction of metallocenes with some wide band gap host lattices ($MnPS_3$, 3.0 eV; $ZnPS_3$, 3.4 eV; $CdPS_3$, 3.5 eV), similar intercalation compounds were formed by reaction with solutions of metallocene salts, for example, with cobaltocenium iodide. This reaction is an example of a different intercalation mechanism involving removal of M^{2+} cations from the layers and is unique to the MPX_3 compounds. Intercalation involves an ion-exchange process whereby loss of M cations from the MPX_3 layers into the solution phase maintains charge balance on intercalation of cations between the layers. The intercalation compounds have the general stoichiometry $G_{2x}[M_{1-x}[\cdot]_xPS_3]\cdot yH_2O$.

After the initial reaction, additional compositions can be made by cation exchange with the interlayer cations. A particularly interesting example is the exchange of $Ni(H_2O)_6{}^{2+}$ with $K_{0.4}[Mn_{0.8}PS_3]\cdot 0.9H_2O$. Complete exchange of the potassium ions followed by dehydration gives the compound $Ni_{0.28}Mn_{0.72}PS_3$, which has identical lattice constants and magnetic properties to the phase prepared by direct reaction of the elements at high temperature. The experiment demonstrates that the ion-exchange process with the layer cations is reversible. The MPS_3 lattices differ in their relative abilities to form vacant sites in the layers by direct ion-exchange reactions. Ion-exchange reactions readily occur for Mn, Cd, and Zn. In contrast, $NiPS_3$ does not undergo ion exchange and $FePS_3$ does so with difficulty and only in the presence

of a complexing agent like ethylenediaminetetraacetic acid (EDTA).

The two distinct types of interlayer reaction observed in the MPS_3 compounds (electron transfer to the layers and ion transfer from the layers into the reactant solution) are partially reversible and occur with simultaneous intercalation of cationic species into the interlayer spaces. The balance between the two different reaction pathways appears to depend on the band gap of the particular solid. Ion transfer reactions are easier in the larger band gap compounds (for example, with M = Zn, Cd, and Mn) where the layers appear to behave as M^{2+} cations weakly coupled to $P_2S_6{}^{2-}$ units. The MPS_3 lattices behave very differently from the dichalcogenides where the strong covalent interactions between formally M^{4+} cations and S^{2-} anions preclude any ion transfer chemistry involving the layers.

3.4 The Transition Metal Oxyhalides[1,107]

The transition metal oxyhalides occur with four main structure types (FeOCl, AlOCl, SmSI, and PbFCl) but only the FeOCl structure undergoes topotactic redox reactions. A layer of the orthorhombic FeOCl structure is shown in Figure 21. The structure is characterized by double sheets of distorted octahedra that share edges. Each iron atom is coordinated to four oxide anions and two chloride ions, with the two chloride ions in cis octahedral positions on the outside of the layer. The arrangement of octahedra within a layer is similar to that found in γ-FeOOH and γ-AlOOH.

The redox intercalation chemistry of FeOCl with inorganic, organic, and organometallic guest cations is very similar to that of the dichalcogenides. For example, some degree of reversible intercalation occurs in electrochemical or chemical reactions with n-butyllithium to form Li_xFeOCl. In aqueous systems, hydrated alkali intercalation compounds can be prepared using chemical reducing agents, but reactions are complicated by the tendency of FeOCl to topochemically hydrolyze to γ-FeOOH. The alkali metal systems $M_{0.14}(H_2O)_y$FeOCl (M = Li, Na, K, Cs), prepared using $Fe(CN)_6{}^{4-}$ as the reducing agent, show large interlayer spacings that are very dependent on the water activity. For example, the interlayer spacing in the potassium compound changes from 11.47 to 22.84 Å when the contacting liquid is changed from 3 M KCl solution to pure water. This behavior is in marked contrast to that of the dichalcogenides, where the spacings primarily reflect cation hydration effects. The behavior of FeOCl indicates much stronger interactions between solvating water molecules with either the chloride layers or with partially hydrolyzed layers in which some Cl^- has been replaced by OH^-.

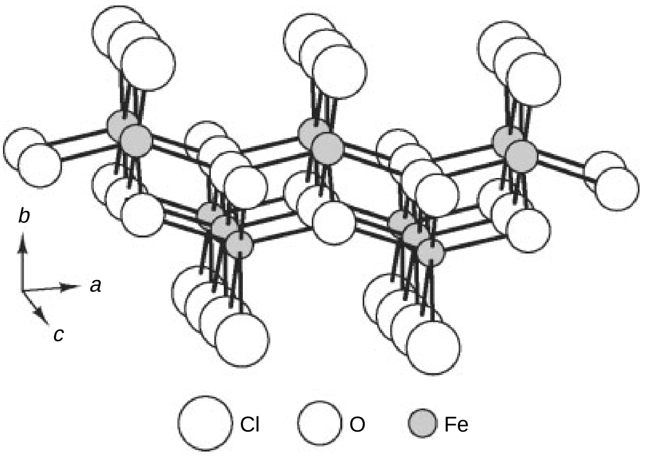

Figure 21 The arrangement of atoms in a single layer of FeOCl

Much more is known about the reactions of FeOCl with organic and organometallic cations than with the simple inorganic ions. The chemistry is generally similar to that of the dichalcogenides, but because FeOCl is more oxidizing, a wider range of organic and organometallic compounds can form by direct reaction. Unlike any of the dichalcogenide or MPS_3 phases, FeOCl will oxidize ferrocene to ferrocenium and form an intercalation compound. The formation of $[(\eta\text{-}C_5H_5)_2Fe]_{1/6}$FeOCl has been studied in detail by Mössbauer Spectroscopy.[108] Resonances characteristic of the ferrocenium cation, two types of lattice Fe^{3+} that differ in the number of Fe^{2+} neighbors, and lattice Fe^{2+} are observed. Quantitative measurements confirm that intercalation occurs with complete electron transfer from the guest to the host lattice.

Intercalation compounds are also formed by reaction of FeOCl with organic compounds that are good electron donors. Several systems have been synthesized with organic molecules such as tetrathiofulvalene (TTF), tetrathionaphthalene (TTN), and tetrathiotetracene (TTT). The organic intercalation compounds have interlayer separations and stoichiometries consistent with near close packing of the guests. Part of the interest in these systems stems from the possibility of obtaining very high conductivities via properly oriented organic guests.[109]

Reactions with Lewis bases are the other major class of redox intercalation reactions that have been explored with the FeOCl lattice. Pyridine, for example, reacts with FeOCl to form two compounds, $(py)_{1/4}$FeOCl and $(py)_{1/3}$FeOCl.[110] Reactions of FeOCl with ammonia and alkylamines are among the earliest reported intercalation reactions of compounds with neutral layers.[111]

$$\mathrm{FeOCl} + 2\mathrm{RNH_2} \longrightarrow \mathrm{FeONHR} + \mathrm{RNH_3Cl} \qquad (12)$$

FeOCl also shows a type of interlayer reactivity not found in other systems. Irreversible topochemical substitution reactions are observed where the outer halide layers of the FeOCl lattice are replaced by other groups. Examples of this type of substitution were first observed in reactions of ammonia and methylamine with FeOCl at ambient temperature. Reaction occurs with two moles of ammonia or methylamine according to equation (12), where R = H or Me. The products of the

substitution reaction are X-ray amorphous, but strong evidence for their formation comes from chemical analysis and infrared (IR) measurements.

Other substitution reactions lead to more crystalline phases. Reaction of (4-aminopyridine)$_{1/4}$FeOCl with methanol at 100 °C, for example, gives crystalline FeOOMe. Reactions with aliphatic and aromatic alkoxides and acids, of the type shown in equations (13) and (14), have also been studied.[112] More rigid and longer molecules, such as 4-hydroxybenzoic acid, can crosslink the iron oxide layers. An initial intercalation step that causes an expansion of the FeOCl interlayer distance is followed by a second substitution step leading to layer crosslinking.

$$\mathrm{KR + FeOCl \longrightarrow KCl + FeOR} \quad (13)$$

$$\mathrm{K_2R + 2FeOCl \longrightarrow 2KCl + (FeO)_2R} \quad (14)$$

Layer derivatization reactions have yet to be fully explored for the layered oxyhalides but the compounds are examples of a growing class of layered compounds with alternating organic and inorganic layers where the organic group is attached to the inorganic layer by a covalent bond. The organophosphonates of zirconium, $Zr(RPO_3)_2$, and vanadium, $VORPO_3$, are other examples (see Section 2.2.3).

3.5 Alkali Metal Intercalated Nitride Halides MNX (M = Zr, Hf; X = Cl, Br, I)

Superconductivity has been observed in the intercalated layered nitride halides of general composition MNX (M = Zr, Hf; X = Cl, Br, I). On intercalation, β-ZrNCl and β-HfNCl, become superconductors with transition temperatures of 13 and 25.5 K, respectively.[113–116] The transition temperature of the electron doped β-HfNCl is higher than that observed in any intermetallic compound.

The structure of β-ZrNCl contains ZrN double layers sandwiched between close-packed layers of chlorine ions that are stacked as in either $CdCl_2$ or CdI_2 or with a random mixture of both sequences. Synthetic techniques have been developed to prepare highly crystalline β-ZrNCl with the $CdCl_2$ arrangement and this structure has been well determined. The stacking sequence is –BABACBCBACACB– for the layers –N Cl Cl N N Cl Cl N N Cl Cl N N– so that the chlorine ions are stacked in a hexagonal arrangement as found in the structure of SmSI.[117] The stacking sequence changes on alkali metal intercalation to that of the YOF structure in which all of the individual layers adopt cubic stacking.

Both β-ZrNCl and β-HfNCl form intercalation compounds that are very similar to those of transition metal dichalcogenides. In the interlayer space between the chloride layers one octahedral and one tetrahedral vacant site per 2ZrNCl formula units are available for guest molecules. Alkali cations can occupy both positions since compositions are observed with $x > 0.5$ in A_xZrNCl (A = Li, Na).

When pale yellow-green β-ZrNCl is allowed to react with n-butyllithium in hexane, lithium atoms are intercalated to give black $Li_{0.16}$ZrNCl an interlayer separation of 9.3 Å only slightly larger than that of β-ZrNCl (9.2 Å). The intercalation compound shows metallic conductivity and becomes a superconductor at 13 K. When $Li_{0.16}$ZrNCl is stirred in THF or PC (propylene carbonate), the interlayer separation increases to 14.9 and 22.2 Å, respectively owing to cointercalation of solvent molecules.

Higher concentrations of lithium ions and other alkali metal (Na, K) intercalated compounds can be prepared by using the corresponding alkali metal naphthalide solutions in THF. THF molecules are cointercalated with lithium and potassium ions but not with the Na intercalation compound, $Na_{0.40}$ZrNCl. PC can, however, form cointercalation compounds with all of the alkali metal intercalated β-ZrNCl phases. The basal spacing varies depending on the alkali metals content intercalated: single layer arrangements are observed at low concentrations and double layers at high concentrations. Cointercalation compounds with other polar solvents, including dimethylformamide, dimethylsulfoxide, and acetonitrile has also been reported.

Reductive intercalation compounds of β-ZrNCl with cobaltocenes have been reported where the metallocene molecules are believed to be oriented with the molecular axes parallel to the layers.[118] The metallocene intercalation compounds also show superconductivity at 14 K.

Alkali metals can be electrochemically intercalated into β-ZrNCl. The results are generally in agreement with those from chemical intercalation with respect to interlayer separations and degree of intercalation. For example, the electrochemical data for the cell Li | $LiClO_4$/THF| –ZrNCl is consistent with the difference in the degree of reduction obtained using n-BuLi and Li-naphthalide.

As mentioned above, $Li_{0.16}$ZrNCl becomes superconducting below 13 K. On lithium intercalation of β-HfNCl with lithium naphthalide/THF the color of the crystals changes from white to black, and the interlayer separation increases from 9.23 Å to either 14.0 and 18.7 Å, corresponding to single or bilayer arrangements of THF molecules. Resistivity data for the 18.7 Å phase of $Li_{0.48}(THF)_y$HfNCl show a sharp drop at 25.5 K and zero resistance at 24.5 K. Superconductivity is confirmed by magnetic susceptibility measurements, which indicate that the compound is a bulk type II superconductor. The composition $Li_{0.48}(THF)_y$HfNCl has the highest transition temperature in this class of superconductors.

The MNX α-polymorphs adopt the FeOCl type layered structure (see Section 3.4) and exist for all combinations of MNX (M = Zr, Hf; X = Cl, Br, I) and for TiNX (X = Cl, Br, I). Superconductivity at 11 K is observed on intercalation of lithium in α-ZrNBr and α-ZrNI using BuLi.[119] Intercalation of pyridine into TiNCl gives pyridine$_{1/3}$ TiNCl, which superconducts at 4–6 K. The latter is reminiscent of the effect of intercalation of organic bases into the superconducting dichalcogenides.

3.6 Layered Transition Metal Oxides[4,5]

Simple layered structures with true van der Waals gaps are found only for the oxides of high oxidation state transition metal cations that form strong multiple covalent bonds to oxygen, such as MoO_3, V_2O_5, and $VOPO_4$. In the absence of this strong covalent bonding, oxide layer structures are destabilized by electrostatic repulsions between layers of negatively charged oxide ions, which are not offset by sufficiently strong attractive van der Waals forces. Transition metal oxide layers may be stabilized when the electrostatic repulsion is reduced by the presence of interlayer cations or hydrogen bonding. The three types of situation that are encountered are illustrated schematically in Figure 22. Intercalation reactions of type I oxides involve reduction of the transition metal whereas, the reaction chemistry of type II oxides involves mainly ion-exchange and oxidative deintercalation.

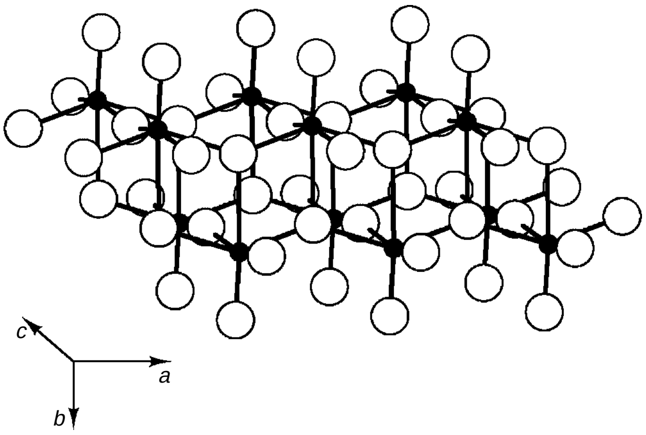

Figure 23 The structure of a single layer of MoO_3; filled and open circles are molybdenum and oxygen atoms, respectively

3.6.1 High Oxidation State Oxides

The compounds MoO_3, V_2O_5, and $VOPO_4{\cdot}H_2O$ each contain a transition metal ion in a strongly distorted octahedral environment arising from $d_\pi-p_\pi$ covalent M=O bonding. The structure of molybdenum trioxide is shown in Figure 23 as an example. The layers of double octahedra are anisotropic. Along the *c* axis the octahedra share cis edges, whereas along the *a* direction they share corners. The octahedra are far from ideal and have two short distances cis to each other, one pointing into the interlayer space and one along the *c* axis. Individual layers in MoO_3 are separated by a true van der Waals gap and consequently the oxide shows the full range of topotactic redox chemistry outlined for the dichalcogenides. Molybdenum trioxide is insulating and white in color when fully oxidized, but reductive intercalation produces both a large increase in electronic conductivity and a dramatic change in color to metallic blue-black, even for small amounts of reduction.

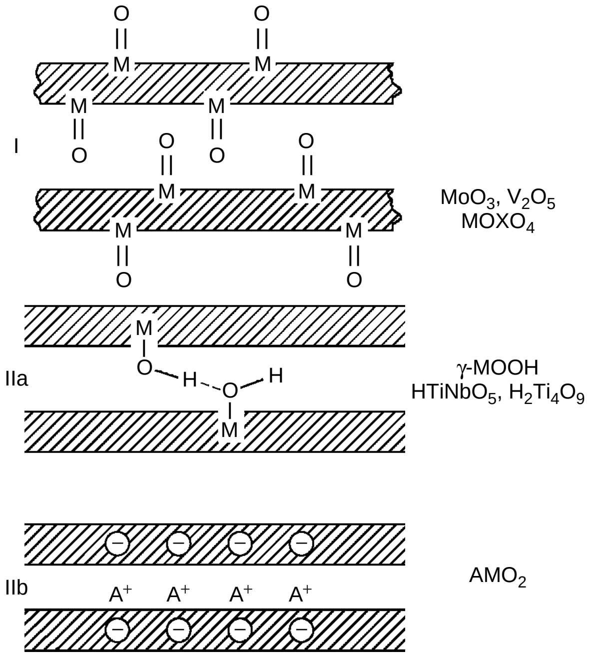

Figure 22 Schematic representation of the different types of layered metal oxides. (Reprinted with permission from Ref. 4 by permission of Oxford University Press (www.oup.com))

The intercalation of MoO_3 by hydrogen is the most extensively investigated of its redox reactions. Chemical reduction of MoO_3 in aqueous acid was first shown by Glemser and coworkers[120] to result in the formation of a series of compounds that could be formulated H_xMoO_3. The hydrogen bronzes can be prepared by electrochemical reduction in acid solution and by chemical reduction ('hydrogen spillover') with hydrogen and a platinum metal catalyst. Four distinct hydrogen bronze phases are formed: blue I ($0.23 < x < 0.40$), blue II ($0.85 < x < 1.04$), red ($1.55 < x < 1.72$), and green ($x = 1.99$).[121] All the H_xMoO_3 phases show metallic conductivity and weak temperature independent paramagnetism. The hydrogen intercalation compounds are Brønsted acids and react with Lewis bases (L) to form intercalation compounds of general composition $L_yH_xMoO_3$, for example, $(py)_{0.3}H_{0.5}MoO_3$.

In other respects the intercalation chemistry of MoO_3 closely resembles that of the dichalcogenides. Reduction in neutral aqueous electrolytes leads to the formation of hydrated cation intercalation compounds with the general composition $A_x{}^+(H_2O)_y[MoO_3]^{x-}$ (A = Na, K, Rb, Cs, NH_4, etc.), which can exchange ions or solvent molecules easily. Cation exchange reactions in aqueous solution are rapid at room temperature and interlayer separations are found to depend on the hydration energy of the interlayer cation, but there is no simple correlation between layer spacing and cation charge:radius ratio as observed for the dichalcogenides.

In the structure of V_2O_5, layers of vanadium–oxygen square pyramids (*see Square Pyramidal*) are connected by $V = O\cdots V = O$ bonds. Unlike MoO_3, these interlayer interactions are sufficiently strong that V_2O_5 behaves more like a three-dimensional lattice and intercalation compounds are formed only with the smallest cations, H^+ and Li^+.[122]

Vanadium pentoxide is more strongly oxidizing than MoO_3 and can be reduced by mild reducing agents such as acetonitrile solutions of lithium iodide. More strongly reducing reagents such as *n*-butyllithium give poorly crystalline products that are not well characterized. Both chemical and electrochemical reactions with lithium at ambient temperature give a series of phases, $Li_xV_2O_5$ with $x < 2.0$.[122]

Hydrogen intercalation compounds of V_2O_5 can be prepared by the same techniques used for MoO_3, and are structurally similar to their molybdenum analogs. Hydrogen 'spillover' gives the composition $H_xV_2O_5$ ($x = 3.8$), but unlike the high hydrogen content molybdenum bronzes the vanadium compounds are X-ray amorphous and semiconducting. Gels of vanadium pentoxide can be prepared by polycondensation of decavanadic acid. Removal of excess water results in a solid gel with approximate composition $V_2O_5{\cdot}1.6H_2O$. X-ray diffraction studies of oriented films show that the gels have a layered structure. Unlike crystalline V_2O_5, vanadium pentoxide gels can form intercalation compounds with large guests (e.g. ammonium, alkylammonium, ferrocenium, and cobaltocenium cations).[123]

Vanadium phosphate shows a wide range of intercalation reactions that parallel in many respects the chemistry of MoO_3. The α form of $VOPO_4$ is a layered compound and is one member of a series of complex oxides of general formula $MOXO_4$ (M = V, Nb, Ta, Mo; X = P, As, S) that are isostructural. The tetragonal layer structure of these compounds is made up of distorted MO_6 octahedra and XO_4 tetrahedra, which are linked by corner-sharing oxygen atoms. Each octahedron is joined to four tetrahedra and the layers are joined along the *c* axis by corner sharing the remaining two trans vertices of the octahedron. The vanadium coordination is consequently better represented as square pyramidal, and is similar to the vanadium atom coordination in V_2O_5. An important difference between V_2O_5 and $VOPO_4$ is the number per unit area of interlayer interactions of the type $V = O\cdots V$, which is reduced in $VOPO_4$ by the presence of the phosphate groups. Consequently, the interlayer interactions in $VOPO_4$ are much weaker and $VOPO_4$ behaves in its chemistry like a two-dimensional system. An immediate indication of the layered nature of the structure is the ease with which it forms mono- and dihydrates. Structural studies of the dihydrate show that one water molecule is coordinated to the vanadium atom and that the second is located in the interlayer space. The intercalation and deintercalation of water between $VOPO_4$ and $VOPO_4{\cdot}H_2O$ can be viewed as a special type of intercalation reaction in which coordination of the guest species to a metal center provides the driving force. Similar reactions have been described for larger donor ligands such as straight chain alcohols and for stronger Lewis bases such as pyridine and 4,4′-bipyridine.[124] With 4,4′-bipyridine, the stoichiometry is $VOPO_4$(bipy)0.5 and adjacent layers are crosslinked or 'pillared' by the bifunctional ligand.

Vanadium phosphate dihydrate readily undergoes redox intercalation reactions with alkali metal and alkaline earth metal cations in the presence of a mild reducing agent.[125] The reactions are analogous to those used to prepare lithium intercalation compounds of V_2O_5; iodide is oxidized to iodine, V^V is partially reduced to V^{IV}, and the metal cation present in solution is inserted between the layers. An important difference between $VOPO_4{\cdot}2H_2O$ and the other oxide lattices discussed above is that the layers have low electronic conductivity. Redox intercalation generally requires both ionic transport of the guest species in the interlayer region and electronic transport in the host lattice. Consequently, it has been proposed that the reductant, I^-, itself is intercalated into the interlayer space of $VOPO_4{\cdot}2H_2O$ and subsequently expelled in oxidized form.

3.6.2 *Intercalation in Oxides Containing Bi–O Double Layers*

Oxides containing bismuth oxygen atom double layers include the bismuth calcium copper oxide series of superconductors exemplified by $Bi_2Sr_2CaCu_2O_8$ (Bi-2212) and the beta phase oxide ion conductors based on the composition $Sr_xBi_{9-x}O_{(27-x)/2}$. While the details of these two structure types are quite different, they have the common feature of containing Bi–O double layers that are only weakly bonded. In Bi-2212, the bismuth atoms are four + one coordinated by oxygen atoms whereas, in $Sr_xBi_{9-x}O_{(27-x)/2}$ they are three + one coordinated and form square and hexagonal layers of Bi–O bonds. Both classes of compounds and be intercalated by iodine atoms that are inserted between the Bi–O double layers.

Iodine intercalation of Bi-2212 via reaction with iodine vapor was first shown to form a stage-1 compound with the composition, $IBi_2Sr_2CaCu_2O_8$.[126] Subsequently, it was shown that by varying the temperature at which the intercalation reaction was carried led to the formation of higher stage compounds with the general composition $IBi_{2n}Sr_{2n}Ca_nCu_{2n}O_{8n}$. Stage 1 and 2 compounds have been obtained as pure phases and stages up to $n = 5$ have been seen in high-resolution transmission electron micrographs.[127] Each intercalated iodine layer produces an expansion of 3.6 Å. Similar compounds were formed with other members of the bismuth superconducting family including $Bi_2Sr_2CuO_6$ (Bi 2:2:0:1) and $Bi_2Sr_2Ca_2Cu_3O_{10}$ (Bi 2:2:2:3).[128] The lowering of the superconducting transition temperature upon intercalation was thought to be primarily due to the change in interlayer coupling owing to the expansion of the lattice in the *c*-axis direction. Micro-Raman spectroscopy, however, provided information that iodine was present between the layers in the form of I_3^- suggesting significant charge

transfer.[129] Evidence for electron hole transfer from iodine to the copper-oxygen sheets is suggested by the observation that $Bi_2Sr_2Y_{0.5}Ca_{0.5}Cu_2O_8$ becomes superconducting on intercalation of iodine.[130] More recently several other guest species including Br_2, IBr, HgI_2, and AgI have been intercalated into Bi-2212.[131]

The layered oxide ion conductors $Sr_xBi_{9-x}O_{(27-x)/2}$ and $BaBi_8O_{13}$ show similar intercalation reactions with iodine.[132] The iodine atoms intercalate into the van der Waals gap between adjacent Bi–O sheets to form stage 1 compounds. The spacing between adjacent Bi–O layers increases by 3 Å corresponding to the intercalation of a monolayer of iodine atoms. Micro-Raman spectroscopy shows that the intercalated iodine species is predominantly I_3^-. Ag–I intercalated $Sr_{1.5}Bi_{7.5}O_{12.75}$, was synthesized by reaction with iodine and then in a second step with silver metal.[133] Intercalation of lithium iodide into the ferroelectric layered compound $Bi_4Ti_3O_{12-x}$ has also been reported.[134]

3.6.3 *The Layered AMO_2 Oxides*[134,135]

The layered oxides AMO_2 (A = Li, Na; M = V, Cr, Mn, Fe, Co, Ni) comprise alternating layers of edge-shared MO_6 octahedra and layers of alkali metal cations, and are structurally similar to the alkali−transition metal dichalcogenides. Nonstoichiometric phases A_xMO_2 can be synthesized at high temperatures by substitution of a tetravalent cation of a different metal or partial oxidation of the trivalent M cation. In general, stable phases cannot be synthesized at high temperature for $x < 0.5$.

The structures of the A_xMO_2 oxides, like those of the alkali metal dichalcogenides, depend on composition, the alkali cation size, and on the ionicity of the M–O bond, but there are important differences. For example, the transition metal is octahedrally coordinated in almost all cases and the pure MO_2 phases cannot be prepared even at low temperature because some alkali metal content is necessary to stabilize the layer structure. Staging is not observed because the interlayers cannot be completely emptied of cations.

Most of the reaction chemistry of the alkali−transition metal oxides involves oxidation of the host lattice, either electrochemically or with chemical reagents such as iodine or bromine in acetonitrile. The chemical reactions are analogous to, for example, the oxidation of $LiVS_2$ to form VS_2 using I_2, though generally the transition metal oxides are much harder to oxidize than the sulfides. In electrochemical oxidation the applied cell voltages are limited only by electrolyte stability, whereas chemical oxidations depend on the particular redox couple chosen. Not all of the alkali metal cations can be removed by either synthetic method without irreversible structural rearrangement. In lithium systems the formation of the three-dimensional spinel structure in preference to the layer structure is particularly favorable. Correspondingly, lithium intercalation of oxide spinels is quite facile and has been studied in its own right by several groups.[136]

The intercalation and deintercalation chemistry of the $LiMO_2$ (M = Ni, Co) phases forms the basis for the operation of lithium-ion batteries and is discussed in more detail in Section 3.7.1. Sodium ions also can be deintercalated from the host lattices Na_xMO_2 (M = Ti, Cr, Mn, Co, Ni) by electrochemical oxidation but the electrochemical behavior is very complicated. Limited ranges of solid solution and large numbers of intermediate phases are observed.

Sodium Cobalt Oxide. The general features of the intercalation chemistry of the layered AMO_2 oxides are described above in Section 3.6.3. Recently superconductivity with a transition temperature $T_c \sim 5\,K$ was observed in the compound $Na_xCoO_2{\cdot}yH_2O$ ($x < 0.35$, $y < 1.3$).[137] The hydrated sodium ion containing phase was prepared from $Na_{0.7}CoO_2$ by oxidative deintercalation using a solution of bromine in acetonitrile followed by washing in water. Analysis of the X-ray powder diffraction pattern showed that the structure contained a bilayer of water molecules. Subsequent studies confirmed the presence of superconductivity and also examined the variation of T_c with sodium ion content.[138] Samples were prepared by the same chemical method but used varying amounts of bromine from stoichiometric to a one hundred fold excess. The results show that like the high-T_c copper oxides, the highest superconducting transition temperature occurs in a narrow composition range and decreases for both underdoped and overdoped materials. Most recently, superconducting single crystals of $Na_xCoO_2{\cdot}yH_2O$ were prepared by electrochemical deintercalation of single crystals of $Na_{0.75}CoO_2$ in 1 M NaOH.[139] After deintercalation large single crystals break up into smaller pieces (~$5 \times 5 \times 2$ mm) and are a mixture of hydrated and partially hydrated phases. After careful hydration, nearly single-phase crystals are obtained in which over 90% of the sample volume corresponds to the superconducting $Na_{0.3}CoO_2{\cdot}1.3H_2O$ structure.

3.7 Lithium Intercalation in Transition Metal Oxides and Phosphates

Reversible electrochemical lithium deintercalation from 2D and 3D materials is important for applications in lithium-ion batteries. New developments have been realized in two classes of materials that show exceptionally promising properties as cathode materials. The first includes mixed layered oxides exemplified by $Li[Mn_xNi_yCo_z]O_2$, where the Mn remains inert to oxidation/reduction and acts as a framework ‘stabilizer’ while the other elements carry the redox load. Another class that shows much potential is metal phosphates, which includes olivine-type $LiFePO_4$, and the NASICON-related frameworks $Li_3M_2(PO_4)_3$.

3.7.1 *Lithium Transition Metal Oxides*

Various advances in this area during the past decade have been recently reviewed,[140] and highlights are summarized here. The layered $LiMO_2$ structure adopted by $LiCoO_2$ described in Section 3.6.3 (α-$NaFeO_2$ type, or 'O3'), is a versatile intercalation host. Isostructural alternatives that target less costly materials were initially based on substitution of M = Co with M^{3+} ions (Ni, Mn, and Al) aimed to reduce the Co content, and stabilize the structure to reversible lithium extraction. Materials with high nickel content $LiNi_{1-x-y}M^1{}_xM^2{}_yO_2$ are appealing,[141] but suffer from oxidation reactions with the electrolyte at elevated temperature/voltage as does $LiNiO_2$. Band structure considerations indicate that extraction of oxygen from the lattice competes with removal of Li^+ at high potential, in the order Ni > Co > Mn.[140]

Mn oxides are especially attractive:[140,142] the most extensively studied of these is the spinel $LiMn_2O_4$. Lithium can be deintercalated from or inserted into the 3D structure to give $Li_{1\pm x}Mn_2O_4$ ($x \leq 1$). Pronounced Jahn–Teller structural distortions in the range $Li_{1+x}Mn_2O_4$ ($Mn^{3.5+} \longleftrightarrow Mn^{3+}$) limit practical reversible (de)intercalation to $Li_{1-x}Mn_2O_4$. Metal dopants act as structural stabilizers, but do not inhibit dissolution of Mn that occurs from disproportionation of $Mn^{3+} \longleftrightarrow Mn^{2+} + Mn^{4+}$. Layered 'O3′ $LiMnO_2$ is not thermodynamically stable: compositions of this stoichiometry crystallize as an orthorhombic phase *o*-$LiMnO_2$. This unique structure contains Li and Mn ions that occupy octahedral sites arranged in an alternative zigzag configuration. Its electrochemical intercalation properties have been investigated by various groups, and shown to be poor. Reduction of crystallite size (to less than 0.3 µm) facilitates (de)intercalation, but repeated cycling of lithium within the structure results in spinel formation. Surprisingly, little intercalation capacity loss is observed and has been attributed to the formation of antiphase nanodomains that arise from the nucleation of the spinel at different points in the orthorhombic structure.[143] The high density of phase boundaries provide elasticity that can accommodate transformation strain arising from intercalation over a wide range of lithium content. Metastable layered $LiMnO_2$ was reported recently, with a structure analogous to that of $LiCoO_2$.[144] The Jahn–Teller effect of the Mn^{3+} ions result in monoclinic distortion from the ideal rhombohedral O3 structure. The material is accessed via a 'chemie douce' route, involving ion exchange of O3-type $NaMnO_2$ with $LiNO_3$ in hexanol or propanol at elevated temperature. During repeated lithium deintercalation/intercalation, transformation to the spinel phase is also observed, although this is advantageous rather than detrimental. As in orthorhombic $LiMnO_2$, nanostructures of spinel/layered oxide intergrowth regions are sustained, and enhance the reversible Li intercalation process by inhibiting strain and stress within the 'splayered' materials.[145]

In a new group of layered metal oxides, Jahn–Teller distortion effects are circumvented by using a combination of Mn^{4+} with a second element as the redox-active species. The first materials to utilize this concept were based on chromium substitution in the ordered rock salt structure Li_2MnO_3.[146] A line phase within the solid solution of Li_2MnO_3 (or $Li[Li_{1/3}Mn_{2/3}]O_2$) and $LiCrO_2$; that is, $[Li_{0.2}Cr^{III}_{0.4}Mn^{IV}_{0.4}]O_2$ was reported to have particularly good properties. Extraction of lithium from this material is concommitant with reversible oxidation of Cr^{3+} to Cr^{6+}, with the Mn^{4+} remaining inert.[147] The redox-inactive Mn^{4+} in the lattice forms an electronically conductive framework, and facilitates the 3-electron redox process at the Cr center. The restriction of Mn to the +4 state provides high stability, as more reduced valence states of Mn are prone to migration.

The high toxicity of Cr^{6+} led to the development of isostructural Mn oxides that incorporate the $Ni^{2+} \longleftrightarrow Ni^{4+}$ redox couple. These can be described as a solid solution between $Ni^{II}O$, and $Li_2Mn^{IV}O_3$. A wide range of compositions have been reported with the general stoichiometry $Li[Li_{1/3-2x/3}Ni^{II}_xMn^{IV}_{2/3-x/3}]O_2$ ($x = 0.5- >$).[148] The end member of the series, $Li[Ni_{0.5}Mn_{0.5}]O_2$ is particularly intriguing. The first reports showed poor intercalation capacity retention[37,140] but improvements in synthesis methods yield materials that demonstrate good stability.[149] Control of stoichiometry, morphology, and cation ordering within the lattice is paramount to achieving excellent reversible intercalation properties. Samples are prepared using a mixed hydroxide method, involving first a precipitation to form homogenously mixed $[Ni,Mn](OH)_2$, which is allowed to react with Li_2O at high temperature (1000 °C) to form the desired composition. Sol-gel methods utilizing a solution-based technique to achieve homogeneous mixing have also been reported. Electrochemical data show that 80% of the lithium can be reversibly deintercalated from optimized materials below 4.7 V.[150] The size of Ni^{2+} (0.83 Å) is similar to that of Li^+ (0.86 Å), making it prone to mix with the Li layer thereby impeding Li^+ ion diffusion. Correlation of mixing with intercalation capacity has been established, with the best materials exhibiting as little as 8% Li/Ni exchange. ^6Li NMR studies are able to differentiate the Li^+ ions within the lithium layer from those within the transition metal layer, and also reveal that Li^+ ions in both sites are subject to deintercalation.[151] The invariance of the Mn^{+4} valence state during (de)intercalation has been confirmed by X-ray absorption studies, which furthermore suggest the oxidation of Ni^{2+} to Ni^{4+} is a two-step process that occurs via Ni^{3+}.[152]

Triple solutions of $LiCoO_2$, NiO, and $Li[Li_{1/3}Mn_{2/3}]O_2$ show equal, if not greater promise as intercalation hosts. Compositions close to $LiNi_{1/3}Co_{1/3}Mn_{1/3}O_2$ prepared by sol-gel methods using citric acid as a chelating agent exhibit very little (<3%) undesirable cation mixing, and excellent intercalation properties, whereas less well ordered materials display poor reversible lithium intercalation capacity.[153] X-ray absorption near-edge studies show the valence states of Ni, Co, and Mn are +2, +3 and +4 in good agreement with calculated valence states.[154]

The success of the $Li[Ni^{2+}, Mn^{4+}]O_2$ materials has prompted investigation into analogous Ti^{4+} materials. Direct high-temperature synthesis of $Li_x[Ni_{1-y}Ti_y]O_2$ yields a disordered rock salt structure for $y > 0.4$; although an ordered layered structure $Li_{0.9}[Ni_{0.45}Ti_{0.55}]O_2$ can be synthesized by means of ion exchange from the sodium compound.[155] In contrast to the Ni, Mn oxides, partially disordered phases show better intercalation capacity then the least disordered. Nonetheless, the migration of Ti^{4+} into the Li^+ layer during electrochemical oxidation/reduction and the poor electronic conductivity of the material ultimately results in low lithium extractability.

3.7.2 Lithium Transition Metal Phosphates

Lithium transition metal phosphates are potentially very versatile and practical hosts for lithium intercalation, owing to their framework structures built of $PO_4{}^{3-}$ tetrahedra and $MO_6{}^{n+}$ octahedra that house highly mobile interstitial Li^+ ions. Much recent interest has been devoted to $LiFePO_4$, the most prominent member of this family. The promise of these materials is based on the 'inductive effect', described by Goodenough as the withdrawal of electron density from the metal centre owing to strong covalent bonding in the $PO_4{}^{3-}$ moiety. The inductive effect results in a very favorable increase in the Li (de)intercalation potential compared to the corresponding oxide. The raising of the $M^{n+}/M^{(n+1)+}$ redox couple is particularly advantageous for iron phosphates, where the potential of the Fe^{3+}/Fe^{2+} couple lies between 2.8 and 3.4V depending on the structural features of the framework. The metal phosphates also exhibit remarkably stable intercalation behavior, and resistance to oxygen loss.

Olivine-type $LiFePO_4$ was first reported by Goodenough in 1997.[156] Phosphates of this type ($LiMPO_4$; M = Fe, Ni, Co, Mn) adopt a common structure displayed by silicate minerals such as $MgFeSiO_4$, that constitute a large fraction of the earth's crust. The olivine architecture comprises a network of MO_6 octahedra connected to SiO_4 or PO_4 tetrahedra. The mobile alkali ions, that is, Li^+, form one-dimensional chains in the structure. These run parallel to planes of corner-shared MO_6 octahedra that are separated by connecting sheets of phosphate tetrahedra. Whereas the lithium-ion mobility along the chain direction is thought to be high based on recent calculations;[157] the electronically insulating tetrahedral phosphate groups on which the inductive effect relies partially isolate the redox centers within the lattice. Thus, the moiety that raises the cell voltage also limits the electronic conductivity. The pristine compound can be classified as a very poor semiconductor ($\sigma \sim 10^{-9}$ S cm^{-1}).

Initially it was reported that only 60% of the Li^+ could be reversibly deintercalated from the structure, even at very slow rates. Goodenough *et al.* proposed that this reversibility was also limited by the migration of the $LiFePO_4/FePO_4$ interface. On oxidation, lithium extraction is initiated from the surface of the particle and moves inwards behind a two-phase $LiFePO_4/FePO_4$ interface. As delithiation proceeds, the surface area of the interface shrinks. For a constant rate of lithium transport per unit area across the interface, a critical surface area is reached where the interface is no longer able to sustain the transport.[140]

The consequence of grain boundary and electronic transport limitations has led to several efforts worldwide to overcome them. These rely on a combination of reducing path length for Li ion/grain boundary diffusion (by restricting particle size) and adding conductive materials to provide good electronic contact to the crystallite surfaces. They include methods to coat the phosphate particles with carbon,[158] embed them in a carbon matrix,[159] and lay down metal particles within the mixture.[160] The latter have all resulted in increase of the working capacity of the material to approach 90–95% theoretical intercalation capacity at relatively fast rates of extraction and insertion in the material. An intriguing report suggested that doping the structure with supervalent cations could result in high inherent bulk electronic transport owing to Fe^{3+} 'hole carriers'.[161] The high conductivity has recently been shown to be due, however, to the formation of highly conductive iron carbophosphides on the nanocrystallite surfaces under certain processing conditions. The resultant nanonetwork gives rise to efficient electron transport at the grain boundaries, and bulk conductivities that approach 10^{-2} S cm^{-1}.[162]

The renewed interest in lithium metal phosphates has led to the investigation of many other important polyanion frameworks. These have been comprehensively reviewed[140] and include, amongst others: $Li_3M_2(PO_4)_3$ (M = Fe, V);[163,164] various $VOPO_4$ phases;[165] and analogous sulfates. Their working potentials also lie in the 3–4 V range depending on the anion, and the choice of the redox couple M^{n+}/M^{n+1}. The $Li_3M_2(PO_4)_3$ phases show rich chemistry. Two polymorphs are known: the rhombohedral framework that $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$ (NASICON) adopts, and a monoclinic modification that has a related, but slightly more compact structure. Lithium cannot be deintercalated from $Li_3Fe_2(PO_4)_3$ owing to the inaccessibility of the $Fe^{3+/4+}$ redox couple, although the structure can accommodate two additional Li ions utilizing the $Fe^{3+/2+}$ couple. The monoclinic lithium vanadium phosphate, α-$Li_3V_2(PO_4)_3$, possesses both excellent ion mobility and high lithium capacity owing to the ability to reversibly extract all three lithium ions from the lattice. It displays particularly complex and unusual behavior characterized by a series of two-phase transformations on deintercalation, followed by classic solid solution behavior on re-intercalation. A combination of neutron diffraction and ^7Li magic angle spinning (MAS) NMR studies revealed that a combination of charge ordering on the vanadium $V^{3+/4+/5+}$ sites and lithium ordering/disordering amongst lattice sites is responsible for the hysteresis.[166] Subtle ion–ion interactions in the solid dictate the intercalation sites that are emptied or filled.

3.8 Other Dimensional Structures

3.8.1 Three-dimensional Structures

The three-dimensional structures comprise two groups, those with intersecting channels (e.g. V_6O_{13}[14] and the *Chevrel Phases*[167,168]) and the one-dimensional channel structures. The intercalation chemistry of both groups is restricted to the insertion of small ions or molecules (H_2O, NH_3) because the sites that form a connected network, internal to the crystal, are nearly fixed in size.

Chevrel Phases.[2b,167] The ternary chalcogenides of molybdenum, $M_x^{m+}Mo_6X_8$ (X = S, Se, Te; M is an alkali, alkaline, rare earth metal, or transition metal cation, or Cd, Sn, Pb), have been of great interest because of their electronic properties, particularly *High Temperature Superconductivity*. The structures can be viewed as an assembly of Mo_6X_8 units, which can be described as X_8 cubes with molybdenum atoms at the centers of the six faces. The Mo_6X_8 cubes are joined by Mo–X bonds between units to form a three-dimensional lattice containing intersecting channels that are occupied by the M cations (Figure 24).

The $M_xMo_6X_8$ phases are obtained by high-temperature reaction of the elements in sealed tubes. The empty frameworks, Mo_6X_8, can be prepared from suitable $M_xMo_6X_8$ phases by either chemical or electrochemical oxidation. For example, Mo_6S_8 can be obtained from $Cu_2Mo_6S_8$ by oxidation with a solution of iodine in acetonitrile at 60 °C. Similarly, Mo_6S_8 can be obtained by electrochemical oxidation of $Cu_xMo_6S_8$ or $Ni_xMo_6S_8$ in nonaqueous electrolytes. Once formed the empty lattices can be intercalated with a wide variety of simple cations, though the three-dimensional nature of the structure places restrictions on cation sizes. Schöllhorn has examined many examples and shown that the critical radius for guest cations in Mo_6S_8 is in the range 0.96–1.26 Å, whereas it is 1.26–1.33 Å for Mo_6Se_8 phases. A typical example is the intercalation of lithium ions. Reaction of Mo_6S_8 with excess *n*-butyllithium in hexane gives a limiting composition of $Li_4Mo_6S_8$, but intermediate phases are observed by electrochemical intercalation. The compositions of the phases formed and the maximum extent of intercalation depend on the details of the electronic structure and the availability of suitable sites for the intercalating cation. The maximum value of electron transfer (4e) to the host lattice is supported by band structure calculations.

Perovskite Oxides.[2b,14,44,169] The perovskite lattice consists of a three-dimensional network of BO_6 octahedra in which each oxygen atom is shared between two B atoms. The 12 oxygen atoms in each unit cell describe a cubo-octahedral site that is occupied by the large A cation in perovskite, ABO_3. Rhenium trioxide and one form of WO_3 have the parent framework structure and can be intercalated with lithium though not with larger alkali metals. Reaction of WO_3 with *n*-butyllithium gives a phase with a limiting composition $Li_{0.67}WO_3$. In contrast, ReO_3 forms three distinct phases on lithium intercalation: cubic $Li_{0.35}ReO_3$, rhombohedral $LiReO_3$, and Li_2ReO_3. In the rhombohedral structures the octahedra rotate to give a structure with nearly hexagonal close-packed oxygens. The transformation is the same as that noted earlier for the ion-exchange reaction $LiNbO_3 \Leftrightarrow HNbO_3$. Both Li_xWO_3 and Li_xReO_3 can readily be reconverted to the parent oxides by electrochemical oxidation, but the reactions are slow.

Empty perovskite lattices can also form oxygen deficient phases by a process known as *Crystallographic Shear*, which introduces edge-sharing octahedra in addition to corner sharing. Examples include the reduced molybdenum oxides Mo_8O_{23}, Mo_9O_{26}, and V_6O_{13}. The latter is a metallic phase with substantial reversible capacity for electrochemical lithium intercalation between 2.8 and 2.2 V with respect to lithium metal.

One-dimensional Channel Structures.[2b] The chalcogenides Nb_3S_4, Ti_3S_4, and $Tl_{0.6}V_6S_8$ have one-dimensional channel structures in which MS_6 octahedra share edges and faces. A similar though more open structure is adopted by TlV_5S_8. The oxidative deintercalation reactions of the thallium ions from both structures are interesting exceptions to the simple electron transfer to and from the host lattice normally observed for redox reactions. The electrochemical results indicate a continuous nonstoichiometric phase from $Tl_{0.6}V_6S_8$ to a composition of $Tl_{0.2}V_6S_8$. The oxidation reaction, however, requires 0.8e (determined by coulometric titration), implying that at least some Tl^+ cations are oxidized to Tl^{3+} cations as they cross the solid–electrolyte interface. Oxidation of TlV_5S_8

also occurs with oxidation of the guest species according to equation (15). The reaction is electrochemically reversible between the composition limits shown. In this case, the ^{51}V NMR data indicate that the charge on the V_5S_8 lattice does not change. Instead the intercalation occurs by changing the oxidation state of the guest species from Tl^+ in TlV_5S_8 to Tl^{3+} in $Tl_{1/3}V_5S_8$.

$$Tl^{I}V_5S_8 \longrightarrow Tl^{III}{}_{1/3}V_5S_8 + \frac{2}{3}Tl^{3+} + 2e^- \qquad (15)$$

The intercalation behavior of some one-dimensional oxide structures has also been investigated, particularly oxides with the rutile structure[170] and the hexagonal form of WO_3.[171] The rutile oxides include MnO_2, which undergoes topochemical reactions with H^+ ions and is of considerable importance in primary battery systems. The ideal rutile structure is derived from edge-shared chains of octahedra that are corner linked to form four sided tunnels (see Figure 25). The structure is the end member of a series of phases with tunnels of different dimensions derived from single, double, and triple rutile chains connected by corner sharing. These structures are found in manganese oxide minerals (see Figure 25),[172] but can be synthesized with manganese or other elements. The difficulty of synthesis increases with increasing tunnel size, though todorokite (3×3) was recently obtained in microcrystalline form.[173] Intercalation of rutile phases has received the most attention. The ion-exchange properties and ionic conductivity of insulating hollandite phases have also been investigated. Lithium intercalation of several rutile phases has been studied by chemical reaction with n-butyllithium and electrochemically. The metallic phases MoO_2, WO_2, RuO_2, OsO_2, and IrO_2 give the highest lithium uptakes, in the range of 1–1.5 per metal atom. The first transition series phases react less readily either because they are difficult to reduce (Ti), the available sites are too small, or other structures are competitive, as in the rock salt related structure of $LiMnO_2$.

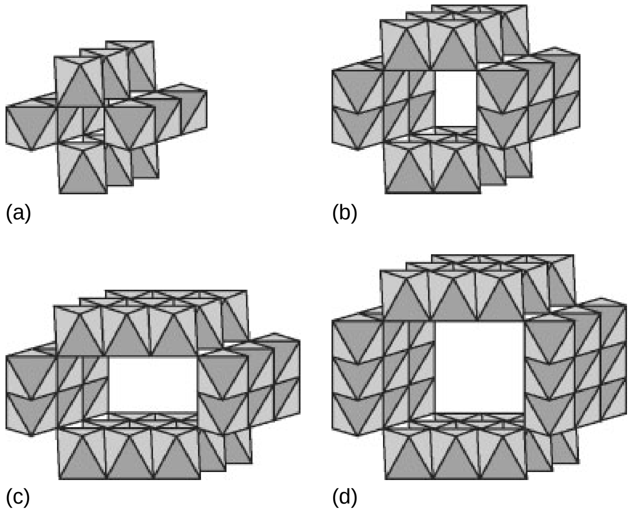

Figure 25 Schematic diagram of tunnel structures built from rutile chains: 1×1, rutile; 2×2, hollandite; 2×3, romanèchite; 3×3, todorokite. (Reprinted with permission from S. Turner and P.R. Buseck, *Science*, 1981, **212**, 1024. © 1981 AAAS)

The final example of a three-dimensional tunnel structure is that of hexagonal WO_3.[44] Alkali metal tungsten bronzes (M = K, Rb, Cs) with this structure type have been known for many years and are metallic conductors and in a few cases superconductors. Only recently, however, has the fully-oxidized parent framework been known. It has been synthesized by careful dehydration of $WO_3{\cdot}1{:}3H_2O$ or by oxidation of $(NH_4)_xWO_3$ at low temperatures. Once formed, the structure may readily be intercalated by reaction with n-butyllithium, sodium, and potassium naphthalides in THF. The larger alkali metal cations form the stable known high-temperature phases on intercalation. Metastable phases, such as $Na_{1/3}WO_3$, previously synthesized only at high pressure, are obtained with Li and Na. Very high uptakes of Li and Na cations occur on electrochemical reaction, but the crystallinity of the phase is lost and eventually the structure becomes completely amorphous. H_xWO_3 with the hexagonal bronze structure and $x \leq \approx 0.5$ has been synthesized electrochemically, by reaction with Zn/HCl, and by hydrogen spillover. Hydrogen intercalation causes a reversible color change from white to blue and, like WO_3 with the perovskite structure, the compound has been considered as a candidate material for electrochromic displays.

3.8.2 One-dimensional Systems

Only a few studies have been made of intercalation of linear chain systems. Like the layered structures, no restrictions are imposed by the structure on the size of guest species. The interchain distance can adjust to accommodate large guest molecules or ions. Unfortunately, intercalation often leads also to loss of correlation between adjacent chains along their length and compounds are difficult to structurally characterize.

The transition metal trichalcogenides MX_3 (M = Ti, Zr, Hf, Nb, Ta; X = S, Se) have been studied in some detail.[3,98] All the trichalcogenides contain anion–anion bonding and consequently a redox competition exists between electron transfer to the metal center and electron transfer to the anions. The situation is the converse of the deintercalation of the thallium vanadium sulfides, where the competition is between oxidation of Tl^+ cations and that of the metal sulfur framework.

The structure of $NbSe_3$, shown in Figure 26, is built up from infinite chains of $NbSe_6$ trigonal prisms. The chains interact through additional niobium–selenium bonds. Each unit cell contains three types of chain that are characterized by three different Se–Se distances (2.37, 2.48, and 2.91 Å). The distances suggest that the 2.37 Å chain corresponds to an electron distribution $Nb^{4+}(d^1)Se^{2-}(Se_2)^{2-}$ (metallic), the 2.91 Å corresponds to $Nb^{5+}(d^0)$ and is insulating, and

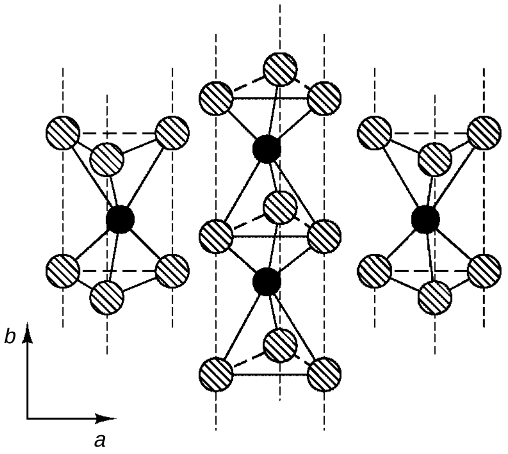

Figure 26 The chain structure of $NbSe_3$. Filled and shaded circles are Nb and Se, respectively. (Ref. 5. Reproduced by permission of John Wiley & Sons, Ltd)

the third chain is intermediate. Electrochemical lithium intercalation gives a maximum composition of $Li_{2.5}NbSe_3$. The electrochemical reaction occurs smoothly over the whole range and is reversible. Changes in slope of the voltage with increasing x have been correlated with the calculated band structure. Similar intercalation reactions occur for the trisulfides, but reactions cleave the $(S–S)^{2-}$ bonds and are not reversible.

Other aspects of intercalation of chain structures are illustrated by $KFeS_2$ and the $M_2Mo_6X_6$ (X = S, Se, Te) phases. Both these structure types have interesting ion-exchange properties. In the structure of $KFeS_2$, the potassium ions occupy eight-coordinate sites between infinite chains of edge-shared FeS_4 tetrahedra. Ion exchange with aqueous solutions of alkaline earth halides gives compounds with compositions $M_{1/2}FeS_2$. Exchange with Li^+ and Na^+ is also facile, but leads to complete separation of the chains and the formation of colloidal dispersions in dilute solutions. Chains of significant length are present in these dispersions. Increasing the electrolyte concentration causes reprecipitation of a crystalline solid phase with the same structure. In the case of sodium ion exchange, the solid phase has the composition $NaFeS_2{\cdot}2H_2O$ and is isostructural with the mineral erdite. Ion exchange with Ag^+ and Cu^{2+} ions under similar conditions causes considerable structural rearrangement and formation of the zinc blende related structures $AgFeS_2$ and $CuFeS_2$. Structural rearrangement also occurs in the electrochemical intercalation of $KFeS_2$ with lithium. A layered compound, $KLiFeS_2$, is formed with Li and Fe atoms occupying tetrahedral sites within a layer; the large K^+ ions fill all the interlayer sites.[174]

The $M_2Mo_6X_6$ (M = S, Se, Tl) compounds are closely related to the three-dimensional Chevrel phases $M_xMo_6X_8$ described in Section 3.6.1. The structures can be thought of as a condensation of the Mo_6S_8 units along the threefold axis of the Mo_6 octahedron to form $[Mo_3X_3]$ chains. The M cations occupy interchain sites. High-temperature reactions have been used to prepare these compounds, which are known for Na, K, In, Tl (Se, Te) and K, Rb, Cs (S). Other alkali metal systems can be prepared from $In_2Mo_6X_6$ compounds by ion exchange, in molten alkali metal iodides or by reductive intercalation with t-butyllithium.[175] Metastable phases such as $Li_2Mo_6Se_6$ and $Na_2Mo_6Se_6$ have been prepared by these routes. In polar solvents such as N-methylformamide or dimethylsulfoxide (NMF or DMSO), behavior like that noted above for $NaFeS_2{\cdot}2H_2O$ is observed. The chains completely separate to form colloidal solutions, but remain intact as shown by *Transmission Electron Microscopy* and light scattering.

3.9 Oxygen Intercalation

With the exception of the reactions of graphite with electron acceptors, the previous discussion has focused on reactions that involve intercalation of cations or solvated cations. Reactions of solids with oxygen that involve intercalation of oxide ions can also be considered to fall under the general definition of intercalation. In most cases, oxide ion diffusion is slow at ambient temperature and consequently somewhat higher temperatures ($<400-500\,°C$) are generally required to achieve reasonable rates. In a few special cases, reactions occur at ambient temperature. The topic has acquired particular importance since the discovery of High-Temperature Superconductivity in cuprates with perovskite related structures. In the cuprates, oxygen stoichiometry can vary by changing the formal oxidation state of copper from +1 to +3 and the Cu–O coordination from linear → square planar → square pyramidal → octahedral as the coordination number and oxidation state increase. Changes in the stoichiometry play a critical role in determining the electronic properties in this class of materials.

Oxygen intercalation was first discussed explicitly in relation to reactions of mixed valence copper oxides with perovskite related structures.[176] Michel and Raveau showed that for three systems ($La_3Ba_3Cu_6O_{14+\delta}$, $La_{2-x}A_{1+x}Cu_2O_{6+\delta}$ (A = Sr, Ca), and $La_{2-x}A_xCuO_{4-\delta}$), oxygen could be reversibly intercalated and deintercalated into the structures at 400 °C by varying the oxygen partial pressure between 1 and 10^{-3} atm. The intercalation of oxide ions occurs by filling vacant lattice sites without significant rearrangement of the structure. An example in which the relationship between composition, structure, and physical properties has been well worked out is that of the 91 K superconductor $YBa_2Cu_3O_{7-\delta}$. Samples prepared at high temperatures with the stoichiometry $YBa_2Cu_3O_6$ can be oxidized in oxygen at temperatures ca. 350 °C. The structural changes that occur are shown in Figure 27. Initially, the structure contains two distinct Cu ion coordination types, CuO_5 square pyramids and CuO_2 linear units. As the oxygen content is increased, the sites shown stippled in Figure 27 are filled in a disordered manner, but eventually become ordered with formation of chains of

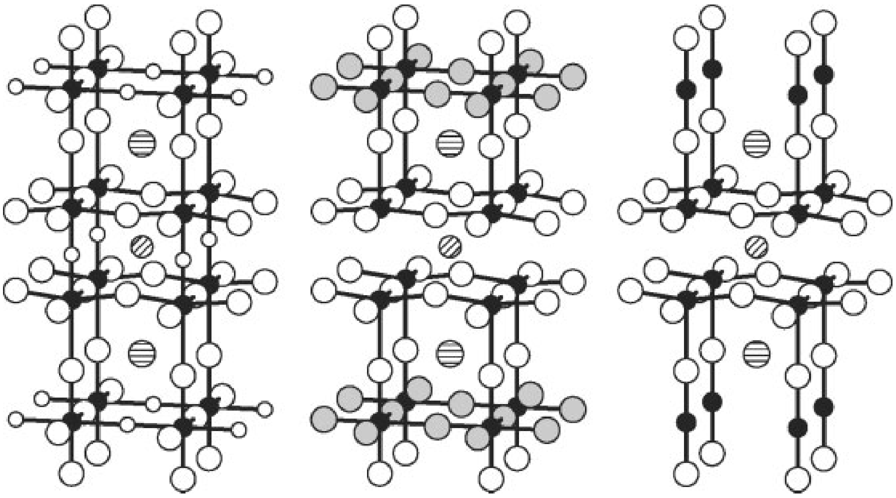

Figure 27 The structure of $YBa_2Cu_3O_{7-x}$ for $x = 0$ (a), $x = 0.6$ (b), and $x = 1.0$ (c). The filled, open, and stippled circles are copper, oxygen, and partially occupied oxygen atom positions, respectively. Yttrium and barium atom positions are shaded. (Ref. 177. Reproduced by permission of Blackwell)

square-planar CuO_4 units sharing corners at the composition $YBa_2Cu_3O_7$. Deintercalation from oxidized phases can be achieved by reduction of the oxygen partial pressure, by equilibration with a sample with a lower oxygen content, or by reaction in a sealed tube with a metal such as zirconium. Intermediate compositions are not completely disordered, but subtle differences in oxygen vacancy distributions are introduced that depend on the precise synthesis conditions used. Short range or intermediate range order shows up in different variations of the superconducting transition temperatures with composition for samples prepared by different procedures.[177]

In addition to the cuprates, oxides with perovskite related structures containing other transition metals or B metal cations show similar behavior. For example, the compounds $BaBiO_{3-x}$ ($0 \leq x \leq 0.5$) and La_2NiO_{4+x} ($0 < x < 0.18$) are other oxides that show wide ranges of oxygen nonstoichiometry. In La_2NiO_4 the excess oxygen is introduced as an interstitial oxide ion between layers in the K_2NiF_4 structure, coordinated by four lanthanum cations. Energy has to be expended in separating the layers in order to form the interstitial site, and consequently a two-phase region is observed up to $x = 0.06$ when the energy of intercalation is sufficient to compensate for that lost in separating the layers.

Several oxides with perovskite related structures can also be intercalated with oxygen ions by an electrochemical method.[178,179] The oxide $Sr_2Fe_2O_5$ with the brownmillerite structure has been electrochemically oxidized to $SrFeO_3$. The reaction was carried out by controlled potential electrolysis at a potential below that for oxygen evolution in 1 M aqueous KOH at room temperature. Bulk oxidation was confirmed by Mössbauer spectroscopy and X-ray diffraction. Similar results have been obtained for electrochemical oxidation of $Sr_2Co_2O_5$, $SrFe_{1-x}Co_xO_3$ (O $< x <$ 1), La_2CuO_4, and La_2NiO_4. The electrochemically oxidized materials are similar to compounds prepared by oxidation in oxygen. For example, La_2CuO_4 can be oxidized electrochemically to a superconducting phase $La_2CuO_{4+\delta}$ with a T_c similar to that obtained by oxidation in high-pressure oxygen. The phase behavior of the 214 compounds $La_2CuO_{4+\delta}$ and $La_2NiO_{4+\delta}$ have been investigated by both electrochemical and diffraction techniques. Neutron diffraction studies show that phase separation occurred near room temperature, implying high oxygen ion mobility consistent with the electrochemical data.

A particularly interesting example of electrochemical oxygen intercalation has been described for epitaxial thin films of La_2CuO_4. The electrochemical experiments were performed at room temperature in 1 M KOH solution with a Hg/HgO reference electrode.[180] For films deposited on $SrTiO_3$, oxygen can be intercalated electrochemically into the grown c-axis thin film. Superconductivity is observed with a double transition with a resistivity drop at 55–58 K, suggesting a more strongly oxidized phase, and a zero-resistance state at 42 K. Films on $SrLaAlO_4$ could not be studied, as they decompose during the anodic polarization. An electrochemical oxidation mechanism that occurs in two steps was proposed. First oxygen is transported into the film by intercalation into the planar defects, and then slower oxygen diffusion into the interstitial sites occurs along the *ab* planes. A similar mechanism for oxygen intercalation into c axis oriented $YBa_2Cu_3O_{7-d}$ (YBCO) has been proposed.[181]

Renewed interest in the superconductivity of cuprate films was generated by the observation that T_c for an epitaxial film of $La_{1.9}Sr_{0.1}CuO_4$ deposited on $SrLaAlO_4$ was 49 K, roughly double the bulk value of 25 K. The increase was initially attributed to the effects of compressive epitaxial strain.[182]

Recent detailed studies of a large number of $La_{2-x}Sr_xCuO_4$ films under both compressive and tensile epitaxial strain that were subjected to post annealing in various partial pressures of oxygen and in ozone suggest, however, that T_c cannot be increased by compressive epitaxial strain alone.[183] The results show that extra oxygen can be intercalated easily into underdoped $La_{2-x}Sr_xCuO_4$ films, even at 150 °C, and that the sensitivity to the intercalated oxygen atom concentration is the primary cause of the large variations of T_c in such films.

As discussed above, oxygen deintercalation from complex oxides at <300 °C can occur topotactically by reduction with molecular hydrogen or by heating samples in sealed systems with zirconium metal as a getter. At lower temperatures, ~200 °C, sodium hydride is an effective reducing agent for oxide deintercalation reactions. For example, the Ni(III) perovskite $LaNiO_3$ can be reduced topotactically to $LaNiO_2$, isostructural with the 'infinite layer' cuprates, using solid sodium hydride between 190 and 210 °C.[184] Structural characterization indicates the presence of some incompletely reduced regions, with five-coordinate Ni centers due to the presence of a small number of oxide anions between the $NiO_2{}^{3-}$ sheets. Neutron powder diffraction and magnetization measurements indicate that the lamellar Ni(I) phase does not show the long-range antiferromagnetic ordering characteristic of isoelectronic Cu(II) oxides. By using the same technique, a new Co(II) phase, $LaSrCoO_{3.38}$, was prepared at 200 °C from $LaSrCoO_4$ by oxygen deintercalation using NaH.[185] Substantial concentrations of Co(I) are present in contrast to higher temperature reduction with molecular hydrogen where the product contains only Co(II).

NaH decomposes at 210 °C and therefore above this temperature the reaction becomes equivalent to using hydrogen gas. To study deintercalation by hydride at higher temperatures the more thermally stable CaH_2 has been used. Reaction of $LaSrCoO_4$ at 450 °C with CaH_2 leads to the formation of an unusual transition metal oxide hydride, $LaSrCoO_3H_{0.7}$.[186]

This compound was shown by neutron powder diffraction to adopt an unprecedented structure in which chains of CoO_4 squares share corners to form chains that are linked to form a layer by H–bridges. The average cobalt oxidation state is 1.7+ and the CoO_2 sheets in the starting material have been replaced with $CoOH_{0.7}$ sheets in the oxide hydride product, which is consistent with a mechanism in which oxide vacancies created by oxide ion deintercalation are filled by intercalation of hydride ions.

1 INTRODUCTION

Electrical conduction occurs by the long-range diffusion of either electrons or ions. Usually conduction by one or the other type of charge-carrier predominates, but in some inorganic materials both ionic and electronic conduction are significant.

Migration of ions at normal temperatures does not occur to any appreciable extent in most ionic and covalent-bonded solids such as oxides and halides. For example, NaCl is an insulator at room temperature with a conductivity of only $\sim 10^{-15}\,\mathrm{S\,cm^{-1}}$.

The idea that ions can diffuse as rapidly in a solid as in an aqueous solution or in a molten salt may seem astonishing. However, since the 1960s, a variety of solids that include crystalline compounds, glasses, polymers, and composite materials with exceptionally high ionic conductivities have been discovered. Materials that conduct anions (e.g. F^- and O^{2-}) and cations including monovalent (e.g. H^+, Li^+, Na^+, Cu^+, Ag^+), divalent, and even trivalent and tetravalent ions have been synthesized. A variety of names that have been used for these materials include solid electrolytes, superionic conductors, and fast-ionic conductors. 'Solid electrolytes' arguably provides the least misleading and broadest description for this class of materials.

In Figure 1, the electrical conductivities of several common substances and representative solid electrolytes are shown at the temperature where the materials have potential application. The solid electrolytes have conductivities that fall between those of a typical semiconductor, silicon, and a typical aqueous electrolyte, sodium chloride.

Research in the area of fast-ion transport in solids has been extremely active in recent years, partly because of the many potential technological applications of solid electrolytes. These applications include high-energy-density batteries, fuel cells, sensors, electrochromic materials for both optical display and 'smart window' devices, low-cost electrolysis of water, and selective atomic filters. Devices using solid electrolytes are already available commercially: oxygen detectors for automotive pollution-control systems employ solid O^{2-} conductors, solid-state batteries with solid electrolytes are employed in heart pacemakers and lithium batteries commercially available since 1990 and widely used in laptop computers and other portable electronic devices employ electrolytes that are highly viscous; the goal is to develop all solid-state electrochemical devices with appropriate solid electrolytes.

1.1 Brief History

Interest in solids with highly mobile ionic species is not new. In 1839, Michael Faraday reported measurements on several materials including lead fluoride (PbF_2) that showed an unusual increase in the electrical conductivity at elevated temperatures, contrary to that found in normal metals.[2] This finding was a surprising discovery, since most simple salts are not good conductors of electricity.

Although Faraday discovered the unusual electrical properties of lead fluoride, he did not explain his observations. It is now known that the high electrical conductivity of PbF_2 is due to the motion of F^- ions, not electrons. At 500–700 °C, fluoride ions diffuse rapidly through the PbF_2 lattice. PbF_2 was the first example of a solid with high ionic conductivity.

In 1914, Tubandt and Lorenz[3] showed that the ionic conductivity of the high temperature α phase of silver iodide, AgI was even higher than that of the molten material. Tuband and coworkers presented evidence for the first time that ions can carry electrical current in solids.[4,5] In a simple experiment, based on Faraday's law (Figure 2), they proved that the conductivity of AgI above 147 °C results from the motion of Ag^+ ions. In Tubandt's electrochemical cell shown in Figure 2, silver electrodes were placed in contact with both sides of an AgI pellet. After a known amount of electrical charge was passed through the cell, the electrodes were removed and weighed; the amount of silver lost from the anode and deposited on the cathode corresponded almost exactly to that expected if the charge carriers through AgI were Ag^+ ions.

Subsequent findings that even conventional ionic solids, such as sodium chloride, have measurable conductivities that are not electronic stimulated the development of theories for ionic motion in solids. Early in this century, Joffe introduced the concept of interstitial ions and vacancies (*see* ***Defects in Solids***), which was the starting point of the theory of defects.[6] Frenkel and Schottky used these theories to develop their classic mechanisms to explain how electricity can be conducted through ionic solids by the flow of ions (*see Frenkel Defects*; *Schottky Defects*).[7,8] They proposed that ionic solids are not perfect, with every lattice site occupied by its appropriate ions, but contain defects in which either ions

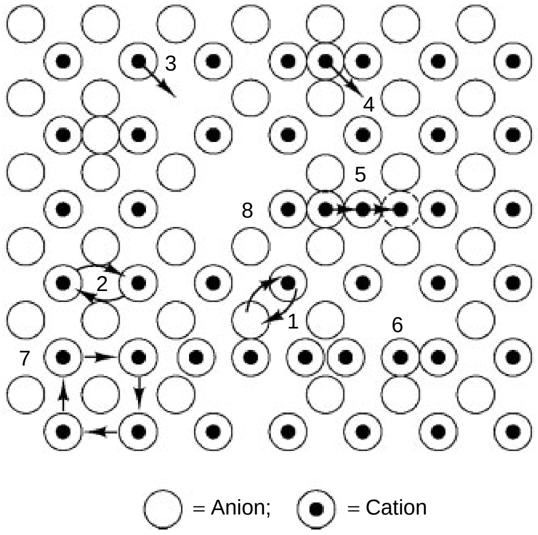

Figure 3 Defects and associated diffusion mechanism: 1 and 2, diffusion mechanism by direct exchange; 3, diffusion through vacancy; 4, direct interstitial mechanism; 5, indirect interstitial or caterpillar mechanism; 6, Frenkel defect; 7, indirect exchange; 8, Schottky defect. (Ref. 9. Reproduced by permission of Cambridge University Press)

are located in interstitial sites or vacancies occur in normally filled sites. The hopping of ions from normal lattice sites to interstitial sites and/or through a series of interstitial sites (Frenkel disorder, Figure 3), or the hopping of vacancies among normal lattice sites (Schottky disorder, Figure 3), established a clear structural basis for the occurrence of ionic conductivity in crystalline solids.

Around the same time, the development of *X-Ray Diffraction* methods made it possible to investigate directly the disorder of mobile ions in crystalline conducting solids. In 1934, Strock, on the basis of X-ray diffraction observations, postulated that the silver ions in α-AgI are distributed over a large number of lattice sites, which are energetically equivalent, while the iodide ions form a rigid framework structure.[10] Latter, Wuensch, and Cava confirmed unambiguously that the large (ca. four orders of magnitude) conductivity increase at the β-AgI $\rightarrow$ α-AgI transition at 147 °C is due to 'sublattice melting'.[11] That is, below 147 °C the Ag^+ ions occupy specific tetrahedral sites in a body-centered cubic arrangement of iodide ions. Both filled and vacant tetrahedral sites exist in the low-temperature structure. Above 147 °C, the silver ions distribute themselves over all the tetrahedral sites in a 'quasi-molten' or 'liquid-like' state (Figure 4) and they can move almost freely in three dimensions (3D). This pre-melting of the cation sublattice of silver iodide was also supported by the anomalously low value of the entropy of fusion (11.3 J K^{-1} mol^{-1}) relative to the mean value of 24.5 J K^{-1} mol^{-1} for alkali halides. The value of the transition entropy of AgI, 14.5 J K^{-1} mol^{-1} at 147 °C, also suggested that the silver ion sublattice might be considered to melt at 147 °C while the remaining iodide sublattice collapses at 557 °C (the melting temperature of AgI).[12–14] Theoretical calculations indicate that the energy barriers at the 'bottlenecks' (i.e. the smallest openings) through

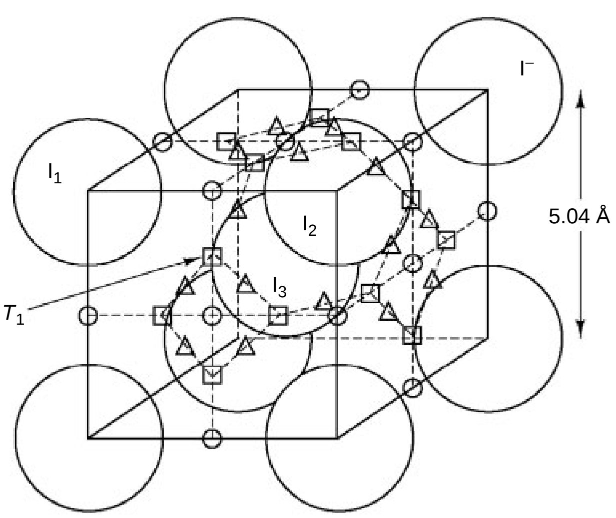

Figure 4 The unit cell of α-AgI depicted as a bcc sublattice of I^- and the Ag^+ sites at: ◯, 6b, octahedral sites; □, 12d, tetrahedral sites; △, 24h, trigonal bipyramidal sites

which the diffusing Ag^+ ions must pass are low, because of small distortions of the iodide ions from their equilibrium crystallographic positions and because of the polarization of the electron clouds of both the Ag^+ and I^- ions.[15–17]

In an attempt to stabilize the highly conducting α-AgI phase at lower temperatures, various anionic and cationic substitutions have been tried.[18] The most successful so far has been the replacement of silver by rubidium in $RbAg_4I_5$. This material has the highest ionic conductivity at room temperature of any known crystalline substance ($0.27\,S\,cm^{-1}$) with an activation energy of 0.07 eV. The electronic conductivity of $RbAg_4I_5$ is negligibly small ($\sim 10^{-9}\,S\,cm^{-1}$).

Although the details differ from compound to compound, most crystalline inorganic electrolytes show behavior similar to that described for AgI. Each has a low-conductivity phase in which ions are ordered (or disordered) in a subset of lattice sites.

Over some higher temperature range, the ions become disordered (or more disordered) among the sites and ionic conductivity is high. More generally, all classes of solid electrolytes share an important characteristic in that they all owe their conductivities to highly disordered regions in their structures. These regions may encompass an entire crystal (e.g. AgI), be restricted to specific interfaces of a composite (e.g. Al_2O_3 dispersed in LiI,[19,20]) occur as highly disordered regions in a crystal (e.g. on two-dimensional (2-D) planes (β-aluminas)[1,21–24] or in one-dimensional (1-D) tunnels (hollandite),[25]) or involve liquidlike disorder of an amorphous material (glasses)[26–28] and polymers.[29–31]

Intercalation and insertion compounds are another class of ionically conducting solids. These materials are mixed ionic and electronic conductors and are also covered by a separate article (*see* ***Intercalation Chemistry***).

The great acceleration of interest in solids with high ionic conductivity was stimulated by the report of Yao and Kummer[32] in 1967 that sodium β-alumina has a sodium ion conductivity at room temperature comparable to that of an aqueous sodium chloride solution. The simultaneous invention of the sodium/β-alumina/sulfur battery by the same group intensified interest in the commercial application of solids with high ionic conductivity.

2 GENERAL FEATURES OF SOLIDS WITH HIGH IONIC CONDUCTIVITY: THEORY

2.1 Conductivity

The electrical conductivity of a single-phase material is the sum of the electronic and ionic contribution (equation 1):

$$\sigma = \sum n_i Z_i \mu_i \tag{1}$$

where n_i is the concentration of the charge carriers with charge Z_i and mobility μ_i. In solid ionic conductors with negligible electronic conductivity, the electrical conductivity follows Arrhenius-type temperature dependence (equation 2):

$$\sigma = \frac{C}{kT}\exp\left(\frac{-E_a}{kT}\right) \quad \text{or} \quad \sigma = \frac{\sigma_0}{T}\exp\left(\frac{-E_a}{kT}\right) \tag{2}$$

where E_a is the activation energy for conduction, and C or σ_0 (differing only by a factor k = Boltzmann constant) is called the pre-exponential term.

Fast ion conduction generally results from low activation energies (a fraction of an electron volt, eV). A model of diffusion by isolated jumps with random walk of the mobile species is generally used to account for this behavior.

To be able to diffuse, an atom must surmount the energy barrier for migration E_m presented by its neighbors. If ν_0 is a characteristic atomic vibrational frequency, the probability for jump per second, ν, is expressed as $\nu = \nu_0 \exp(-E_a/kT)$. The atom makes ν_0 passes at the barrier with a probability $\exp(-E_m/kT)$ on each try of surmounting it by thermal energy (ν_0 is the so-called attempt frequency).

The diffusion constant D depends on the jump distance d and on a geometrical factor α (equation 3):

$$D = \alpha d^2 \nu_0 \exp\left(\frac{-E_m}{kT}\right) \tag{3}$$

The mobility μ, and hence the ionic conductivity, are directly related to the diffusion through the Nernst–Einstein equation, $\mu kT = ZeD$, giving equation (4):

$$\sigma = nZe\mu = \alpha n(Ze)^2 \nu_0 d^2 (kT)^{-1} \exp\left(\frac{-E_m}{kT}\right) \tag{4}$$

The specific character of a fast ionic conductor (FIC) arises from the value n of the concentration of the charge carriers with respect to n_0 the total number of ions.

In normal ionic materials the number of charge carriers (Frenkel or Schottky defects) is only determined by thermal generation (equation 5):

$$n = n_0 \exp\left(\frac{-E_{\mathrm{f}}}{kT}\right) \tag{5}$$

where E_{f} is the energy of defect formation. The conductivity then becomes (equation 6):

$$\sigma = \alpha n_0 (Ze)^2 \nu_0 d^2 (kT)^{-1} \exp\left\{\frac{-(E_{\mathrm{m}} + E_{\mathrm{f}})}{kT}\right\} \tag{6}$$

In FICs, the number of charge carriers represents an important fraction of the potentially mobile ions because of the presence of structurally inherent vacant positions (equation 7):

$$n = \beta n_0 \quad \text{and} \quad \sigma = \alpha\beta n_0 (Ze)^2 \nu_0 d^2 (kT)^{-1} \exp\left(\frac{-E_{\mathrm{m}}}{kT}\right) \tag{7}$$

Normal ionic compounds contain a limited number of charge carriers, and their activation energy for conduction is the sum of both the energy for defect formation (usually a few electron volts) and the energy for defect migration. In contrast, FICs have a large number of moving species with an activation energy representing only the energy for migration of defects. This last term may be only a fraction of an electron volt and has the same order of magnitude as observed activation energies in FICs.

Nevertheless, such a simple model that assumes the harmonic vibration of an isolated particle in a rigid potential well cannot take into account anharmonicity, polarization effects, and correlation between moving species, which are influential factors in fast-conducting materials.

Atomic vibrations with a large anharmonic character have been found to be responsible for fast conduction. There are numerous examples of studies of FICs by diffraction techniques that show unambiguously large thermal parameters for the mobile ion and/or diffuse/smeared-out electron density corresponding to the mobile species.

The lattice polarizability strongly influences the ionic conduction. A large amount of local polarization is unfavorable for migration: when hopping, the ion has to carry its polarization cloud with it. This ionic *Polaron* behavior[33] seems to be of major importance in FICs. Highest ionic conductivity values are obtained for migration of highly polarizable ions (Ag^+ and Cu^+ are the most mobile ions) in a deformable framework (iodides or derivatives). Compounds involving Pb^{2+} or Bi^{3+} give rise to higher anionic conduction than homolog phases containing less polarizable cations (like alkaline earth or rare earth cations) of comparable size. For example, β-PbF_2 exhibits a higher conductivity by fluorine migration than the alkaline earth fluorides with the same structure.[34]

For nonstoichiometric phases the stabilization of ‘extended defects’ depends on the ion polarizability.[35] The formation of extended defects is associated with a drastic decrease in the ionic conductivity, as for instance in calcia-stabilized zirconia (Section 3.2.1).

Correlation between the moving species is another important factor to consider, as all the atoms of a given sublattice (i.e. cationic in α-AgI, anionic in fluorites) or all the atoms of the conducting plane (β-alumina) may be involved in the conduction process.

In recent years, computer simulation (*see* ***Solids: Computer Modeling***) methods have been used successfully to examine the relationship between structural properties and transport mechanism in crystalline amorphous and polymeric materials.[36–41]

2.2 Structural Features

In the search for new inorganic crystalline solid electrolytes, a set of guidelines which show likely structural characteristics for high ionic conductivity has been established.[42,43]

1. A large number of the ions of one species should be mobile (i.e. a large value of n in $\sigma = ne\mu$).
2. There should be a large number of empty sites for the mobile ions to jump into.
3. The empty and occupied sites should have similar potential energies with a low activation energy barrier for jumping between neighboring sites (i.e. there is no use having a large number of available empty sites if the ion does not have enough energy to get into them).
4. The structure should have a framework (a rigid subarray or ‘skeleton’) with interconnected interstitial space (open channels) in which ions move preferably in three dimensions.
5. The anion framework should be highly polarizable.
6. Retain a negligible electronic conductivity σ at the operating temperature, T_{op} under operating atmospheres, that is, retain a transport number

$$\mathrm{t} = \frac{\sigma_i}{\sigma} \tag{8}$$

where the total conductivity is $\sigma = \sigma_i + \sigma_{\mathrm{e}}$ where σ_i is the conductivity due to only the mobile ions, and σ_{e} is the electronic conductivity.
7. Chemical stability in the working environment, which includes reactions at electrode/electrolyte as well as reactant/electrolyte interfaces. Thermodynamic stability vis à vis the reactants is achieved only by placing the bottom of the electrolyte conduction band above the highest occupied molecular orbital (HOMO) of the reductant and the top of the electrolyte valence band below the lowest unoccupied molecular orbital (LUMO)

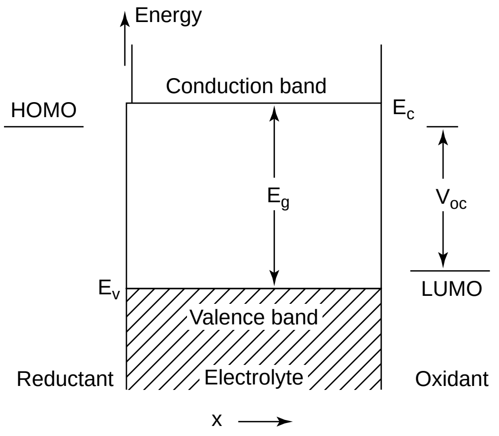

Figure 5 Placement of reactant energies relative to the edges of the electrolyte conduction and valence bands in a thermodynamically stable electrochemical cell at flat-band potential. (Reprinted, with permission, from the Annual Review of Materials Research, Volume 33 © 2003 by Annual Reviews www.annualreviews.org)

of the oxidant as illustrated in Figure 5. Note: The Fermi energies of the metallic electrodes should also lie in the energy gap E_g of the electrolyte, with that of the anode rising to the HOMO of the reductant and that of the cathode falling to the LUMO of the oxidant under operating conditions.

8. Mechanical stability against thermal cycling between ambient temperature and T_{op} requires matching of thermal-expansion coefficients of the electrolyte and electrodes, the interconnects, and the seals. Note: Ceramic strength is improved where cell design retains the ceramic membrane under a compressive stress.
9. Costs of material and fabrication as well as operational life are always considerations.

In addition, alkali-ion transport is governed physically by the size of the 'bottlenecks' (i.e. smallest opening at the site interface) between interstitial alkali-ion positions and chemically by the bonding energy between the mobile ions and the network anions. The shortest diameter of the bottlenecks should be larger than twice the sum of the mobile-ion and anion radii. The covalent bonding between the mobile ion and the anion network should be as weak as possible, which may be achieved if the anion forms a strong covalent complex with the network cations and/or if the anion is bonded to more than two of these cations.[44]

3 CRYSTALLINE ELECTROLYTE MATERIALS

As mentioned in the Introduction, a large variety of solid electrolytes have been synthesized and characterized in recent years. In addition to a good number of fairly recent review articles[41,43,45–51] and books on the subject,[9,52–61] publications dealing with research in this area appear regularly in the journals including *Solid State Ionics, Ionics, Chemistry of Materials, Materials Research Bulletin, J. Solid State Chem., J. of Materials Chemistry, J. Electrochemistry, J. Power Sources, Sensors and Actuators, Solid State Sciences, MRS Symposium Proceedings on Solid State Ionics, Annual Reviews of Materials Research, and Annual Review of Material Science.*

Some examples of solid electrolytes are presented in Table 1. In the limited scope of this article, only a few examples of some of the most important (i.e. for potential commercial applications) monovalent cation (Li^+, Na^+, and H^+) and anion (oxide and fluoride) conductors will be discussed. Amorphous materials, glasses, and polymers are treated in Section 4. However, it should be noted that relatively good ionic conductors are known with many other monovalent ions including K^+, Rb^+, Cu^+, Tl^+, and Ag^+, divalent ions, for example, Pb^{2+}, Ca^{2+}, Ba^{2+}, Zn^{2+}, Sn^{2+} in β'-alumina,[62] and even trivalent cations,[23,63,64] and tetravalent cations.[65] In Section 5, the application of some of these materials in electrochemical devices including batteries, sensors, smart windows and fuels cells are discussed.

3.1 Cation Conductors

3.1.1 Sodium Ion Conductors

β- and β''-aluminas. The β-aluminas are one of the most important and widely investigated family of solid electrolytes. They permit not only fast Na^+ diffusion, but also the diffusion of other alkali ions, protonic species, divalent and even trivalent cations. The β-aluminas combine interesting chemistry with wide-ranging potential technological applications.

Sodium β- and β''-alumina are nonstoichiometric aluminates that are typically synthesized from sodium oxide (Na_2O) and alumina (Al_2O_3) at high temperature.[66,67] More recently synthesis of β- and β''-alumina by microwave processes could lead to a high density stoichiometric maore cost-effective product.[68] Single crystals can be grown by the Czochralski method from excess Na_2O melt.[69–71] Both can be thought of as derivatives of the yet-unknown stoichiometric sodium aluminate $NaAl_{11}O_{17}$. Both contain excess Na^+ compared to this composition. The general formula of β-alumina is $Na_{1+x}Al_{11}O_{17+x/2}$ with x being typically 0.2. Structural studies show that the excess sodium content is compensated for by oxygen ions in interstitial sites.[72–74] It is now clear that β- and β''-alumina are particular examples of a larger family of complex oxides with the general formula, $A_2O{\cdot}nM_2O_3$, where A is most commonly a monovalent alkali cation and M is Al, Fe, or Ga.

The crystal structure of β-alumina with nearly ideal composition was elucidated in 1937, about 30 years before

the discovery of its fast ionic conductivity.[75] It crystallizes with hexagonal symmetry ($a = 5.38$, $c = 22.53$ Å) where the $Al_{11}O_{16}$ layer with basically the same atomic arrangement as that of spinel ($MgAl_2O_4$, *see* ***Oxides: Solid-state Chemistry***) sandwiches the Na–O layer as shown in Figure 6(a). The spinel blocks are connected by Al–O–Al bonds. The connecting oxygens are referred to as bridging or column oxygens. The packing of the O^{2-} in the spinel layer is close (ccp), while quite open in the inter-spinel Na–O 'conduction planes'. In the latter there are three kinds of sites for the Na^+ ions, as shown in Figure 6(b), called the BR (Beevers–Ross), aBR (anti-Beevers–Ross), and mO (mid-oxygen) sites. At low temperature the Na^+ ions are preferentially located at the BR sites. At higher temperature, however, the Na^+ ions are statistically distributed over the three sites, because the potential energy difference among the sites becomes negligible. This situation can be regarded as a 'half-fused' state of the Na^+ lattice. Thus the Na^+ ions can be easily transported in the 2D honeycomb-like pathways around the column oxygens, perpendicular to the c-axis, in a similar way as previously seen in α-AgI.

Sodium β'-alumina has the general formula $Na_{1+x}M_xAl_{11-x}O_{17}$ in which M is a divalent cation such as Mg^{2+}, Ni^{2+}, or Zn^{2+}. A typical composition of sodium β''-alumina is $Na_{1.67}Mg_{0.67}Al_{10.33}O_{17}$. β''-Aluminas have a structure[67] similar to the β-aluminas, except that there are three spinel blocks in the β'- and only two in the β-aluminas. The β''-phase contains a greater number of sodium ions than the β-phase, therefore exhibiting greater conductivity. The excess sodium charge is compensated for by substituting the divalent or monovalent cation into a lattice site normally occupied by Al^{3+}. The relationship between the charge compensation mechanism and ion transport in β''-alumina has been studied by single crystal X-ray diffraction.[77,78]

Ionic conductivity in β- or β''-aluminas is anisotropic, because it takes place along the planes sandwiched between

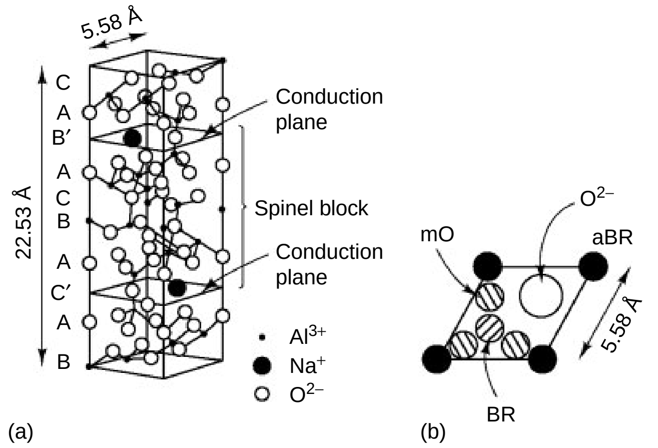

Figure 6 Crystal structure of β-alumina and sodium sites in the conduction plane: (a) unit cell structure; (b) site model of conduction plane. (Reprinted from Ref. 76 © 1978, with permission from Elsevier)

the spinel layers (Figure 6). Ionic conductivity measurements on single crystals of β-alumina show conductivity as large as $\sim 10^{-2}$ S cm^{-1} at 25 °C perpendicular to the crystallographic c-axis,[79] while it is several orders of magnitude lower in the direction parallel to c. The temperature dependence of the ionic conductivity measured for single crystal samples in a wide range from −190 to 800 °C follows Arrhenius behavior with $E_a = 0.16$ eV.[80] Sintered, polycrystalline pressed-pellet samples show isotropic conduction with $\sigma \approx 10^{-3}$ S cm^{-1} at 25 °C.[81] However, conductivities reported for sintered pellets are very diverse and appear to depend strongly on sample density and structure and/or composition at the grain-boundary layer.

Sodium β- and β''-alumina have a fascinating *Ion Exchange* chemistry.[62] The sodium-ion content in a crystal or polycrystalline sample can be replaced by a large variety of monovalent cations, including K^+, Cs^+, Rb^+, Ag^+, Cu^+, and Tl^+. The ion exchange reactions are straightforward. For example, when a small ($\sim 2 \times 2 \times 0.5$ mm^3) crystal of sodium β-alumina is immersed in molten potassium nitrate (KNO_3) at 400 °C, the sodium ions are replaced entirely by potassium ions in a few minutes. Ion exchange takes place also in aqueous solution to yield proton conductors. Of the monovalent cation β- and β''-aluminas, the sodium analogs exhibit the highest ionic conductivity and the lowest activation energy. This is probably because the spacing between the spinel layers is optimal for Na^+ ion mobility. In contrast, Li^+ is too small and too polarizing, so its mobility is diminished, while the others are too large for the conduction path. Tables 1–3 show the ionic conductivity of various β- and β''-aluminas.

Sodium Ion Conductors with Framework Structures. The so-called NASICON (Na super ionic conductors) materials, with the general formula $Na_{1+x}Zr_2P_{3-x}Si_xO_{12}$ ($0 \le x \le 3$), are another important class of Na^+ ionic conductors under intense investigation. These materials may be regarded as solid solutions of $NaZr_2(PO_4)_3$ and $Na_4Zr_2(SiO_4)_3$.[44,85] The host compound, $NaZr_2(PO_4)_3$, has a rhombohedral 3-D network structure built up of corner sharing PO_4 tetrahedra and ZrO_6 octahedra with interconnected tunnels (Figure 7). The conductivity is not very high, because Na^+ occupies one of three sites preferentially. In solid solutions, all the Na sites are occupied partially and the conductivity improves. The maximum conductivity of 2×10^{-2} S cm^{-1} at 300 °C is observed around the $x = 2$ composition of $Na_3Zr_2PO_4(SiO_4)_2$ (monoclinic system) and is comparable to that of Na β''-alumina. The conductivity decreases if x exceeds 2 as the Na sites become increasingly occupied. The synthesis of NASICON materials either by hydrothermal or sol–gel methods (*see* ***Sol–Gel Synthesis of Solids***) requires a final high-temperature (>900 °C) sintering to result in crystalline materials.[86] This high-temperature treatment leads to loss of Na and P content, because Na_2O and P_2O_5 are highly volatile, and an uncertain composition of the final product. Although the conductivity of the

Table 3 Selected proton ionic conductors[57,83,84]

Material	σ_{RT} (Ω^{-1} cm^{-1})	E_a (eV)	Assumed mechanisms
β-$Al_{11}O_{16}(1+x)M_2O$			
$M = NH_4^+$, $x = 0.25$	1.5×10^{-6}	0.5	Ion jump
$M = H_3O^+$, $x = 0.25$	$\sim 10^{-10}$	0.8	Ion jump
β''-$Al_{11-y}O_{17}Mg_yM_{1+y}$			
$M = H^+(H_2O)_2$, $y = 0.66$	7×10^{-6}	0.17	Ion jump + Grotthus
β''-Al_2O_3	$\geq 10^{-3}$	0.2	Surface (liquidlike)
$H_3OZr_2(PO_4)_3$ (NASICON)	$< 10^{-6}$	0.56	Ion jump
Zeolite (NH_4^+)	$0.5/2.5 \times 10^{-5}$	0.36/0.84	
$HSbO_3 \cdot 1-2H_2O$ (pyrochlore)	3×10^{-3}	0.20	
H^+-montmorillonite	$\sim 10^{-4}$	–	
$H_3Sb_3P_2O_{14} \cdot 10H_2O$	4×10^{-3}	0.33	
$H_3AlP_3O_{10} \cdot nH_2O$ (600 K)	10^{-2}	–	
$H_3PW_{12}O_{40} \cdot 28/29H_2O$	$\sim 10^{-4}$	0.15/0.25	
$H_3PMo_{12}O_{40} \cdot 29H_2O$	1.7×10^{-1}	0.15	
$Zr(HPO_4)_2 \cdot nH_2O$	$10^{-3}-10^{-8}$	0.3–0.0	Surface and bulk
$H_3OUO_2AsO_4 \cdot 3H_2O$	5×10^{-3}	0.27	Ion/water jump
$H_3OU_2PO_4 \cdot 3H_2O$			
$UO_2(H_2PO_4)_2 \cdot 3H_2O$	5×10^{-5}	0.20	
$ZrO_2 \cdot 1.75H_2O$	2×10^{-5}	0.34	Surface (liquidlike)
$SnO_2 \cdot 2H_2O$	4×10^{-4}	0.20	Surface (liquidlike)
$CsHSO_4$ ($\sim$250 °C)	10^{-2}		Bulk
$SrCeO_3$:Yb (500 K)	10^{-6}	0.63	Bulk
$BaCeO_3$:Y (500 K)	10^{-2}	0.51	Bulk
$BaZrO_3$:Y (300 K)	10^{-2}	–	bulk

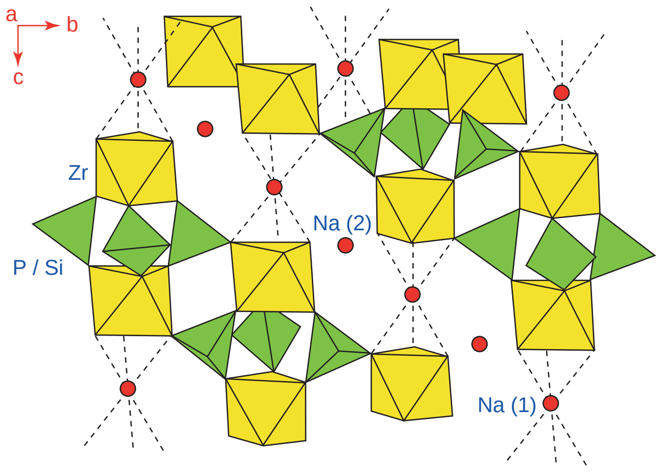

Figure 7 Schematic structure of NASICON

$x = 2$ NASICON is quite comparable to that of the β-aluminas in the temperature range 300–400 °C (the expected working temperature of the Na/S battery), some problems (including the chemical stability to fused Na) still remain for NASICON.

A series of compounds $Na_5MSiO_4O_{12}$ (M = Fe, In, Sc, lanthanides) with NASICON-like structure also exhibit high ionic conductivity; of these, Na_2GdSiO_{12} shows conductivity of 0.26 S cm^{-1} at 300 °C, which is higher than that of NASICON.[87]

3.1.2 *Li^+ Ion Conducting Solid Electrolytes*

Lithium is the most electropositive metal and the lightest; consequently there has been a lot of interest in electrochemical devices using components that include Li metal electrodes and Li^+ conducting solid electrolytes. Hundreds of materials have been studied for applications as potential lithium conducting solid electrolytes. Tables 1 and 2 give representative examples of the more important Li^+ solid electrolytes, some of which are discussed in this section.

All LiX (X = F, Cl, Br, I) form with the NaCl structure. Except for LiI they are all almost perfect ionic crystals and insulators at room temperature. The bonding in LiI is partly covalent because of the large polarizability of I^-,[88] giving it a Li^+ conductivity of 5.5×10^{-7} S cm^{-1} at 30 °C.[89] It is noteworthy that LiI was the first solid electrolyte used practically in a LiI/I_2 (complex) battery in 1972 (e.g. heart pacemaker battery). The many efforts to improve the ionic conductivity of LiX-based solid electrolytes led to the discovery of LiI–Al_2O_3 composites[19] with dramatic improvement of the conductivity. Merely dispersing fine particles of Al_2O_3 in LiI (at an experimentally determined optimal concentration) improves the conductivity by two orders of magnitude. The mechanism of conductivity in LiI–Al_2O_3 composites is not certain, but it is explained by the formation of a space-charge layer consisting of either Li^+ ion vacancies or interstitials at the interface between the host and the dielectric particles of Al_2O_3.[90] LiI–Al_2O_3 is one of the few solid electrolytes that has been put to practical

use. Moreover, the dispersion effect found in this system is also useful for developing other useful high-conductive solid electrolytes, because the effect should be universally applicable to other/similar component systems.

Complex metal halides with the inverse spinel structure (*see* ***Oxides: Solid-state Chemistry***), Li_2MCl_4 with M = Mg, Cr, Mn, Fe, Co, and Cd, are also examples of halide-type Li^+ conductors; these materials have conductivities of the order of 10^{-2} S cm^{-1} at ∼300 °C.[91]

Lithium nitride, Li_3N, is an ionic crystalline compound; it is synthesized by the direct reaction of Li metal with nitrogen. The structure of Li_3N consists of alternating layers of $Li(2)_2N$ and Li(1).[92] Conduction takes place primarily in the Li(1) layers, as demonstrated by single crystal experiments. The conductivity at room temperature is $\sim 10^{-3}$ S cm^{-1} in the *ab* plane and $\sim 10^{-5}$ S cm^{-1} in the direction along *c*, while in polycrystalline samples it is $\sim 10^{-4}$ S cm^{-1}. Thus the conductivity of Li_3N is several orders of magnitude higher than those of the LiX-based materials. However, its application is limited by its low decomposition voltage 0.445 V (i.e. free energy of formation of Li_3N), since a battery with an emf greater than this value, at least theoretically, cannot be constructed. To overcome the decomposition problem, various systems based on Li_3N have been investigated. Of these, a Li_3N–LiI–LiOH (1:2:0.77 in molar ratio) ternary system, prepared by sintering the components at 500 °C in N_2 for 3 h, is the most successful. This composite has nearly as high a conductivity as Li_3N, and its decomposition voltage is as high as 1.6–1.8 V.[93]

In Table 2, the Li^+ ionic conductivities of some representative compounds based on Li_4SiO_4 and its solid solutions are shown. The highest conductivity is exhibited by those phases that crystallize with the γ-Li_3PO_4 structure[94] with orthorhombic symmetry. In this structure the oxygens are packed in an array intermediate between hcp and tetragonal packing (*see* ***Oxides: Solid-state Chemistry***), with the cations distributed over various tetrahedral sites. These phases are sometimes also called lithium ion conducting solid electrolytes (LISICONS). Li^+ diffusion can occur via vacant interstices. However, in the ideal γ-Li_3PO_4 structure all the Li^+ are used to build the framework structure; hence the ionic conductivity is only significant at very high temperatures. Li^+ ion mobility can be facilitated by introducing vacant interstices by aliovalent substitutions. Thus the highest conductivity is achieved in xLi_3PO_4–$(1-x)Li_4SiO_4$, which may be formulated in the γ-type defective structure as $Li^*_{1-x}Li_3Si_{1-x}P_xO_4$, where Li* corresponds to the mobile Li ions. The conductivities are maximized (4×10^{-6} S cm^{-1} at 25 °C) when $x = 0.5$, which means that only half of the cation sites in the conducting plane are occupied.

LISICON, $Li_{14}Zn(GeO_4)_4$, is an interstitial solid solution based on the HT γ-Li_2ZnGeO_4 structure with the substitution mechanism 2Li ⟷ Zn.[44,95] $Li_{14}Zn(GeO_4)_4$ has very high conductivity at high temperature (HT) (0.13 S cm^{-1} at 300 °C), but at room temperature (RT) the conductivity is low 10^{-7} S cm^{-1} owing to lithium ion trapping. Moreover, this composition is thermodynamically unstable below ∼630 °C and reacts with atmospheric CO_2 and violently with molten Li.[96] However, the composition $Li_3Zn_{0.5}GeO_4$ in this system retains its high conductivity at HT and is thermodynamically stable down to RT.

A variety of other γ-type phases with high Li^+ conductivity are derived from the Li_3XO_4 phases with X = P, As, or V. The substitution mechanisms are of the type X ⟷ (Si, Ge, Ti) + Li, and lead to the creation of interstitial Li^+ ions which are responsible for the high ionic conductivity. The highest conductivity at room temperature, 4×10^{-5} S cm^{-1}, is found in the series $Li_{3+x}(Ge_xV_{1-x})O_4$.[97] Neutron diffraction has been used to locate the interstitial lithium ions, to determine their site occupancy, and correlate the high ionic conductivity with the connectivity of the interstitial sites.[98]

Li_2SO_4 and related materials have been studied for many years by Kvist, Lunden, and coworkers.[99] The high temperature, cubic, α-form of Li_2SO_4 has very high ionic conductivity, ∼ 1 S cm^{-1} between 575 °C and its melting point (879 °C), which makes this potentially a very interesting solid electrolyte. The low-temperature, monoclinic β-form of Li_2SO_4 has much lower conductivity. Many attempts have been made to reduce the temperature of the $\beta \rightarrow \alpha$ transition by various substitutions, but without much success so far. There is little change in the ionic conductivity of Li_2SO_4 upon melting; it appears that the Li^+ ions in crystalline α-Li_2SO_4 are in an essentially liquidlike environment. The precise mechanism of conductivity in Li_2SO_4 is a topic of some current controversy.[100–103] The key issue concerns the rotation of the $SO_4{}^{2-}$ groups: are they rigidly fixed in the structure, or do they undergo small rotational motion, or are they in free rotational motion? There is evidence for rotational disorder of the sulfate groups from neutron diffraction, which suggests rapidly reorienting $SO_4{}^{2-}$ ions which effectively gate the movement of Li^+ ions, that is, a 'paddle-wheel' mechanism,[103] however report of the increase of conductivity with substitution of $WO_4{}^{2-}$ for $SO_4{}^{2-}$ is consistent with the interpretation of fast ion transport in Na_2SO_4-based compounds via a percolation-type mechanism where lattice free volume plays a predominant role.[101,102]

Li β-alumina, prepared from Na β-alumina by ion exchange in LiCl at 650 °C, has the one of the highest Li^+ conductivities reported in a crystalline material, 3×10^{-3} S cm^{-1} at 25 °C in a single crystal sample.

Some of the other important Li^+ solid electrolytes with reasonably high conductivities include: $Li_{5+x}Al_{1-x}Si_2O_8$ with a γ-$LiAlO_2$ structure;[104] lithium analogs of NASICON, $Li_{1+x}Zr_2Si_xP_{1-x}O_{12}$; substituted framework silicates, $LiAlSiO_4$ with good 1D Li^+ conductivity;[105] $Li_4B_7O_{12}$(Cl,Br) and $Li_5B_7O_{12}S$ with 3D cagelike structures;[106] $Li_{5+x}M_{1-x}M'_x$ O_4 (M = Al, Ga; M′ = Zn) phases with the antifluorite structure and high vacancy contents.[107]

A recent review article by Sebastian and Gopalakrishnan[48] surveys high lithium ion conducting oxides based on ionic

conductivity, redox insertion/deinsertion and ion exchange properties. In addition to the wide variety of compounds discussed above, the review includes compounds with mixed ionic and electronic conductivity. The survey shows that considerable lithium ion mobility occurs in close packed (CP) structures including rock salt type (α-AMO_2, A = Li, M=V, Cr, Mn, Co, Ni); Figures 8 (a–c). It is now well established that the β and γ polymorphs of these compounds, where the A and M cations are not ordered in the 111 planes of the cubic close packed (CCP) oxide lattice (Figure 8c) do not undergo facile ion exchange are poor ion conductors in general, and also do not undergo Li insertion/deinsertion readily. Hence the correlation between a layered structure, ion exchange, and redox insertion/extraction in α-AMO_2 phases is clear. Other examples of CP oxides with high Li mobility are the spinels, namely AB_2O_4 compounds in which the A and B cations partially occupy tetrahedral and octahedral sites of the CP lattice of oxygens (Figure 8(d)). Typically Li^+ ions in partially occupied tetrahedral sites can diffuse in the 3D pathways provided by the interconnected empty tetrahedral and octahedral sites. $LiMn_2O_4$ spinel, a mixed conductor and various substituted analogs are currently researched for application as cathode material in lithium batteries.[108] Other CP oxides with hexagonal close packed (HCP) structures with high Li^+ion mobility include $LiMO_3$ phases (M = Nb, Ta, Sb), the trirutiles, LiMM'O_6 (M = Nb/Ta; M′ = W/Mo), $LiFePO_4$ and the above described LISICONS, Li_2ZnGeO_4 and Li_3VO_4 solid solutions.

3D (Li,La)TiO_3 perovskite-type phases, first reported by Belous *et al.*[109] exhibit high Li^+ion conductivity, $\sim 1 \times 10^{-3}$ S cm^{-1} at room temperature.[110] This remarkable result initiated extensive research in these A-cation deficient ABO_3 perovskite materials. In the perovskite structure, a 3D network structure is built up by corner sharing BO_6 octahedra where the A cations occupy the 12 coordinated interconnected interstitial sites (Figure 9). Thus, in (Li,La)TiO_3, the Li and La ions partially occupy the A site, which provides the 3D pathway for the high mobility of Li^+ ions. Stramare *et al.*[82] in a recent review survey most of these materials and show that $Li_{3x}La_{2/3-x}\square_{1/3-2x}TiO_3$ with $x = 0.1$ has the highest bulk lithium-ion-conductivity, σ(RT) $\sim 1 \times 10^{-3}$ S cm^{-1} and $E_a = 0.40$ eV in this series. A major problem with the possible use of these materials as solid electrolytes in lithium batteries is the reduction of Ti^{4+} at relatively low potentials (∼2V), with the onset of electronic conductivity and short-circuiting. Thus analogous materials with similar high Li mobility, but suitable nonreducible B cations are necessary for applications. In an effort to achieve that various compositions including LiABB'O_6 and LiA_2B_2B'O_9 with A = Ca, Sr, Ba; B = Ti, Zr; and B′ = Nb, Ta were investigated.[48]

NASICON ($Na_3Zr_2PSi_2O_{12}$) is a well-known framework oxide (Figure 7) with high Na^+-conductivity.[111] The substitution of $2Zr^{4+} \rightarrow M^{5+} + M^{3+}$ in NASICON is possible, yielding A $M^{5+}M^{3+}(PO_4)_3$ (A = Na, Li; M^{5+} = Nb, Ta; M^{3+} = Ti, V, Cr, Fe, Al). An investigation of the ionic conductivity of the Li derivatives showed that $LiTaAl(PO_4)_3$ exhibits the

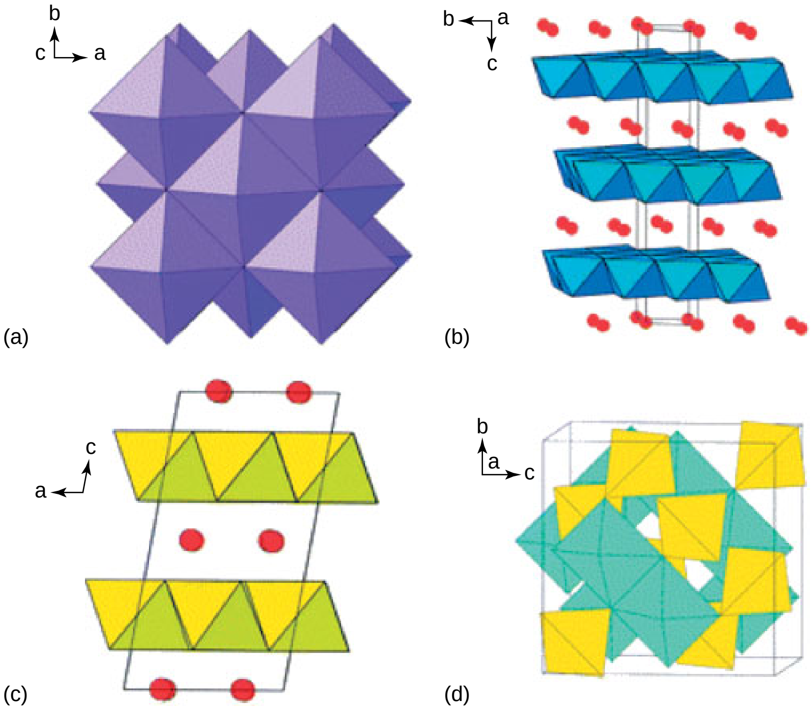

Figure 8 Structures based on cubic close-packed anion arrays: (a) rocksalt; (b) a-$NaFeO_2$; (c) b-Li_2SnO_3; (d) spinel. In (b) and (c), the red circles denote interlayer alkali metal ions.[48] (Reproduced by permission of Royal Society of Chemistry)

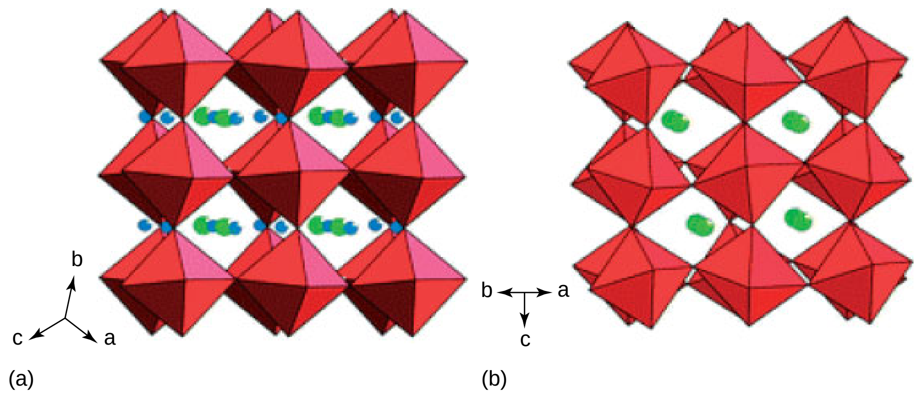

Figure 9 Structures of perovskite lithium ion conductors: (a) (Li, La)TiO_3; (b) $LiCa_{1.65} * **_{0.35}Ti_{1.3}Nb_{1.7}O_9$. ($\sigma_{800\,°C} = 3.1 \times 10^{-3}$ S cm^{-1}; $E_a = 0.71$ eV). In (a), the green and blue circles denote La and Li, respectively. In (b), the green circles denote Li and Ca in the $GdFeO_3$ structure.[48] (Reproduced by permission of Royal Society of Chemistry)

highest conductivity, $\sim 1 \times 10^{-2}$ S cm^{-1} with $E_a = 0.47$ eV.[48] Recently Goodenough *et al.* investigated various transition metal analogs and found that $Li_2NaV_2(PO_4)_3$ and $Li_3V_2(PO_4)_3$ insert/deinsert Li at 3.7 V.[112,113] The NASICON framework is indeed unique in that it exhibits all three properties: high ionic conductivity, ion exchange, and redox insertion/extraction, that characterize high Li mobility in solids.

3.1.3 Proton Conductors

Development of good proton conductors has recently acquired great significance, primarily because of their potential application as solid electrolytes in fuel cells, batteries sensors and other electrochemical devices. In general, the term proton conductor refers not only to H^+ ion transport, but also includes materials with complex ion transporting groups such as $NH_4{}^+$, H_3O^+, OH^-, and so on. There have been many reviews on the subject[9,83,114–120] including several International Conference Proceedings.[121–128]

Mechanism. Because of the small radius of the free proton, 'isolated' H^+ ions are not present in solids under equilibrium conditions. Owing to its strongly polarizing power, H^+ is covalently bonded to one or two electronegative atom/ions of its surroundings, for example, hydrogen bonds. Tunneling effects may explain some of the low-temperature conductivity of proton conductors, for example, $HTaWO_9{\cdot}H_2O$;[129] however, at room temperature and above, thermally activated processes will dominate the conductivity. An excellent discussion of the different transport modes has been given by Kreuer *et al.*[84,130,131] At least three bonding situations for the proton are relevant: (1) the acceptor site may be an ion of the immobile lattice, for example, formation of a hydroxo group; (2) the proton may be attached to a mobile ion, for example, oxide ion, thus forming an OH^- group; (3) the proton is attached to a mobile molecule, for example, water or ammonia, thus forming a hydronium ion or ammonium ion. The question is: how is the proton delivered from one site to another in the direction of the field? In the first case, proton conduction can only take place by a simple hopping mechanism of the proton to an adjacent acceptor site, followed by the rotation of the new H-acceptor bond in the direction of the field. The mechanism may be described as a 'point defect migration' with rapid exchange of cations between filled and empty sites in a disordered cation sublattice. This mechanism, sometimes referred to as the Grotthuss, or free-proton mechanism (Figure 10). This is the accepted mechanism for proton conduction in the high-temperature (>500 °C) proton conductors such as the proton-containing doped pervoskite-type phases, $MCeO_3$ (M = Ca, Sr, Ba), $BaZrO_3$ and $MTaO_3$.[84]

When the proton is attached to a mobile ion, two modes of transport have been proposed. (1) Polyatomic ions like H_3O^+ or $NH_4{}^+$ may migrate by a simple jump from site to site in the lattice, as has been claimed in the β-aluminas[132] and in the zeolites.[133] (2) A more involved mechanism based on the simultaneous diffusion of two types of polyatomic units, the so-called 'vehicular' mechanism, was suggested

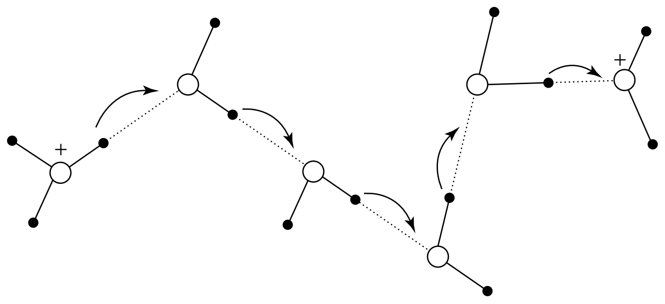

Figure 10 Proton conductivity according to the Grotthuss mechanism. (Reprinted from Ref. 131 © 2003, with permission from Elsevier)

by Kreuer *et al.*[134] The proton travels through the lattice on a 'vehicle', which may itself be neutral or charged; there must be a counter diffusion of the vehicles, for example, H_3O^+ in one direction and H_2O in the opposite direction. The mechanism involving polyatomic ions can be often ruled out by structural considerations, that is, if the bottlenecks are too small to allow the passage of the relatively large polyatomic ions. Positive indication for transport mechanism involving polyatomic species is the absence of an *Isotope Effect* when the conductivity of the protonic and the fully deuterated analogs are compared. If H^+ and D^+ are the mobile species, the conductivities should be approximately in the ratio of $\sqrt{2}:1$. If this is not the case, or a very small isotope effect is observed, then it may be assumed that the H/D is part of a larger ion and the mass difference is 'drowned'.

Surfaces of crystals and the grain boundaries may have disordered regions where proton transport is facilitated. Adsorbed water or electrolyte solution trapped between the grains will also increase the conductivity and give rise to false conclusions concerning the solid-state nature of conductivity. Surface or liquidlike conductivity has a low activation energy ($E_a \approx 0.1–0.4$ eV), approaching the E_a of aqueous acidic solutions (0.1–0.15 eV)

Materials. In Table 3, the conductivities of selected proton conducting materials are presented. There are a diversity of proton conducting materials, sometimes classified according to the mechanism of H^+ motion as bulk conductors and surface conductors.[135] Many solid protonic conductors have liquid, or liquidlike regions, or layers of water, and thus substantial water contents. Such materials maybe borderline between solid and liquid phase, or maybe two-phase systems. The materials with the highest protonic conductivities are found in the group of heteropolyacid hydrates, for example, $H_3[PW_{12}O_{40}]\cdot 29H_2O$, which has a conductivity of 2×10^{-2} S cm^{-1} at 25 °C.[9] This material has a diamond-type lattice of clustered ions, $[H_3\cdot 29H_2O]^{3+}$ and $[PW_{12}O_{40}]^{3-}$, interpenetrated by each other in which a hydrogen bonding network spreads over the entire crystal. The high conductivity may be due to H^+ transport via molecular H_3O rotation. The Mo analog has similar properties. Hydrogen uranyl phosphate (HUP, $HUO_2PO_4\cdot 4H_2O$) and arsenate (HUAs, $HUO_2AsO_4\cdot 4H_2O$) are layered materials and also among the best proton conducting hydrates. The room temperature conductivities are high ($\sim 10^{-3}$ S cm^{-1}) and are attributed to H^+ migration through a hydrogen bonding network in the layers similar to that in $H_3[PW_{12}O_{40}]\cdot 29H_2O$.[9] In HUAs there is evidence for direct diffusion of H_3O^+. The α-$M(HPO_4)_2\cdot nH_2O$ (M = Zr, Ti, Ce) are another class of layered materials with relatively high proton conductivity ($\sim 10^{-3}$ S cm^{-1} at 25 °C) that have been investigated thoroughly.[136]

The close connection between ion exchange properties of solids and solid electrolyte behavior was stressed by England *et al.*,[135] who were also among the first to explain proton conduction in particle hydrates, such as $ZrO_2\cdot nH_2O$ and $SnO_2\cdot nH_2O$, where adsorbed hydrous layers on each grain provide the proton conductive medium.

The β- or β''-aluminas exhibit H^+ conductivity when the Na^+ ions are replaced by H_3O^+ or $NH_4{}^+$ by ion exchange. Of these materials, the best conductivity of 10^{-4} S cm^{-1} at 25 °C is found in $(NH_4{}^+)(H_3O^+)_{2/3}Mg_{2/3}Al_{31/3}O_{17}$, derived from the β''-phase.[137] Ammonium exchanged zeolites (*see* ***Zeolites***) also show high H^+ conductivity. One of the highest room temperature conductivities, 2×10^{-3} S cm^{-1}, has been reported for the fully hydrated NH_4-zeolite-A.[138] A dehydrated H-analog of NASICON, prepared by deammoniation of a hydrothermally prepared $NH_4Zr_2P_3O_{12}$ sample, also shows excellent proton conducting properties for potential applications.[139] In these network structures sufficiently large bottlenecks allow the direct diffusion of $NH_4{}^+$ or H_3O^+ charge carriers.

Most proton conducting solids until fairly recently were inorganic hydrates and stable conductivities much above 150 °C in such materials are seldom found (i.e. after the water is lost, conductivity disappears); moreover, the conductivity is highly dependent on the water content, including the surface water of the material. Thus there is a need to develop proton conductors for various applications in the higher temperature range, which are not dependent on water content.

The most prominent high-temperature proton conducting materials are the perovskites, of doped ABO_3 type (*see* ***Oxides: Solid-state Chemistry***), exemplified by Yb-doped $SrCeO_3$, first studied by Iwahara and his group since 1980.[140] When a trivalent ion replaces Ce^{4+}, the material may be formulated as $SrCe_{1-x}Yb_xO_{3-\delta}$ under dry conditions in air, but when heated in water vapor it becomes $SrCe_{1-x}Yb_xH_yO_{3-\delta}$ with $\delta = x/2$ and $y = x$. A typical dopant concentration is $x = 0.05$. The value of y is dependent on the synthetic conditions and the x content. The material is a p-type semiconductor in air at ~1000 °C; however, in a H_2O atmosphere the conductivity is $\sim 10^{-2}$ S cm^{-1} at 900 °C and occurs by protons. Thus protonic defects are formed by the dissociation of gaseous water into a hydroxide ion and a proton; the OH^- ion fills an oxide ion vacancy and the H^+ covalently attaches to a lattice oxygen. This reaction may be represented according to: $H_2O + h^+ \leftrightarrow 2H^+ + 0.5O$, or in Kröger–Vink notation as: $O_O + V^{\bullet\bullet}{}_O + H_2O \leftrightarrow 2OH_O$, where O_O is a normal oxygen site, $V_O^{\bullet\bullet}$ is an oxygen vacancy, and $OH_O^{\cdot}$ is an OH ion in the normal oxygen site. In general, this reaction is exothermic, so protons rule at low temperatures and oxygen vacancies at high temperatures. Transport in the doped $M^{II}CeO_3$ perovskites by H^+ ions was well established by the work of Iwahara[140] and others.[141,142] In the past decade, a great deal of work has been carried out on a large variety of substituted proton conducting oxides mostly with the perovskite structure.[84] Figure 11 shows that one of the best proton conductors is Y-doped $BaCeO_3$; this perovskite has the highest molar volume and compared with the $SrCeO_3$ analog, its deviation from the ideal cubic perovskite structure is smaller. Data for $Ba_2YSnO_{5.5}$[143] and

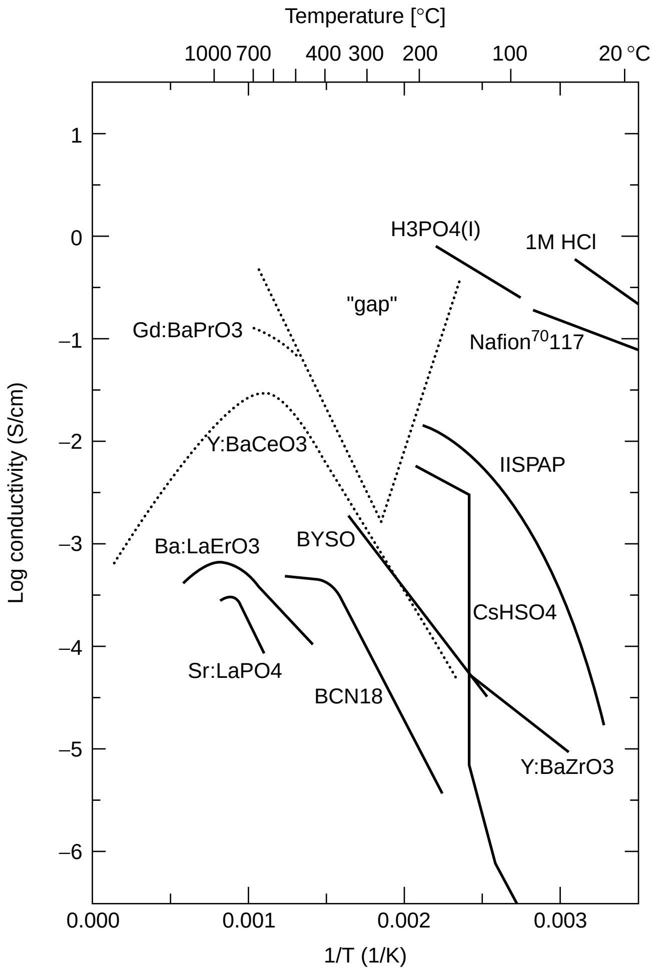

Figure 11 Selected literature data for proton conductivity as a function of inverse temperature. Imidazole-intercalated sulfonated polyaromatic polymer (IISPAP); $Ba_2YSnO_{5.5}$ (BYSO); $Ba_3Ca_{1.18}Nb_{1.82}O_{8.73}$ (BCN18), the curve for Y:$BaCeO_3$ is a calculated estimate. The interpretation of the conductivity of Gd:$BaPrO_3$ as protonic is somewhat ambiguous at present. For further explanation and discussion, see Ref. 119. (Reprinted from Ref. 119 © 1999, with permission from Elsevier)

Y-doped $BaZrO_3$ show that these compete in terms of proton conductivity with Y-doped $BaCeO_3$. The principal features of the transport mechanism are rotational diffusion of the protonic defect and proton transfer towards a neighboring oxide ion. The first has been shown experimentally[144] and by quantum MD simulations[145] to be fast with activation barriers below 0.1 eV, which suggests that the proton transfer reaction is the rate-limiting step. On the other hand, the strong, red-shifted OH-stretching absorptions in the IR spectra are indicative of strong hydrogen bond interactions, which favor fast proton transfer reactions rather than fast reorientation processes, the latter requiring the breaking of such strong bonds.[146]

It is clear from Figure 11 that, at present, proton conductors do not parallel the best oxygen ion conductors (i.e. $\sigma > 1\ \mathrm{S\,cm^{-1}}$).

However proton conductors, in general, work at substantially lower temperatures and may offer the highest conductivities at intermediate or low temperature. Nevertheless, there are no solid proton conductors working in the range between ~200–500 °C (Figure 11). This range is the most desirable operating temperature for both chemical processes and energy conversion processes. Thus finding new materials with proton conductivity in this temperature range is critical for practical applications for example in fuel cells.

Solid acid compounds with a fixed crystallographic proton including $CsHSO_4$, $CsHSeO_4$ and CsH_2PO_4 and CsH_2AsO_4 have been intensely investigated recently as inorganic proton conducting solid electrolytes for low temperature applications in fuel cells and other devices. These compounds are made up of hydrogen-bonded tetrahedral oxyanions, (i.e. SO_4, SeO_4, PO_4, and AsO_4), and metal cations (e.g. Cs), which provide overall charge balance to the hydrogen bonded network. Several solid acids exhibit an ordered arrangement of hydrogen bonds at room temperature and, upon slight heating, become structurally disordered. A typical example is $CsHSO_4$, which transforms from a monoclinic to a tetragonal structure at 141 °C.[147] Accompanying this transformation is an increase in proton conductivity of two to three orders of magnitude, reaching values as high as $10^{-2}\ \mathrm{S\,cm^{-1}}$. Recently Haile and her group have demonstrated that CsH_2PO_4 is a 'superprotonic' conductor, which does not decompose, or become reduced (as do the corresponding S and Se analogs) up to ~270 °C, and have many advantages over the proton conducting polymer film electrolyte Nafion used in similar fuel cells.[148]

3.1.4 Multivalent Ion Conductors

Divalent cations (as monovalent ones) also can exchange for sodium in β-alumina, but the reactions are slow, and the resulting divalent β-aluminas are not good ionic conductors. However, cation exchange of divalent ions in β''-aluminas is much more rapid; the ionic conductivity of divalent β-aluminas at room temperature can be as high as $10^{-3}\ \mathrm{S\,cm^{-1}}$ for Pb^{2+}-β-alumina, although most are in the range of $10^{-7}\ \mathrm{S\,cm^{-1}}$ (e.g. Ba^{2+}, Ca^{2+}, among others).[149] The sodium ions in β'-alumina can also be replaced by trivalent cations, such as the lanthanides. For example, almost total replacement of Na^+ by Eu^{3+} occurs in a small crystal of β''-alumina by heating it in $EuCl_3$ powder at 650 °C (mp of $EuCl_3$, 850 °C) for 24 h.[150] Similar ion exchange via vapor phase takes place between β''-alumina and rare earth chlorides such as $NdCl_3$, $EuCl_2$, $SmCl_3$, or $TbCl_3$.

Although the conductivity of the trivalent-ion β''-aluminas is too low for solid electrolyte applications (e.g. batteries, sensors), they have potential use in optics, phosphors, and lasers because they can serve as single crystal or powder hosts for the optically active lanthanide ions. For example, Eu^{3+}-β''-alumina emits red luminescence when excited by UV rays.[151] A Nd^{3+}-β''-alumina single crystal shows luminescent

characteristics similar to those of YAG:Nd^{3+}.[152] The Er^{3+} and Ho^{3+} analogs have similar encouraging laser application properties. Another example of controlled valence and composition by ion exchange techniques in β''-alumina is the doping of this material by Cu^{I}, which emits in the blue–green region of the spectrum. Cu(I) with another 'codopant' ion (e.g. Ca^{2+}, Ag^{+}) produces materials that exhibit tunable emission over much of the visible spectrum.[153] These and similar promising optical data are accelerating the development of phosphors and/or laser materials based on rare earth incorporated β''-aluminas.[154]

The multivalent β''-aluminas are the first family of high-conductivity solid electrolytes with multivalent cations. They demonstrate that fast ion transport is not limited to a few monovalent cations, but occurs with many different cations.

More recently Adachi and Imanaka[155–158] have been investigated a variety of network oxides with tri- and tetra-valent ion mobility. For example the conductivity, $\sigma_{600\,°C} \sim 10^{-5}\,S\,cm^{-1}$ of trivalent cations in NASICON-like compounds, $R_{1/3}Zr_2(PO_4)_3$ (R = Sc^{3+}, Y^{3+}, Er^{3+}, Tm^{3+}, Lu^{3+}) was observed;[159] similarly in solid solutions of $Sc_2(WO_4)_3$-$Gd(WO_4)_3$, Sc^{3+} and Gd^{3+} ions exhibit $\sigma_{600\,°C} \sim 6 \times 10^{-5}\,S\,cm^{-1}$ (Ref. 160); and in $MNb(PO_4)_3$ (M = Zr^{4+}, Hf^{4+}), the tetravalent ions show $\sigma_{600\,°C} \sim 10^{-4}\,S\,cm^{-1}$ (Ref. 161).

3.2 Anion Conductors

Propagation of an ion in a solid involves the diffusion of a rather large species through a structure, which is densely populated. Therefore the motion of smaller ions, the cations, is expected to be more likely than those of the larger anions. While this indeed is the trend, fast anionic conduction in solids can be observed at high temperature with conductivities of the order of $1\,S\,cm^{-1}$.

Fast anionic conduction is found mainly in solids of the fluorite (CaF_2) and fluorite-related structures. It is also observed in solids with the perovskite, YF_3, tysonate (LaF_3), and simple cubic structures (for these structures, *see* ***Oxides: Solid-state Chemistry*** and ***Fluorides: Solid-state Chemistry***). The smaller anions O^{2-} (r ~ 1.4 Å) and F^- (r ~ 1.2 Å) show the fastest conduction; however, good anionic conductivity is also found for Cl^-(r ~ 1.7 Å), Br^-(r ~ 1.8 Å), I^-(r ~ 2.1 Å), and for S^{2-}(r ~ 1.7 Å).

The highest anionic conductivity is found in δ-Bi_2O_3 and doped Bi_2O_3, with an oxygen-deficient fluorite structure, with $\sigma \approx 1\,S\,cm^{-1}$ at 800 °C and $E_a = 0.47\,eV$. The best F^- ion conductors are $RbBiF_4$, $KBiF_4$, and $Pb_{0.75}Bi_{0.25}F_{2.25}$ with $\sigma \approx 1\,S\,cm^{-1}$ at ~300 °C and $E_a \approx 0.39\,eV$.

A number of good reviews have been published in the past several years on oxide ion conductors, and they provide more detail on this subject.[43,46,162–166]

The materials that display oxygen ion conductivity have highly unusual crystal structures with partially occupied oxygen sites and, hence, the number of oxides we need to consider is relatively small. Figure 12 shows selected oxide ion conductors (with the exception of $BaZr_{0.9}Y_{0.1}O_3$ which is a proton conductor as discussed above) that are the focus of major research and development for application as electrolyte membranes in fuel cells.

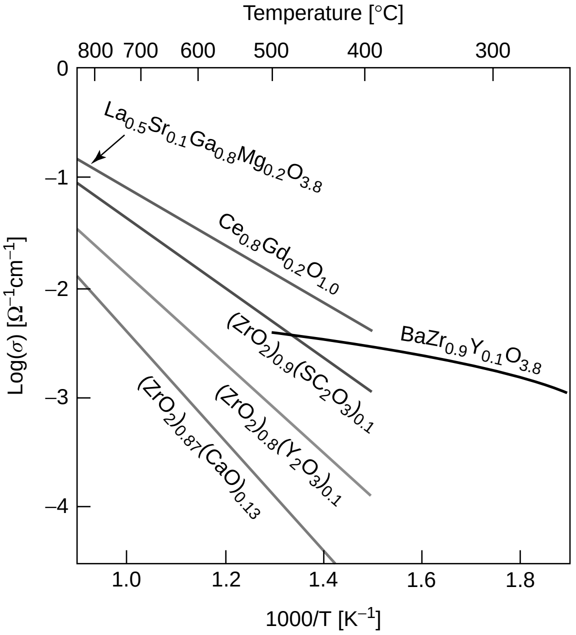

Figure 12 Conductivities of selected oxides as a function of temperature. Doped ceria and zirconia, and lanthanum gallate are oxide ion conductors, while barium zirconate is a proton conductor (From S.M. Haile Materials for fuel cells, *Materials Today* **6**: 24–29 (March 2003)). (Reprinted from Ref. 148. © 2003, with permission from Elsevier)

In order to obtain a material that is a 'pure' oxygen ion conductor (a solid electrolyte), the level of any electronic contribution to the total electrical conductivity must be negligible. This, again, is not easy to achieve. Even very low concentrations of electronic carriers will give rise to a significant electronic component because of the very high mobility of electrons and holes in comparison with the ionic mobilities. Most oxygen ion conductors are, in fact, mixed conductors and only very few are capable of being classed as 'pure' ionic conductors.

3.2.1 *Oxide Ion Conductors in Fluorite-type Solid Solutions*

The fluorite oxides are the classical oxygen ion conducting oxide materials; the study of these materials as electrolytes derives from the early investigations of Walther Nernst ~1900. The fluorite structure illustrated in Figure 13 is best described for the purposes of the present discussion as a primitive cubic array of anions (O^{2-}) with half the cube centers occupied by cations; the latter form a face-centered-cubic (fcc) arrangement of the cation sublattice. The unoccupied cube centers play a central role in the defect physics and ionic conductivity of fluorites, because they

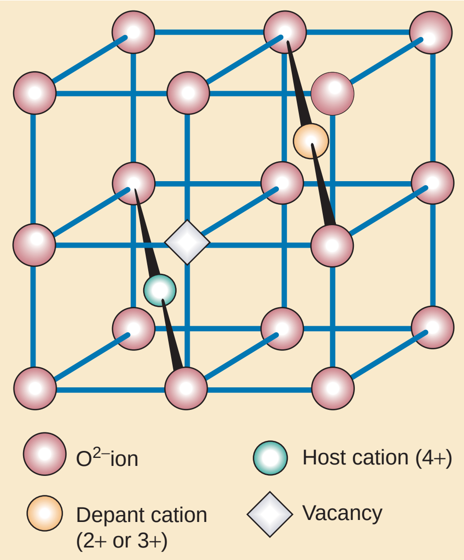

Figure 13 The ideal fluorite, AO_2 oxide structure; oxides with this structure have high-ionic conductivity when the host cations (such as A = Zr^{4+} or Ce^{4+}) are replaced by lower-valent cations such as Y^{3+} for Zr^{4+} in YSZ and Gd^{3+} for Ce^{4+} in $Ce_{1-x}Gd_xO_{2-x/2}$. (Ref. 167. Reproduced by permission of Nature Publishing Group (www.nature.com))

provide effective sites for the interstitial ions. It is indeed the availability of these sites that leads to anion Frankel disorder, responsible for the anion mobility in the fluorite structure. Anion transport in fluorites can be affected by both vacancy and interstitial mechanisms. A combination of experimental studies based on conductivity, NMR, and diffusion measurements and calculations established that E_a for vacancy migration (~0.40 eV) is about half of that for interstitial motion. Thus high mobility of anion vacancies is the most important single factor leading to fast ionic conductivity in anion conductors with the fluorite structure.

Of the oxides, ZrO_2, HfO_2, CeO_2, PrO_2, TbO_2, ThO_2, UO_2, PuO_2, δ-Bi_2O_3 with the fluorite-type structure, CeO_2, and ThO_2 form with the cubic fluorite structure shown in Figure 13. The other oxides form with a distorted fluorite-type lattice. These oxides form solid solutions with alkaline earth and rare earth oxides over a fairly wide range of composition. ZrO_2 is a refractory material with a melting point of 2700 °C; in its pure form, it is monoclinic at room temperature, tetragonal at ~1500 °C, and cubic only at higher temperatures. However, incorporation of as little as 8% (mol) of CaO in $Zr_{1-x}Ca_xO_{2-x}$ $(V^{\bullet\bullet}{}_O)_x$, or ~ same doping by Y $Zr_{1-x}Y_xO_{2-x/2}$ $(V_O^{\bullet\bullet})_{x/2}$ stabilizes the cubic fluorite structure. The ZrO_2–CaO or ZrO_2–Y_2O_3 system is the so-called calcia- or yttria-stabilized zirconia (CSZ or YSZ). Thus, substitution of a divalent cation (Ca^{2+}) for Zr^{4+} generates x amount of vacancies, while a trivalent cation (Y^{3+}) will generate $x/2$ vacancies in these fluorite-type oxides. The major reason for the high ionic conductivity of fluorite-type solid solutions is the high concentration of vacancies ($V_O^{\bullet\bullet}$), via solid solution formation, through which O^{2-} ion can diffuse.

These solid solutions have been prepared by many synthetic routes; for example, by firing appropriate amounts of the component oxide mixtures at high temperature (>1000 °C). A transparent sintered, high-density body of yttria-stabilized zirconia can be obtained by sintering a coprecipitated powder of $Zr(OC_3H_7)_4$ and $Y(OC_3H_7)_3$ at 1000 °C for ~30 min.[168]

The oxygen ion transport properties of CeO_2 have long been known; the ionic conductivity of Gd-doped CeO_2 ($Ce_{1-x}Gd_xO_{2-x/2}$; GDC) is significantly greater than that of the conventional solid oxide fuel cell (SOFC) electrolyte, yttria-stabilized zirconia (YSZ; Figure 12), but CeO_2 had not been considered viable for fuel cell applications because of its high electronic conductivity. However, at temperatures below ~700 °C (and at 10^{-18} atm O_2 partial pressure), the ionic transference of CeO_2 is greater than ~0.9, a value that results in good fuel cell efficiency.[169]

A simple analysis would predict that the conductivity should be a maximum when half the oxygen lattice sites are vacant; however, this is not the case. In Figure 14, the effect of various rare earth dopants on the properties of CeO_2 show that the ionic conductivity is highly dependent on the ionic radius of the dopant. Moreover, the conductivity increases and then decreases across the rare earth dopant series[170] from Yb to La, peaking at Gd (Figure 14). A similar observation has been made for Zr, with the peak occurring at Sc. It is clear that the conductivity drops with relatively modest additions of the rare earth ion, when the vacancy concentration is only a few percent.

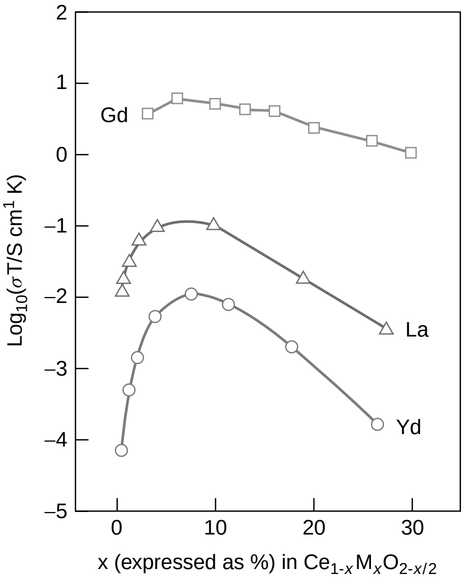

Figure 14 The isothermal conductivity of selected $Ce_{1-x}M_xO_2$ at ~200 °C. (Reprinted from Ref. 171. © 2003, with permission from Elsevier)

This conductivity maximum is common to all the classical ionic conductors studied and has been the subject of debate. However it is now well established, from a combination of atomistic modeling[172,173] and experimental studies,[174] that the maximum is caused by the interaction of the substitutional rare earth ion and the oxygen vacancy. Originally, it was thought that this was a Coulombic effect, as both the substitutional ion and the vacancy act as if they were oppositely charged species within a neutral lattice. However, if this were the case, then all substitutional ions of the same charge would give rise to exactly the same level of conductivity, which is clearly not the case as Figure 14 sOChows. The modeling has clearly shown that the major interaction between these point defects is through the elastic strain introduced into the crystal lattice by a mismatch between the size of the dopant ion and the ion that it replaces. Thus to make good oxygen ion conductors, it appears that in addition to introducing vacancies, leaving the crystal lattice as undisturbed as possible is highly desirable. This explains why some of the best oxygen ion conductors are materials such as zirconia-scandia, $Zr_{1-x}Sc_xO_{2-\delta}$, and ceria-gadolinia $Ce_{1-x}Gd_xO_{2-\delta}$ where the host and dopant ions are very close in size.[174] Zirconia-scandia is often ruled out on cost grounds, but the next best material, YSZ, is a standard material for use in high temperature SOFCs and GDC is a strong candidate for use in lower temperature cells operating at temperatures as low as 550 °C.

3.2.2 *Bi_2O_3-based Oxide Ion Conductors*

The highly conducting high-temperature (>730 °C) cubic phase of δ-Bi_2O_3 forms with the fluorite structure in which one quarter of the anion sites are vacant (i.e. $Bi_4O_6\square_2$). The δ-phase can be stabilized at room temperature by rare-earth ion substitution; for example, for $(Bi_2O_3)_{1-x}(Y_2O_3)_x$ with $x \geq 0.25$ the O^{2-} conductivity is 1.3×10^{-3} S cm^{-1} at 500 °C, vs. that of 5×10^{-4} S cm^{-1} for CSZ at the same temperature. However the Bi_2O_3-based materials are unstable to a reducing atmosphere at even moderate temperatures, and therefore are not considered for SOFC application.[166]

3.2.3 *Perovskite-based Materials*

Pure oxygen conducting materials based on oxygen deficient $LaGaO_3$ were developed by Huang *et al.*[175] and Ishihara;[176] the optimized material with the composition, $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{2.85}$ has an oxide-ion conductivity of $\sigma > 10^{-2}$ S cm^{-1} at 600 °C with a transport number t ∼ 1 over an oxygen pressure range $10^{-20} < p_{O2} < 0.4$ atm. However it is difficult to prepare single-phase materials and nonconducting $SrLaGa_3O_7$ and $La_4Ga_2O_9$ impurity phases are often detected in the grain boundaries. It has been shown that a single phase stable cubic form $La_{0.8}Sr_{0.2}Ga_{0.83}Mg_{0.17}O_{2.85}$ operating at 800 °C in a

$$SrCo_{0.8}Fe_{0.2}O_{3-\delta}/La_{0.8}Sr_{0.2}Ga_{0.83}Mg_{0.17}O_{2.85}$$
$$/La_{0.4}Ce_{0.6}O_{1.8} + NiO$$

dry H_2 and air fuel cell gave comparable performance with that of an yttria-stabilized zirconia as an electrolyte.[43]

The high oxygen diffusivity, even at room temperature, of the 90 K high-temperature superconductor $YBa_2Cu_3O_{7-\delta}$ ($0 \leq \delta \leq 1$) is one of its remarkable properties. The large concentration of anion vacancies of the perovskite-related structure (i.e. $A_3B_3O_{9-2}$) is responsible for the high O^{2-} mobility of this phase.

3.2.4 *Aurivillius Phases*

$Bi_2VO_{5.5}$ has an oxygen-deficient Aurivillius intergrowth structure of $(Bi_2O_2)^{2-}$ sheets alternating with perovskite $(A_{n-1}B_nO_{3n+1})^{2-}$ layers.[177,178] On heating, $Bi_2VO_{5.5}$ ($n = 1$) undergoes two transitions, from a monoclinic α to an orthorhombic β phase at 450 °C, and from the β phase to a tetragonal γ phase at 570 °C. Abraham *et al.*[179] found a high oxide-ion conductivity in the tetragonal γ phase; they subsequently stabilized the tetragonal, vacancy-disordered phase to room temperature by substituting other elements for vanadium. Various doped compositions of γ-$Bi_2V_{0.9}Cu_{0.1}O_{5.5}$ (Ref. 180) γ-$Bi_2V_{0.85}Ti_{0.15}O_{5.5}$ (Ref. 181), so called BIMEVOX materials, where ME represents the substituted metal atom, for example, BICUVOX-10 for $Bi_2V_{0.9}Cu_{0.1}O_{5.5}$, were shown to have excellent oxide ion conductivity at low temperature ($\sigma \sim 10^{-4}$ S cm^{-1} at 227 °C). In air BICUVOX-10 has transfer number t ∼ 1 and was shown to separate oxygen from air at 437 °C with 100% efficiency.[182] However at ∼500 °C and an oxygen partial pressure, $p_{O2} < 10^{-2}$ atm these materials are reduced, and in the reducing atmosphere at the anode of a SOFC, irreversible reduction to other phases occurs.

3.2.5 *Apatite-based Oxide Ion Conductors*

$La_{10-x}Ge_6O_{26+y}$ and $La_{10-x}Al_6O_{26+y}$ with the apatite structure have been synthesized by several groups.[183–190] The highest oxide-ion conductivity ($\sigma = 0.14$ S cm^{-1} at 950 °C) was achieved in $La_9SrGe_6O_{26+y}$.[189]

3.2.6 *LAMOX Phases*

Lacorre and his group[191–193] developed the LAMOX family of oxide ion conductors. Theses materials are based on the $La_2Mo_2O_9$ parent compound and are competitive with existing electrolytes at temperatures above the α-to-β first-order structural phase transition, at ∼580 °C. Associated with this transition is a dramatic improvement in the ionic conductivity to ∼10^{-2} S cm^{-1} at ∼720 °C. The structure of

$La_2Mo_2O_9$ is made up of isolated $(MoO_4)^{2-}$ units in a 3D matrix of $(La_2O)^{4+}$. It was proposed that $La_2Mo_2O_9$ could be viewed as β-$SnWO_4$ ($Sn_2W_2O_8$) substituted by La for Sn and for Mo by W. In this case, the $5s^2$ lone pair electrons of Sn^{2+} in β-$SnWO_4$ are substituted by one oxygen ion and one oxygen vacancy, and it is the disordering of the lattice oxygens on the two sites in the β-phase that results in the high oxygen mobility. Substitution for La and Mo stabilizes the high-temperature phase of $La_2Mo_2O_9$. Lacorre and his coworkers suggests a similar 'lone pair substitution' principle as a novel approach for searching for new oxygen conductors. The Mo (or other transition metal) content of this material leaves it susceptible to reduction and, therefore, significant development of this material is needed before it is commercially useful, either as an electrolyte in fuel cells or as an oxygen separator. There have been limited studies with doping strategies to overcome the reducibility of the material and to stabilize the high temperature phase.[194–196]

3.2.7 *Fluoride Ion Conductivity*

Calcium fluoride, CaF_2, is fluorite itself. Hence, similar to CSZ, F^- can conduct through vacancies ($V_F^\bullet$) generated by the partial replacement of Ca^{2+} with a monovalent cation such as Na^+. Thus CaF_2:1%NaF has a conductivity of 10^{-3} S cm^{-1} at 400 °C, which is several orders of magnitude larger than that of CSZ at the same temperature.

β-PbF_2 with the same fluorite structure was discovered by Faraday to have substantial conductivity (10^{-6} S cm^{-1}), even at room temperature, and the conductivity is as large as 1 S cm^{-1} at 400 °C without alleo-valent dopants. Neutron diffraction studies show the presence of significant concentrations of interstitial F^- in β-PbF_2 and the high conductivity observed at low temperature is attributed to the hopping of these Frankel defects. At about 300 °C, there is a diffuse transition from a low conducting to a high conducting state with the conductivity being almost as large as in fused PbF_2 (mp 818 °C). It has been confirmed by high-temperature diffraction methods, which show evidence of anharmonic large temperature factors for F^- in β-PbF_2, that in the high-temperature phase the high conductivity is associated with the disordering of the anion sublattice, similar to that of the fusion of the cation sublattice of α-AgI.

Fluorite-type fluorides (CaF_2, SrF_2, and BaF_2) also form a wide range of solid solutions with higher valent cations like LaF_3 that are also very good F^- ionic conductors. For example, in $Ca_{1-x}La_xF_{2+x}$ the excess F^- ions occupy the interstitial sites of the fluorite structure. At high concentration of the rare earth ion (up to 40 mol%), the conductivity is low owing to the formation of defect clusters between the dopant cations and their charge-compensating F^- interstitials. A great deal of attention has been paid to the nature of the structure of these clusters. The problem has been investigated by computer modeling and magnetic resonance techniques. It is now well established that a wide range of cluster structures are possible

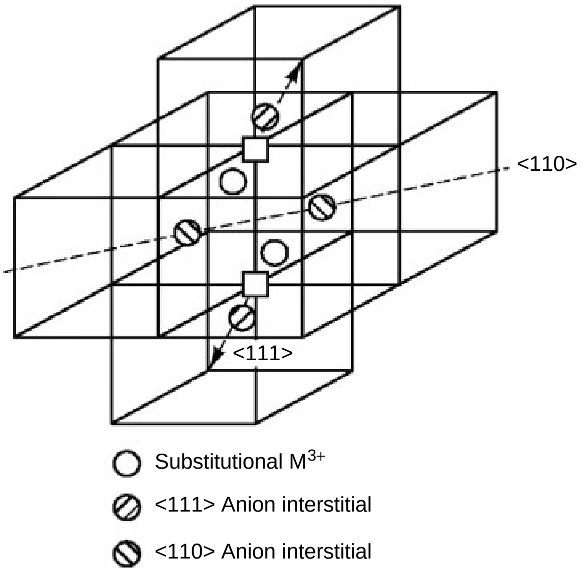

Figure 15 The '2:2:2' cluster. (Ref. 163. Reproduced by permission of Springer)

from the simple dopant–interstitial pairs to the complex, celebrated, so-called '2:2:2' cluster shown in Figure 15.

3.3 Mixed Oxide and Electron Conductors

3.3.1 *Perovskite-based Materials*

Significant developments have been made in the field of perovskite and perovskite-related mixed ionic-electronic conductors for use as cathodes in SOFCs.[197] Both YSZ- as high-temperature (~800–1000 °C) and GDC as intermediate-temperature (~650 °C) electrolytes have been considered. The $La_{1-x}Sr_xCoO_{3-\delta}$ lanthanum strontium cobalt (LSC) perovskite, is among the highest oxide-ion conductors, with only δ-Bi_2O_3 with a higher conductivity over the temperature range of 600–1000 °C.[198] In contrast to the high ionic conductivity of LSC, the electronic conductivity was found to be relatively low, whereas the Mn analog, $La_{1-x}Sr_xMnO_{3-\delta}$ lanthanum strontium manganese (LSM) was found to have electronic conductivity of the order of 300 S cm^{-1}, but poor oxide ion conductivity.[199,200] However, the thermal expansion of the LSC/LSM materials are too high ($\geq$ 20 ppm K^{-1}) and not compatible with those of the electrolytes. Co-doping on the B-site with Fe in $La_{1-x}Sr_xCo_{1-y}Fe_yO_{3-\delta}$ was found to reduce the thermal expansion coefficient of the cathode material and match with that of the electrolytes.[201–203] Among the attractive alternatives to the perovskites mentioned above for application as fuel cell cathodes are the Gd- and Sm-based perovskites, and the compositions $Sm_{1-x}Sr_xCoO_{3-\delta}$ (SSC) have been demonstrated to operate at temperatures as low as 500 °C.

Other developments of perovskite-type oxides as cathode materials for fuel cells have been discussed in detail in the reviews by Skinner[204] and Brandon.[205]

Despite the many problems that still exist with these perovskite cathodes, several commercial developers including Siemens–Westinghouse, Rolls Royce, and Sulzer–Hexis have adopted the LSM material for use in current devices and they are likely to be incorporated in first generation commercial SOFCs.

3.3.2 *K_2NiF_4-type Oxides*

Perovskite-related oxides of the K_2NiF_4 ($A_2BO_{4+\delta}$; B-transition metal ion) structure (Figure 16) have been investigated by several groups as alternative mixed conductors for SOFC.

In this structure there are perovskite layers of ABO_3 separated by AO rock salt layers. It is this layered structure that allows great flexibility in the oxygen stoichiometry of these materials. It is possible to incorporate excess oxygen ($\delta > 0$) in the unusual form of *interstitial* oxygens, which provide an alternative to the vacancy-based conduction mechanism present in the perovskite and fluorite oxides, where the dopant-vacancy interactions can limit the observed conductivity. The mobility of the oxide ions in these materials occurs mainly through an interstitialcy mechanism in the *ab*-plane, although evidence of low E_a for the conduction in the *c*-direction via a Frenkel mechanism has also been reported.[206]

Preliminary work on these materials indicates that the permeation properties of these oxides are competitive with those of the perovskite discussed above; for example, both $La_2Ni_{1-x}Fe_xO_{4+\delta}$ and $La_2Cu_{1-x}CoO_{4+\delta}$ exhibit a maximum flux density of 10^{-7} mol s^{-1} cm^{-2} at 850 °C.[205–210]

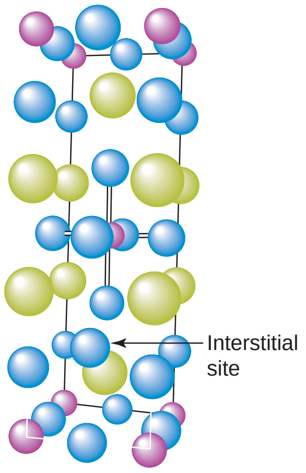

Figure 16 Representation of the $A_2BO_{4+\delta}$ structure, where the red spheres represent the B-cations, the blue spheres represent oxygen ions, and the yellow spheres represent A-cations. An interstitial oxygen ion is also shown

4 AMORPHOUS GLASS ELECTROLYTES

4.1 Glasses (*see Noncrystalline Solids*)

Although initially crystalline materials were more widely investigated, more recently great efforts have been directed towards the study of glassy FIC, because of the unique properties specific to the glassy state. The advantages over crystalline solid electrolytes include: isotropic conduction; ease of fabrication into films or complex shapes; wide compositional flexibility, allowing control and optimization of electrolyte properties through composition; absence of grain boundaries; and high ionic conductivity coupled with low electronic conductivity which often results in good redox stability.

Hundreds of FIC glasses have been prepared by melt quench techniques and in the last three decades by the sol–gel method (*see* ***Sol–Gel Synthesis of Solids***). Several excellent reviews have been published in the past[26–28,55,56,58] and more recently.[211–214]

In Table 4 are some representative FIC oxide and sulfide glasses. Most of these glasses have a simple composition consisting of a network-forming oxide (sulfide), for example, SiO_2, B_2O_3, P_2O_5, (GeS_2), and a network-modifying oxide (sulfide), for example, Li_2O, Na_2O, Ag_2O, (Na_2S). A 2-D

representation of a silicate glass is shown in Figure 17. Ionic conductivity is the result of the motion of cations (i.e. hopping of Li^+ from one nonbridging – SiO^-Li^+ site to another) through the random network of these disordered materials where the mobile carriers are produced from the dissociation of the 'electrolyte' M_2O in the 'solvent' network-forming oxide, SiO_2 for example. The general principles required for good ionic conductivity outlined in Section 2 apply to glasses as well. Table 4 indicates that the ionic conductivities of Ag glasses are the highest, approaching $\sim 10^{-2}$ S cm^{-1} at room temperature. Sulfide glasses often have a conductivity several orders of magnitude higher than their oxide analogs (e.g. $\sigma(Na_2O–SiO_2)_{25\,°C} \approx 10^{-7}$ vs. $\sigma(Na_2S–SiS_2)_{25\,°C} \approx 10^{-5}$ S cm^{-1}), which is attributed to the higher polarizability of the sulfide network (i.e. the greater ease of deforming the lattice, or the electron cloud, when the cation changes site).

Glasses that have higher ionic conductivity than crystalline materials of the same composition are fairly common. A case in point is the room-temperature conductivity of glassy $Li_2B_4O_7$, which is many orders of magnitude higher than that of the crystalline material of the same composition (Table 4).

In the past thirty years, much research has been done on the characteristics that lead to high conductivity in glasses. Addition of alkali metal salts (AgI, LiI, LiCl) with anions of high polarizability often increases the cation conductivity of the glass. For example, with glasses of the composition $LiX–Li_2O–B_2O_3$ the conductivity increases as X is changed from the least polarizable halogen, fluorine, to the most polarizable one, iodine (Table 4). Many researchers have investigated glasses with various proportions of two different alkali metals. The rather unexpected observation that the conductivity passes through a minimum as one alkali metal is substituted for another is called the 'mixed-alkali effect' and it is most pronounced with alkali metal ions having very different radii, such as Li^+ and Rb^+. Several models have been proposed to explain the mixed-alkali effect, but none are entirely satisfactory.

Only a small number of anionic conductive glasses are known. The most conductive are ZrF_4-based glasses with $\sigma \approx 10^{-6}$ S cm^{-1} at 200 °C.

Theoretical models for ion transport in glasses must take into account the disorder inherent in the glass structure. The determination of equilibrium sites for cations and ion-conduction paths in glasses is complicated by the random structures of the framework and the resulting lack of precise structural information.

Recent models for ion transport in glasses include the 'weak electrolyte', the 'random site', and the Anderson and Stuart models.[26–28,44,45,48,215,216]

4.2 Solid Polymeric Electrolytes (SPE)

Solid polymer electrolytes (SPE) represent the newest and one of the most important (i.e. as far as potential applications are concerned) class of FIC solids. The area of polymer/salt complexes became extremely active following the work of Wright,[165] who first reported that PEO is an excellent polymer host for a number of salts and that the resulting polymer/salt complexes have significant electrical conductivities near room temperature. Armand[29,54] extended the investigation of the electrical properties of the polymer/salt electrolytes and

recognized that these solvent-free polymer/salt complexes might be excellent electrolytes for high-energy-density batteries and other electrochemical devices.

The subject is now too vast to be covered in any detail here; extensive reviews[9,29,30,52–58] in the past and a complete book[31] on the subject are recommended for further information.

These materials consist of alkali-metal salts dissolved in a solid polar polymer, which can be denoted by equation (9):

$$\mathrm{p(ru)} + \mathrm{MX(s)} \longrightarrow \mathrm{p[(ru)}_n\cdot\mathrm{MX]} \qquad (9)$$

where p stands for poly, ru is the repeat unit of the polymer structure, and MX is the salt. Most of the materials studied involve univalent salts, with $M = H^+$, Li^+, Na^+, K^+, Ag^+, and $X = CNS^-$, $CF_3SO_3{}^-$, I^-. In the earlier materials, the polymer repeat units always contained backbone oxygens or nitrogens, which acted as Lewis-base sites to complex the alkali. There are several criteria now established for the formation of stable polymer/salt complexes. (1) The polymer host must have low cohesive energy density, high flexibility, and a high density of Lewis-base sites. (2) The salt involved must have a relatively low lattice energy, that is, the lattice energy of the MX salt must be overbalanced by the solvation energy of the p(ru) host, so that the formation reaction will proceed to the right.

SPE can be prepared by dissolving the polymer and an alkali metal salt in a mutual solvent and then evaporating the solution on a teflon fluorocarbon resin plate in a dry atmosphere. SPE films are obtained by casting the solution and heating at relatively low temperatures (~150 °C) under vacuum. The existence of a polymer/salt complex, however, is no guarantee that the material will be a good ionic conductor.

The ionic conductivities of selected polymer electrolytes given in Table 1 show that these materials are poorly conducting compared to the best inorganic/ceramic crystalline or glassy materials. Moreover, the nature of the transport mechanism in the SPE is quite different from that of the ceramic materials. The SPE can transport charge only above their glass transition temperature where, on a microscopic scale, the material is molten. Thus ion transport in SPE is more similar to liquid electrolytes than ceramic conductors. Indeed, more detailed mechanistic studies indicated clearly that ionic motion in these materials does not occur by hopping in a locally crystalline region, but rather by a liquidlike mechanism in which the local motion of the polymer assists the migration of the ion through the solid. This liquidlike migration of a lithium ion assisted by the large-amplitude motion of the polymer, shown schematically in Figure 18, is drastically reduced if the polymer chains are crystallized. To prevent crystallization, cross-linked polymers based on poly(ethylene oxide), $(–CH_2CH_2O–)_n$ (PEO), poly(propylene oxide) $(–CHMeCH_2O–)_n$ (PPO), and others have been synthesized. Such cross-linked polymer/salt complexes, in addition to exhibiting higher ionic conductivity, have the advantage of better mechanical and thermal stability, which is important for applications.

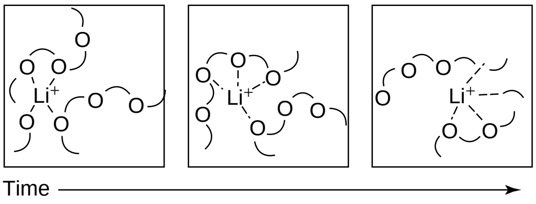

Figure 18 Scheme of ion transport in a polymer electrolyte: Li^+ motion is assisted by the local motion of the polymer chains. (Reprinted from Ref. 1. Published 1985, American Chemical Society)

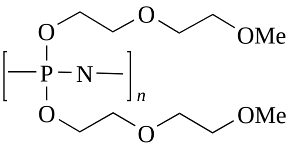
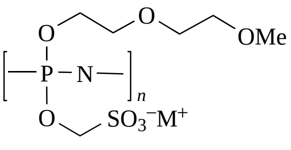
Typical polymer hosts have Lewis-base sites and include the simple linear polymers: PEO, PPO, and poly(ethyleneimine), and a number of comb polymers, in which oligoether side chains are built on a flexible backbone. A tremendous variety of polymer electrolytes can be prepared. Not only can the anion and cation of the salt be varied, but a wide range of polar polymers that might be suitable hosts for salts can be envisioned.

This provides many opportunities for controlling electrical, mechanical, and chemical properties. For example, the recognition that polymer flexibility promotes high conductivity has led to the synthesis of a new electrolyte based on a highly flexible polyphosphazene (*see* ***Polyphosphazenes***) backbone to which short-chain polyether groups are attached (see **1**). This polymer forms complexes with a wide variety of salts, and the resulting complexes have room-temperature conductivities that are about 1000 times greater than those of their poly(ethylene oxide) analogs.



(**1**)



(**2**)

New rubbery 'polymer-in-salt' solid electrolytes in which lithium salts are mixed with PEO or PPO have been reported initially with conductivities as high as 10^{-2} S cm^1 at room temperature.[217] More recently Xu *et al.*[218] report on a plasticized and crosslinked poly(lithium oligo-etherato mono-oxalato borate) and (lithium polyMOB). In heavily plasticized forms of both polyMOB, and a LiBH4-crosslinked polyMOB, the ionic conductivity reached 10^{-3} S cm^{-1} at room temperature, while single ion conductivity is automatically retained. The electrochemical stability window of the electrolytes is up to 5 V, for stainless steel (SS) electrodes. The plasticized forms are fluid, not gel like, owing to the low molecular weight of the polyanions. Free-standing gel electrolytes with high single ionic conductivity of 10^{-4} S cm^{-1} at ambient temperature can be obtained by incorporation of high molecular weight

poly(Me methacrylate) (PMMA) into the solution. Electrochemical cells with these electrolytes will not experience concentration polarization problems. Also from Austin's group, hybrid polymers combining P_2S_5 moieties with oligoether spacers were reported to be highly viscous, but not rubbery.[219] A high ambient temperature conductivity of $\sim 10^{-4}$ S cm^{-1} was measured with LiTFSI dissolved in the P_2S_5-PEO matrix, i.e, in salt-in-polymer materials. The decoupling of Li^+ motions from polymer segmental motions was demonstrated, suggesting that, in certain cases, the transport number for Li^+ ions in the phosphorus sulfide-PEO matrix will be much higher than in a typical PEO-based salt-in-polymer system.[219]

The polymer/salt electrolytes discussed above generally exhibit both cation and anion mobilities; this makes the study of single-ion transport difficult and can lead to polarization in static electrochemical applications. Another class of polymer electrolytes consists of high-mobility charged backbone species, or polyelectrolytes (**2**).[30] Both cationic and anionic transport is possible, depending on whether the backbone charge is positive or negative. These polyelectrolytes exhibit transference numbers of unity for a small counter ion, and are therefore promising for electrolyte application.

The most successful 'solid' protonic membrane for fuel cell use is 'NAFION®' membrane (saturated with aqueous acid solution) used in kW-size fuel cells in the US Gemini space program up to 150 °C. NAFION is a perfluorinated polymer with sulfonic acid groups.

Unlike hard inorganic electrolytes, polymer electrolytes can deform under stress. This makes them extremely promising materials for use as electrolytes in solid state batteries. The chief difficulty in making a successful solid state battery arises from dimensional changes in the electrodes during charging and discharging. In a typical high-energy-density battery, lithium might be used as the negative electrode (see Section 5). As the battery discharges, oxidation of the electrode gradually strips lithium metal away from the metal/electrolyte interface. Unless the interface can deform so that lithium/electrolyte contact is maintained, the battery will cease to function. Similarly, the insertion/deinsertion of Li^+ into the cathode material, swells/shrinks the lattice volume of the cathode material, which is deleterious for contact at that interface. Many all-solid-state batteries using hard, crystalline solid electrolytes have been proposed but have been unsuccessful because interfacial contact is not maintained as the battery is operated. The polymer electrolytes can flow and thus may be able to better maintain interfacial contact with the electrodes.

Polymer electrolytes also are attractive because they can be cast as thin films. Thin films minimize the resistance of the electrolyte and reduce its volume and weight. Although an electrolyte is essential for a battery, it adds weight and occupies space, it therefore reduces the energy stored per unit weight and volume that might otherwise be devoted to the active electrodes.

For battery application, SPE can be classified into three types:[220] dry SPE, gelled SPE[221,222] and porous SPE.[223] Figure 19 shows the concept of gelled SPE and Figure 20 shows the improvement of ionic conductivity of these three categories of SPEs.

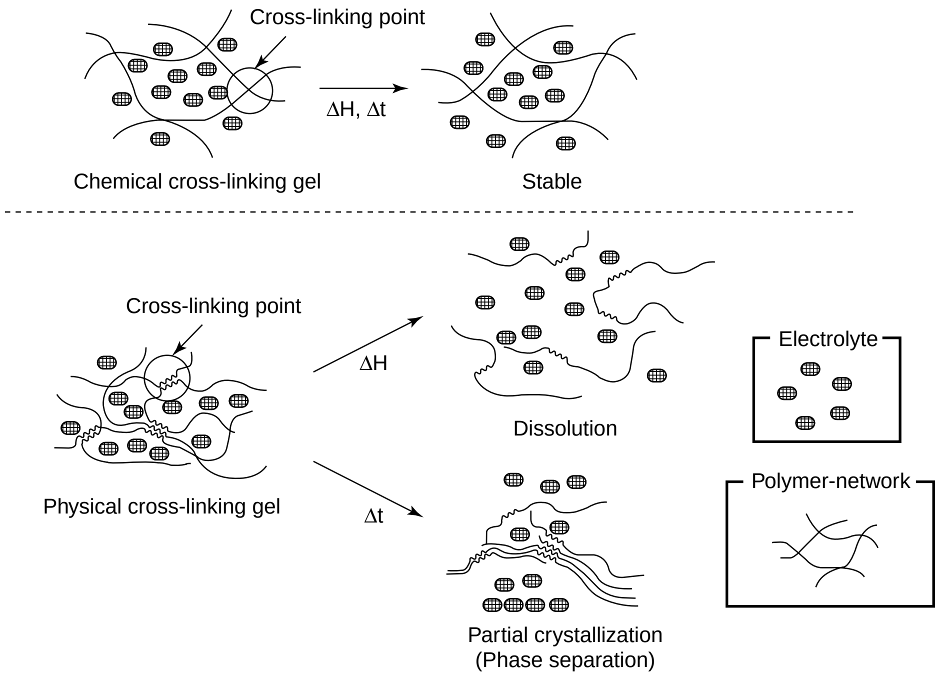


Figure 19 Gelled SPE model-top chemically[221] and bottom physically[222] cross-linked polymer. (Reprinted from Ref. 220. © 2000, with permission from Elsevier)

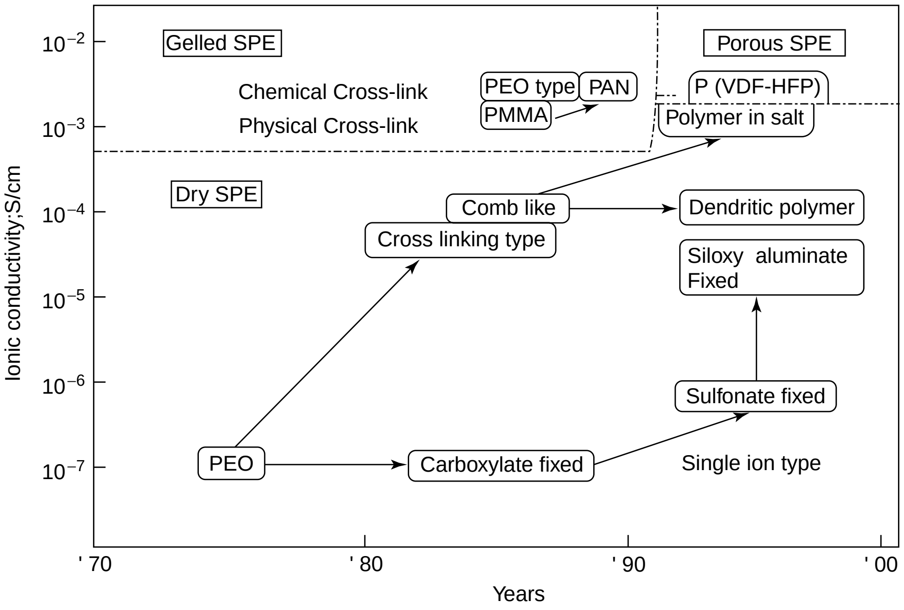

Figure 20 History of ionic conductivity improvement of SPE. (Reprinted from Ref. 220. © 2000, with permission from Elsevier)

The improvement of the performance of the dry SPE has been carried out along two approaches: (I) enhancement of the mobility of the polymer chains, and (II) an increase in the carrier density. With the combination of the above (I) and (II), the ionic conductivity at room temperature is now about $1 \times 10^{-4}\ S\ cm^{-1}$, while with the polymer-in-salt based on the above (II), it is now about $1 \times 10^{-3}\ S\ cm^{-1}$, and with the single ion conductor approach, it is about $1 \times 10^{-6}\ S\ cm^{-1}$. In considering the use of a battery at a lower temperature, $1 \times 10^{-3}\ S\ cm^{-1}$ is probably needed for SPE, except for the single-ion conductor type, which probably requires $1 \times 10^{-4}\ S\ cm^{-1}$. Although the polymer-in-salt now shows $1 \times 10^{-3}\ S\ cm^{-1}$ at room temperature, it tends to crystallize at lower temperature, which prevents its practical use. Therefore, the future needs are as follows: 1. A high-mobility polymer by increasing the mobility of the interpenetrated polymer in SPE and/or increasing the mobility of the polymers in the dendritic polymer system; 2. a single ion conductor with increasing number of dissociating lithium ions; 3. the polymer-in-salt polymer with molten salt; 4. preventing crystallization below $-10\,°C$, and 5. molten salt with a wide stability window.

Recently, studies on the porous SPE with similar performance as liquid electrolyte are active. Considering leak-proof and safety, however, SPE should preferentially have a homogeneous macro-structure, which physically prevents separation of the matrix polymer and the electrolyte. For leak-proof in particular, retention of sufficient osmosis pressure is important. Thus the design of a gelled SPE with good ionic conductivity, should have a structure with a large domain (a matrix with a long molecular chain length and coarse cross-linking) composed of polymers with less interaction with lithium ions, or a micro-phase separation type, is favorable. In addition, a gelled structure composed of the matrix polymer, which has affinity for anions and solvents, but repels lithium ions might bring about an ionic conductivity comparable, or superior to that of liquid electrolyte. Figure 21 summarizes recent improvements in the conductivity of various polymer electrolytes.

5 APPLICATIONS

An electrolyte is an essential component of an electrochemical cell, be it a battery or fuel cell for producing electrical energy or a sensor for determining the concentration of a specific ion or molecule. The primary electrochemistry occurs at the interface between the electrolyte and the electrodes. At this interface, a metal atom on the surface of an electrode might be oxidized to a metal ion, which then enters the electrolyte. At the other electrode, metal ions from the electrolyte might be incorporated into a solid such as a layered transition metal oxide ($LiCoO_2$) or chalcogenide (TiS_2). Thus the function of the electrolyte is to provide a path for the migration of ions from one electrode to the other. The flow of charge by ions through the electrolyte is balanced by the electrons flowing through an external circuit.

If the cell is a battery, it is desirable to channel all of the electron flow through the external circuit, where it can perform a useful function. The electrolyte must not conduct electrons. If electronic current were to flow through the electrolyte, it would be unavailable to carry out useful functions in the external circuit. Electronic conductivity in the electrolyte also would cause a battery to discharge as it stands unused.

(Ref. 47. Reproduced by permission of Nature Publishing Group (www.nature.com))

For these reasons, a minimum requirement of a battery electrolyte is that it must be a good ionic conductor and a poor electronic conductor.

Because all electrochemical devices such as batteries, fuel cells, sensors, and electrochromics require an electrolyte, the potential applications for ionic conductors are enormous. In addition to these more conventional applications, solid electrolyte materials are investigated for use as electrochemical memory devices, oxygen pumps, gas phase electrolyzers, and thermoelectric generators.[57]

Among the various electrolytes, yttrium stabilized zirconia (YSZ) has been developed, for use in high-temperature fuel cells and oxygen sensors; similarly, various $\beta(\beta'')$-alumina materials are in development for sodium–sulfur batteries.

5.1 Sodium Sulfur Battery

Since the principle of the sodium–sulfur battery was established in 1967, it has been under development throughout the world. The schematic set-up of a sodium–sulfur battery, operated at 300–350 °C, is shown in Figure 22. Molten sodium, the anode active material, is placed in a sintered β-alumina solid electrolyte tube, and molten sulfur impregnated in the porous graphite cathode, outside. The

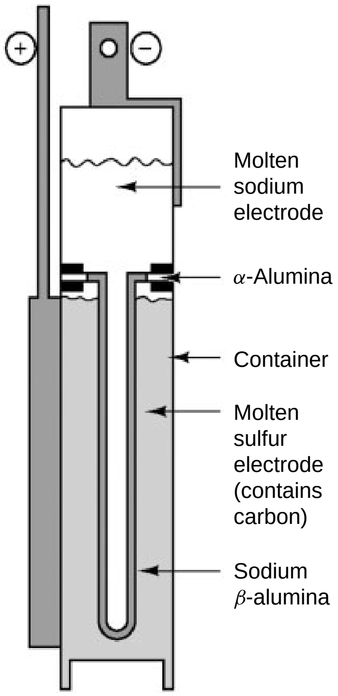

Figure 22 The sodium/β-alumina/sulfur battery. (Reprinted from Ref. 1. Published 1985, American Chemical Society)

ceramic electrolyte serves as ionic conductor and heat-resistive separator of the very active electrode materials at the same time. The anode and cathode reactions of the cell are expressed in equations (10) and (11).

$$\text{anode}: \quad Na \longrightarrow Na^+ + e^- \tag{10}$$

$$\text{cathode}: \quad Na^+ + \frac{x}{2}S + e^- \longrightarrow \frac{1}{2}Na_2S_x \tag{11}$$

During discharge, Na is oxidized at the molten Na/β-alumina interface. It is then transported through the solid electrolyte as Na^+ ion and is combined with reduced sulfur in the outer chamber to form sodium polysulfide, Na_2S_x. These processes are reversed during charging. The cell generates 2.1 V and is rechargeable for $x \leq 3$. Sodium–sulfur batteries feature high energy densities (storageable energy per battery weight or volume); the theoretical density by weight is 790 W h^{-1} kg^{-1} for $x = 3$, which is 4.7 times greater than that of the lead–acid battery. The power density (peak or average wattage per cell weight or volume) is also high, ~50 W kg^{-1}. These are very favorable properties for the development of sodium–sulfur batteries as the power source for electrical vehicles and power storage systems. However, presently, economical techniques for the production of crack-free β-alumina, and a container for the highly corrosive electrode materials required for the safe operation of such batteries, have not been established.

5.2 Oxygen Sensors

The principle of the emf-type oxygen sensor using a CSZ oxide conductor in the form of an open ended tube is illustrated by the oxygen concentration cell in Figure 23. Inside the tube is a reference gas such as air. The tube is coated with porous Pt electrodes to allow the absorption and liberation of oxygen gas. If the partial pressure of oxygen gas that is to be measured, P'_{O2}, is less than the reference pressure, P''_{O2}, the electrode reactions shown in Figure 23(b) take place and O^{2-} ions migrate through the solid electrolyte from right to left. The Nernst equations for the reactions at each electrode may be combined into a single equation (equation 12) that relates the oxygen partial pressures in the two compartments of the cell to the cell voltage.

$$E = \left(\frac{RT}{4F}\right) \ln \left(\frac{P''_{O_2}}{P'_{O_2}}\right) \quad (12)$$

Therefore, P'_{O2} can be determined by measuring E and T. Partial pressures of oxygen as low as 10^{-16} atm can be determined with the CSZ sensor.

Such stabilized zirconia sensor devices are widely used for combustion control in automobiles. All new cars sold in the US contain one of these devices in the exhaust system to sense the partial pressure of oxygen. This sensor is a key component in the carburetor control of pollution. Other applications of such devices are as oxygen sensors in steelmaking.

5.3 Fuel Cells

Fuel cells convert chemical energy into electrical energy, and are already used as power sources in spacecraft. Fuel cells are efficient (more than conventional energy sources, for example, the combustion engine, whose efficiency is thermodynamically limited) and environmentally friendly. Currently, there are large government supported efforts in the US (SECA) and in Europe to develop fuel cells for applications (large power sources, automobiles, energy for houses etc.) by the year 2010. There are already experimental electrical cars powered by fuel cells. The various fuel cell types, including solid oxide (SOFC), molten carbonate (MCFC), phosphoric-acid (PAFC), polymeric-electrolyte-membrane (PEMFC), and alkaline (AFC) fuel cells currently in development are illustrated in Figure 24. Here only SOFC will be discussed in any detail.
